The proposed superstructure is formulated as a mixed-integer nonlinear programming (MINLP) problem and implemented in GAMS 35.2.0 (McCarl *et al.*, 2021) in order to determine the optimal design of an integrated cyanobacteria-based biorefinery and its HEN. The objective function is to maximize the monetary-based sustainability metric, Sustainability Profit (SP) (Zore *et al.*, 2017). The proposed superstructure includes mass and energy balances for the integrated biorefinery process, as well as its heat exchanger network (HEN) design and connection equations to link process design variables with HEN variables. Binary variables are associated to potential units and to heat exchanger matches.

### 4. Numerical Results

The MINLP model formulated for sustainability optimization and simultaneous process and HEN design includes 4,522 discrete variables, 24,840 continuous variables and 34,905 constraints. It was solved to an objective function value of SP=50.77 MMUS\$/y using DICOPT, with CONOPT and CPLEX as nonlinear and linear subsolvers, respectively (Grossmann *et al.*, 2003). Table 1 shows the alternative strain yields, used as input for the model.

Table 1. *In-vivo* (S1) and *in-silico* (S2, S3, S4) strain yields

Strain	Biomass yield (g/(L.d))	Ethanol yield (g/(L.d))	PHB yield (g/(L.d))
S1	0,339	0,288	0
S2	1,375	0	0
S3	0,669	0,875	0
S4	0,229	0,00	0,119

A required production of 180 t/y of phycocyanin/h (industrial level) and 1700 t/y of ethanol is fixed. The optimal scheme corresponding to SP maximization includes the use of *Synechocystis* strains S2 and S3 for the production of 20.55 kg phycocyanin/h, 0.53 kg zeaxanthin/h, 200 kg /h ethanol and 10.86 kg biofertilizer/h. The flowsheet, with the optimal mass flowrates of the main biorefinery streams is presented in Fig. 2. It must be noted that the production of PHB is not selected in the optimal biorefinery scheme.

Regarding heat integration, additional runs were carried out without heat integration and numerical results show that the optimal integrated scheme increased the number of heat exchangers required, as compared to the optimal base case without HEN (10 vs 7) and it also reduced the cost of external utilities by 60 %. Moreover, the reduction of utilities matches from 7 to 5 accounts for significant utility savings that improve the sustainability objective function. As it occurs with other sustainability analysis papers from the literature, the most important contribution to the objective function is given by the economic pillar (Pedrozo *et al.*, 2022). According to the results shown in Table 2, a negligible difference of 0.53 % is found in this pillar between the two proposed cases.<sup>a</sup>

This is due to the increase in the number of heat exchangers for the heat integration case (10 HXs) with respect to the one without heat integration (7 HXs). However, there is a meaningful improvement of nearly 22 % in the environmental pillar, while only an enhancement of 2.70 % can be reached in the social pillar. Regarding the economic pillar, a further analysis demonstrates that utilities reduction does not impact this pillar as other variables, such as maintenance and repairs cost. The social pillar difference is associated with the increase in the number of heat exchangers after heat integration, representing more workers' contracts. A decrease of fossil fuels requirements (external utilities), positively benefits the environmental pillar in the objective function.

In order to gain more insight into the study of the genetically engineered *in-silico* strains, we run an additional optimization case, imposing that S3 (*in-silico* ethanol producer) cannot be selected. *In-vivo* (S1) and *in-silico* (S2) strains are selected for ethanol and pigment production. A comparison between the latter case with the optimal one, can be found in Table 2 (fourth column). The sustainability objective function has a 60% decrease (from 50.78 to 20.55 MMUS\$/y) by the use of the *in-vivo* strain. The main difference is due to higher capital and operating costs associated to the suboptimal solution (S1 and S2) that negatively impact the economic pillar. Moreover, a decrease in the environmental pillar was also found. The obtained results are associated with the *in-vivo* lower biomass and bioethanol yields, which result in higher process flowrates that demand larger equipment size and energy requirements.

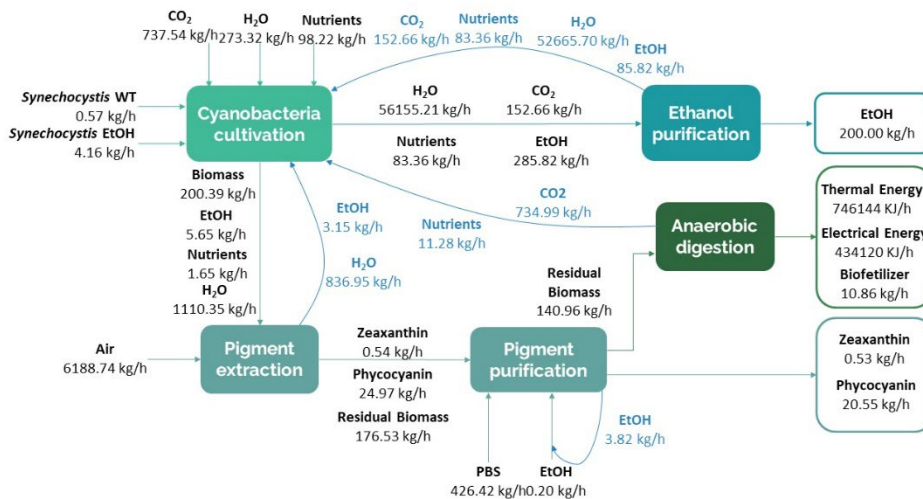

Figure 2. Integrated biorefinery optimal scheme for SP maximization

Table 2. Sustainability Profit pillars comparison

	Without HEN	With HEN	
	S2 and S3 (optimal)	S2 and S3 (optimal)	S1 and S2
SP (MMUS\$/y)	50.44	50.78	20.55
$P_{\text{economic}}$ (MMUS\$/y)	47.43	47.18	19.14
$P_{\text{environmental}}$ (MMUS\$/y)	2.64	3.22	1.02
$P_{\text{social}}$ (MMUS\$/y)	0.37	0.38	0.39

## 5. Conclusions

In this work, we have addressed the production of pigments, biopolymers, bioethanol, biogas and biofertilizers with alternative strains of *Synechocystis* sp. PCC 6803 by a mixed integer nonlinear programming (MINLP) model for the optimal design of an integrated biorefinery and its heat exchanger network (HEN). A superstructure with different process alternatives and different *Synechocystis in-vivo* and *in-silico* strains was formulated. *In-silico* strains S2 and S3 are the ones selected in the optimal solution. Both the SP and the NPV for the biorefinery are positive. A production cost of 0.38 USD/kg for fourth generation bioethanol is achieved due to incomes from pigments (phycocyanin and zeaxanthin) sales. Overall, the numerical results obtained are encouraging into further improving and testing the superstructure model, as well as they show that the use of *in-silico* S2 and S3 strains increases up to 60% the SP, as compared to the *in-vivo* ethanol producer strain S1. Strains S2 and S3 would be possible candidates to be designed by metabolic engineering through gene editing tools such as CRISPR-Cas systems.

## Abstract

Methane pyrolysis involves a simple 1-step endothermic reaction with solid carbon (C) and hydrogen (H<sub>2</sub>) as the main products. The aim of this study is to perform a sustainable conceptual process design including heat integration and sustainability analysis of hydrogen production through natural gas (NG) thermal decomposition. Natural gas was used as process feed instead of pure methane and five component products: H<sub>2</sub>, C, C<sub>2</sub>H<sub>4</sub>, C<sub>2</sub>H<sub>2</sub>, and C<sub>6</sub>H<sub>6</sub>. The process design, thermodynamic analysis, heat integration and sustainability analysis considering the economics and emissions using different energy sources was performed. As expected, results show conversion at lower temperatures for NG as compared to pure methane feed. It also showed the potential of utilizing heat from the process to improve energy efficiency in an integrated process. The cost of NG, C sales and C credit incentive significantly influence the process profitability. The economics also showed operating cost reduction by 21.6% after heat integration and about 78kgCO<sub>2</sub>/kgH<sub>2</sub> was avoided using this process to produce H<sub>2</sub>.

**Keywords:** methane pyrolysis, process design, hydrogen.

## 1. Introduction

The global pressure for sustainable processes and fuels to mitigate carbon footprint has garnered considerable attention to hydrogen. As a versatile and valuable raw material for industrial processes, hydrogen can also serve as clean fuel, being an energy carrier. Moreover, it can easily be mixed with one of its main raw materials CH<sub>4</sub> for cleaner and better combustion (Ishaq & Dincer, 2020). Even though hydrogen itself is a clean and abundant element present in most compounds, its production is usually not as clean. Hydrogen is primarily produced through the reforming of hydrocarbons, which produce high CO<sub>2</sub> content as a process by-product besides the emission from the process energy source, about 8-12 kgCO<sub>2</sub>/kgH<sub>2</sub> is produced from the steam methane reforming process (SMR). A cleaner alternative is the use of water splitting, but the process is thermodynamically limited given that only the hydrogen in the water compound contains energy, the oxygen byproduct is essentially not so useful. This is why thermal decomposition of methane (TDM) also known as methane pyrolysis (MP) has received considerable attention in recent years as an economical means of producing low to zero emission hydrogen, in comparison to other hydrogen alternatives. It involves a simple 1-step endothermic reaction primary process to produce hydrogen and solid carbon as the main products. Due to the stability of methane, the decomposition process involves some secondary and auxiliary reactions producing other higher hydrocarbons at increasing

temperature and consequent considerable heat consumption before it fully decomposes to the primary products (Sánchez-Bastardo et al., 2021). However, most literature only report the main products  $H_2$ , C without considering the impact of the intermediate products. Furthermore, the two main challenges limiting its commercialization involves the complexity of dealing with high temperature production, as well as the production of excess carbon beyond market demand. This is why several researches are ongoing to exploit this potential low to zero emission hydrogen production route in the current climate faced with increasing energy demand and declining climatic conditions due to increased emissions. (Naikoo et al., 2021) provided a detailed analysis on the different types of MP such as thermo-catalytic decomposition to reduce reaction temperature however, limited by catalyst degeneration due to high temperature, the use of molten metals or salt to promote heat integration (Leal Pérez et al., 2021) or the use of plasma torch and regenerative heat exchanger reactor (RHER) (Keipi Tiina, 2017; Kerschler et al., 2021) at very high temperature. Additionally, more studies of heat integration to reduce energy waste from the process are necessary. In this study, the thermodynamical feasibility of a sustainable process design is investigated and analyzed, even though the kinetics could be also limiting it is important to investigate the boundaries of the process to enable further research and innovative process design. Therefore, they are not going to be considered in this contribution.

## 2. Methodology and Process Description

### 2.1. Methodology

The process of hydrogen production using natural gas thermal decomposition was simulated using the Peng-Robinson- Boston-Mathias (PR-BM) as the property model method. The Gibb's energy minimization as the model for the reactor in ASPEN Plus. The base process as presented by Cheon, et al. (2021) was simulated, although in this work a RHER was not used. One of our objectives is to study the thermodynamically feasible extent of process heat integration, so as to investigate the important modalities required for a sustainable process design. The process data from ASPEN Plus simulation was used to perform heat integration via the PINCH analysis in the ASPEN Energy Analyzer, given that the reaction is slightly endothermic, but is favored by high temperatures. The analysis enabled minimum utility requirement/maximum exchanger requirement and the cheapest design was selected as seen in figure 1. The thermodynamic and sustainability analysis of the heat integrated process design considering the economics and the carbon footprint from energy sources was performed since the process itself does not produce  $CO_2$  directly. The main process components include a pyrolysis reactor, a cyclone for solid separation and a PSA separation unit as shown in the process flow diagram from fig 1. The analysis based on the process thermodynamic properties performed enabled the choice of initial process flow design operating conditions.

### 2.2. Process simulation description and assumptions

As shown in the base process flowsheet diagram in figure 1, the natural gas feed is pre-heated to reactor temperature and fed into the reactor at  $1195^\circ C$  and 1 bar, this provides a global conversion rate of 95% and the products consisting of  $H_2$ , solid carbon, ethylene, acetylene and benzene, are sent to a cyclone (dust collector) with high efficiency to remove the solid carbon before it is cooled for hydrogen purification in the PSA unit (compressor, cooler and SEP component). For the separation 90% of the product gas is considered hydrogen, 8% unconverted methane and other hydrocarbons are recycled and 2% purged as flue gas. 5% of the recovered hydrogen is fed back to the process to improve the feed quality and the 95wt % pure hydrogen contains some gases from the product

mixture. The base heat supply for the process is natural gas, other sources of heat supply (grid electricity (coal), renewable sourced energy) was also investigated for economic and emission footprint, given that process itself does not produce CO<sub>2</sub> directly but through the heating sources. The simulation was performed for a H<sub>2</sub> capacity of 414 kg/hr this equals a medium scale hydrogen production process.

Given the peculiarity of the high temperature favored pyrolysis process, the economic feasibility analysis was performed using the order of magnitude costs curve methods of capital and operating cost estimation techniques proposed in Towler and Sinnott (2012). Here the total invested cost (TIC) is divided by the total hydrogen produced to obtain the unit cost of hydrogen, and an optimization was performed to minimize the unit cost of hydrogen produced subject to the plant capacity. The itemized cost data was obtained from literature (Chen et al., 2021; Cheon et al., 2021; Towler & Sinnott, 2013) and ASPEN Plus software, and scaled to the predefined plant capacity; with preliminary capital cost estimation accuracy of +/- 30%. Table 1 shows the simulated process flow information.

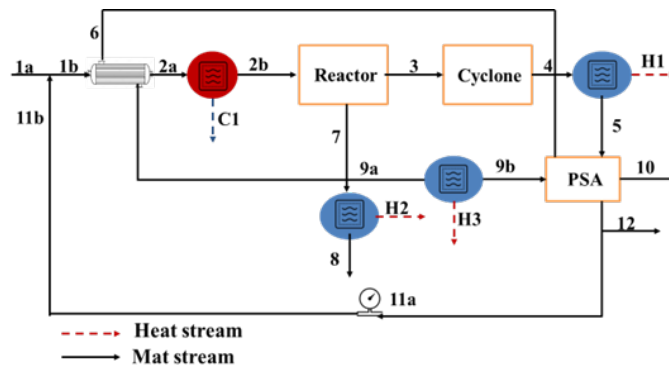

Figure 1: Heat Integrated methane pyrolysis process

### 3. Results and Discussions

#### 3.1. Thermodynamic Analysis

The influence of the presence of other hydrocarbons in natural gas can be seen in the decomposition at lower temperatures when compared to utilization of pure methane feed from figure 2. The secondary products ethylene, benzene and acetylene were produced in very little quantities, with acetylene produced at higher quantity than the ethylene and benzene at very high temperature. Given that the quantity produced is very small, the secondary products considered were separated from the H<sub>2</sub> in the PSA unit and sent together with the unconverted methane to recycle, this significantly improved conversion rate to primary products. Figure 2 also showed that conversion rate is favored by low pressure. The consequence of utilizing methane as opposed to natural gas for process feed is evident in the emission rate as shown in table 1. This is due to the heat duty required to raise the temperature high enough to decompose pure methane.

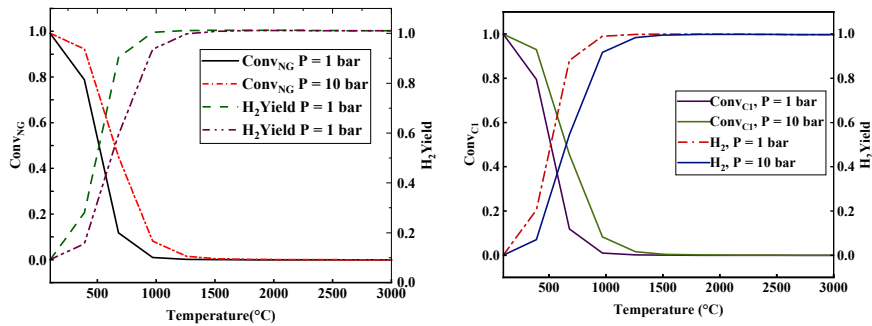

Figure 2: NG decomposition vs Methane conversion rate and product yield

Table 1: Material balance of thermal decomposition process

### 3.2. Sustainability analysis

#### 3.2.1. Economics

For the economic analysis, the heat integration performed reduced the utility cost by 52% and consequently the operating cost by 21.6%. The heat integration for the single process of thermal decomposition was constrained by the process thermodynamics, more heat could be recovered when this process is integrated with other processes depending on the end use of the produced hydrogen and carbon. Furthermore, there is added technological complexity due to the high temperature required for the process as well as solid carbon recovery from the reactor, one challenge is the ability to recover heat from the solid carbon produced. This process requires a special heat exchange design as it cannot be simulated with the common shell and tube heat exchanger. (Pérez, et al. 2021) utilized a plate heat exchanger designed for solid-fluid (liquid or gas) heat exchange. These challenges reflect on the total cost of production and consequently on the price of hydrogen from MP process. Sensitivity analysis was performed on the designed process plant to ascertain parameters that can facilitate the point of ‘break even’, that is the point where the net profit value (NPV) equals zero. The selling price of hydrogen, carbon, discounted cash flow rate of return (DCFRROR) from 0-35%, as well as carbon credit for

CO<sub>2</sub> emission avoidance was evaluated varying hydrogen price from 1 – 10\$/kg, NG feed cost 0.1-1\$/kg, carbon price from 0.00 – 2 \$/kg, and carbon credit from 0-0.01\$/kgCO<sub>2</sub> avoidance. The analysis showed that hydrogen selling price, considering NG price at 0.4651\$/kgNG (being the highest spot price with NG cost hike), without any carbon sales and carbon credit must be 2.5\$/kg to break even. This hydrogen selling price is a slightly above the price of hydrogen from SMR but less than and competitive with hydrogen produced via SMR with carbon capture sequestration (CCS). Carbon sales at 0.1618\$/kg could enable hydrogen from MP to be competitive or at par with SMR with selling price of 2\$/kg and feed cost of 0.4651\$/kg. Moreover, carbon credit at 0.0051\$/kgCO<sub>2</sub>avoided could also lead to break even resulting in the 2\$/kgH<sub>2</sub> and feed cost of 0.4651\$/kgNG. However, for the price 0.3\$/kgNG (the average spot price) used for this work, H<sub>2</sub> selling price of 1.8\$/kg breaks even, the DCFROR analysis also showed that at 29.48% interest rate, the NPV equals zero as shown in figure 4.

Figure 3: DCFROR and Hydrogen selling price sensitivity analysis

### 3.2.2. Carbon footprint

For the carbon footprint, we analyzed of the CO<sub>2</sub> emitted and CO<sub>2</sub> emission avoided when using NG as process feed against methane as process feed with three different energy sources (Natural gas, Coal electricity from the grid (US) and renewable energy sources). As expected, the process with methane as a feed emits slightly more than natural gas feed given that the main source of CO<sub>2</sub> emission is the energy source, and the heat required for the decomposition is higher with methane feed. On the average the process produces 3.3kg CO<sub>2</sub>/kgH<sub>2</sub> and 0.04 kgCO<sub>2</sub>/kgH<sub>2</sub> when renewable energy source is used, noting that the process with NG gas presents some CO<sub>2</sub> in the waste stream, accounting for the CO<sub>2</sub> limit in pipeline gas. Notwithstanding, this stream waste is insignificant as the process with pure methane still emitted more than that with NG feed. When comparing to other hydrogen production processes such as steam reforming with an average of 10kg CO<sub>2</sub>/kgH<sub>2</sub> without carbon capture, the thermal decomposition of NG/methane significantly reduced the carbon footprint.

The total heating duty required for the base case was 5,474kW and 5,874kW, for NG feed and CH<sub>4</sub> feed respectively, and the cooling duty was 4,167kW and 4,353kW respectively for each feed. And after heat integration, the heating duty was reduced to 4,699kW and 5,054kW for each feed, and cooling duty was also reduced to 3387kW and 3715kW for each.

Table 2: CO<sub>2</sub> emission and CO<sub>2</sub> avoidance per heat source

CO <sub>2e</sub> (kg CO <sub>2</sub> /kg H <sub>2</sub> )	NG source	Grid elect (coal)	Renewable source
NG feed	3.42	9.99	0.046
C1 feed	3.53	10,282	0.015
Tot.CO <sub>2av</sub> (kg CO <sub>2</sub> /hr)	NG source	Grid elect source	Renewable source
NG feed	-33885	-31160	-35284
C1 feed	-43437	-40448	-44993

#### 4. Conclusion

A sustainable design of the thermal decomposition of natural gas was considered in this work, an optimal process heat integration design was made and the process analyzed considering thermodynamics, economics and carbon footprint mitigation. The results showed that selling carbon and carbon tax/credit is essential for plant profitability as enable an economical low emitting hydrogen production process. Furthermore, results show that the methane pyrolysis process enables better energy efficiency when integrated with other processes than as a stand-alone based on process complexity from thermodynamics and technological limitations. Given the economic potential, it will be beneficial to develop novel designs to overcome these challenges. Further works will focus on integrating the process with the end use process, conceptual heat exchanger network design that could enable recovery of heat from the hot carbon

## Abstract

Sustainable aviation fuel (SAF) plays an important role in decarbonizing the aviation sector. The ASTM D7566 dictates several pathways to produce sustainable fuels that share the same characteristics as the conventional jet fuel. One of the common pathways to produce SAF is via the gasification of biomass to generate syngas. In this work a model was developed for the process to evaluate the use of different biomass sources on the SAF yield. Moreover, the influence of the measurement uncertainty in the biomass characteristics on the process performance was investigated. The study has shown that the hydrogen content is the most crucial element in the biomass to obtain a higher SAF yield. On the other hand, the uncertainty of the biomass characteristics such as the moisture content causes a 1.5% variation in the final SAF yield. Such analysis shows the urge for an accurate and reliable measurement of the biomass characteristics, this allows for a structural embedding of the uncertainty while making decisions during the process design and evaluation stage.

**Keywords:** Biomass gasification, sustainable aviation fuel, biomass characteristics.

## 1. Introduction

Aviation fuel accounts for 3% of the EU's total greenhouse gas emissions. To tackle this problem, the EU proposed a mandate to include a sustainable aviation fuel (SAF) uptake as a drop-in fuel, with 2% SAF starting from 2025 and increase up to 63% by 2050. SAF can be produced via different pathways which are regulated by the ASTM standard D7566. These pathways vary for different feedstocks. The most common feedstocks are waste oil and fats, cover crops, agriculture and forest residuals and the organic fraction in municipal solid waste (MSW). The Hydro processed Esters Fatty Acids (HEFA) process uses waste oil and fats to produce SAF, while for the agriculture and forest residual, gasification coupled with fischer tropesch (GFT) or alcohol to jet (ATJ) could be used. As gasification technology is widely and commercially established on coal gasification, the focus of this study is on utilizing different types of biomass in the gasification process to produce syngas. This syngas will be upgraded by the Fischer-Tropsch process (FT) to produce liquid hydrocarbons. To describe and understand which potential yields of SAF can be obtained from biomass, data on the biomass characteristics is required. However, such attributes are subject to enormous variations from source to source and from season to season. Therefore, the aim of this study is to analyze the effect of the different biomass

types, their characteristics such as moisture content, elemental analysis and the energy content as well as their respective uncertainties on the production process of SAF. The biomass data used in the analysis was provided by the BIOFMET project where different biomass types were characterized and their respective uncertainties were determined.

## 2. Methodology

A block diagram was developed for the process of biomass conversion into sustainable aviation fuel based on the available literature data for biomass gasification and the Fischer-Tropsch process as shown in figure 1. (Almena et al. 2022; König et al. 2015; Larson et al. 2020).

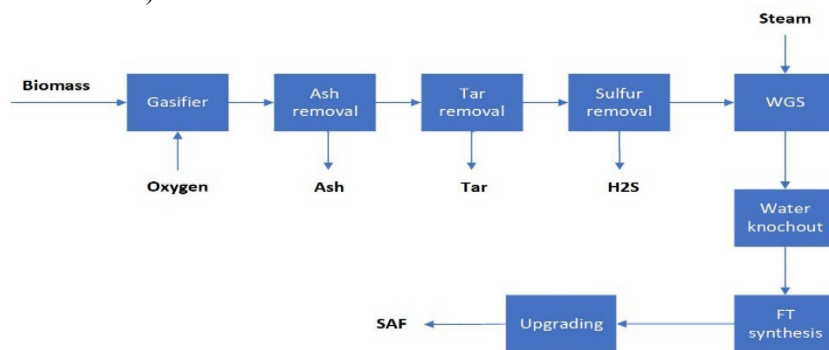

Figure 1. Block diagram for biomass to SAF conversion process.

The biomass is fed to a gasifier to produce syngas using oxygen. The syngas produced from the gasifier contains ash, tar and H<sub>2</sub>S which need to be removed before being supplied to the water gas shift reactor (WGS) as those impurities can deactivate the catalyst in both the WGS and FT. In the WGS, the clean gas reacts with a super-heated steam to increase the H<sub>2</sub>-CO ratio to 2:1 according to equation 1.

The steam will react with the carbon monoxide to produce more hydrogen and carbon dioxide. The syngas will be directed to the FT to produce long chain hydrocarbons according to equation 2.

After the formation of hydrocarbons, the syngas enters a series of flash drums where the temperature and pressure are adjusted accordingly to distil the SAF fraction. ASPEN Plus V10 was used to simulate the process and calculate the mass- and energy balances of the process streams. As a property method, the Peng-Robinson equation of state in combination with the Boston-Mathias equation was used. Oxygen gasification was selected as the air separation unit produces a nitrogen-free syngas which results in a syngas that is better suitable for the Fischer-Tropsch process. FT can be performed at lower as well as at higher temperatures. For the synthesis of long chain hydrocarbons low temperature operation of FT is recommended. In the FT reactor a closed loop design was opted to maximize the CO conversion which resulting in a higher SAF yield. The scale of the model was set around 1 GW which is equivalent to a feed rate of 300 ton/hour biomass. Three different types of biomass were analysed, wood chips of high quality (WC-HQ), wood chips of industrial quality (WC-IQ) and wood pellets (WP). Within the

framework of the BIOFMET project, the characteristics of those samples were measured, and their respective uncertainties were determined and minimized.

Table 1. Biomass properties.

Property	Wood chips - IQ	Wood chips – HQ	Wood pellet
C	47.13	47.08	50.22
H	5.69	5.61	5.84
N	0.198	0.074	0.093
S	0.01245	0.0058	0.0069
O	44.99	46.99	43.56
Ash	1.97	0.24	0.28
Moisture	10.76	11.24	5.93
Volatile Matter (VM)*	<u>17–25</u>	<u>17–25</u>	<u>17–25</u>
Fixed Carbon (FC)*	<u>70–90</u>	<u>70–90</u>	<u>70–90</u>

\* The values of the volatile matter and fixed carbon are assumed based on the literature data for woody biomass. An average value of for VM and FC were used (Dai et al. 2015).

The model was used to test how the different biomass sources and their characteristics could influence the production of SAF. Operating conditions such as the temperature, pressure and the flow rate need to be optimized and fixed to have a fair comparison.

### 2.1 Model optimization

The gasification process decomposes the biomass and leads to a syngas that contains CO, CO<sub>2</sub>, H<sub>2</sub>, CH<sub>4</sub> along with undesired impurities such ash, tar and H<sub>2</sub>S. Therefore, optimizing the gasifier is crucial to maximize the CO and H<sub>2</sub> yields, while lowering the concentration of the impurities. An effective gasification process operates at an equivalence ratio (ER) of 0.2 to 0.4. A value less than 0.2 lead to a dominant pyrolysis reaction, while for an ER of more than 0.4, the combustion reaction will dominate and more CO<sub>2</sub> and H<sub>2</sub>O produced. In figure 2, a temperature of 840 °C was selected for the gasifier and different flowrates of oxygen were tested to determine the optimum ER ratio.

Figure 2. Sensitivity analysis for the oxygen flowrate against the syngas composition.

An oxygen flow rate of 78 ton/hr was opted which corresponds to an ER ratio of 0.2. This flow rate guarantees that more CO and H<sub>2</sub> are produced. For FT, different catalysts such as Ru, Fe, Ni and Co can be used to produce hydrocarbons. Ni has a high selectivity towards methane, while Ru is too expensive for use at a commercial scale. An iron catalyst is relatively tolerant to sulfur as compared to cobalt and can be used to adjust the H<sub>2</sub>/CO ratio thanks to its water gas shift reaction capability. However, it has a low selectivity towards long chain hydrocarbons. Therefore, iron is not suitable for the production of sustainable aviation fuel. Cobalt based catalysts produce less unsaturated hydrocarbons and alcohols, they have a long lifetime and are suitable to produce long

chain alkanes. The Anderson–Schulz–Flory distribution, with a propagation probability  $\alpha$  (growth factor = 0.95) as the only parameter was used to predict the fractional distribution of the different alkanes. The temperature and pressure of the FT reactor was adapted from the experimental results performed by König et al. (König et al. 2015). The reactor operates at 225 °C and a pressure of 2.5 MPa.

### 3. Results and discussion

The Aspen model was used to analyse the differences between the wood chips and wood pellet in terms of their influence on SAF production as shown in figure 3.

Figure 3. SAF yield of different biomass types.

WP provides the higher SAF yield compared to WC because of having a higher hydrogen and carbon content, lower moisture and ash content.

#### 3.1. The influence of moisture uncertainty on the SAF yield

After drying the biomass and before feeding it to the gasifier, a sample is analysed to determine its final moisture content. Determining the moisture content and its respective uncertainty is scientifically challenging as a lot of factors influence the final results, starting from the experimental procedure, the surrounding conditions and the biomass composition. Typically, the uncertainty of the moisture content of the biomass can vary from  $\pm 1\text{--}5\%$ . In the model, the operating parameters were maintained fixed to analyse the influence of the moisture change on the final SAF yield as shown in figure 4.

Figure 4. SAF yield of WP vs moisture uncertainty.

Wood pellet was used to perform the above-mentioned analysis. The actual value represents the obtained yield by using the measured moisture of 5.93% as given in table 1. It can be concluded that the final yield varies depending on the uncertainty. At an uncertainty of  $\pm 5\%$ , the SAF production will increase or decrease by 1.5% (around 0.83 ton/hr). Theoretically, 1.5% could be accepted, in reality a decrease of 0.83 ton/hr is significant as this corresponds to thousands of tons per year. Moreover, unforeseen higher/lower level of the moisture content due to the uncertainty leads to problems in the

gasifier. In case of an increase in the moisture content, the temperature of the gasifier will decrease which influences the syngas quality and lowers its heating value. Furthermore, the rate of tar cracking would decrease due to lower temperatures. In that case, the operator has to adjust the gasifier temperature. Therefore, accurately measured data with specified uncertainty is important to help the operator in deciding how to minimize the impact of any unpredicted variation in the process.

### 3.2. The influence of C,H,N,S,O uncertainty on the SAF yield

As syngas contains primary CO and H<sub>2</sub>, the percentage of carbon, hydrogen and oxygen in the biomass would largely determine the SAF yield. Generally, biomass has an average ratio of 45–55% carbon, hydrogen of 5–7% and oxygen of 35 – 50% (Dai et al. 2015). During the process design phase it is important to consider the uncertainty of the different parameters to correctly size the instruments and have an accurate average for the final yield. For example, hydrogen has a very low density which leads to a large specific volume. For the given values above, the average uncertainties as provided from the BIOFMET data is for H around ± 0.15 %, while for both C and O is ± 1%. Small changes in composition can influence the yield as shown in figure 5.

Figure 5. SAF yield vs the uncertainty of the elemental analysis.

A change of ±1% in C and O would influence the SAF yield by up to ± 3 and ± 1% respectively. In case of hydrogen a change of ± 0.15 % influences the yield by ± 1.3%. Hydrogen is the most influential factor in the process. Therefore, the choice for a biomass source should be based on its hydrogen content and not the carbon content. The average range of carbon in the different biomass types is enough to provide the process with a sufficient CO.

### 3.3 The influence of the calorific value on the gasification performance

The energy content of the biomass could be determined experimentally by a bomb calorimeter or by using the elemental analysis. According to a survey performed within the scope of the BIOFMET project, the uncertainty of the energy content supplied to industry reaches up to 5 % (Shehab et al. 2022). The energy content influences the calculations of the cold gas efficiency (CGS) of the gasifier and the overall process performance. Therefore, a small error in the measurement raises the overall uncertainty of the process, as the uncertainty distribution might not be concentrated around the average. To calculate the cold gas efficiency, the lower heating value (LHV) of biomass should be calculated as  $LHV = HHV - 10.55(W + 9H)$ .  $W$  is the moisture weight fraction and  $H$  is the hydrogen percentage in the biomass. An example is given below for the wood pellet. Shehab *et al.* 2022, provided an improved technical protocol to determine the energy content of the biomass with low uncertainty of ± 1%. Based on those experimental data, the LHV of wood pellet is 19.92 MJ/kg, while the resulting LHV of the syngas provided by the ASPEN model is 13.56 MJ/kg. Equations 3

was used to calculate the CGS of the gasifier in case of 5% uncertainty and 1% uncertainty.

$$\text{Cold gas efficiency: } \frac{\text{LHV of syngas}}{\text{LHV of Biomass}} * 100 = 68.08 \% \quad (3)$$

An uncertainty of  $\pm 5\%$  causes inaccuracy in the efficiency of the gasifier by over  $\pm 3.2\%$ . While an uncertainty of  $\pm 1\%$  in the energy content will lead to a substantially lower uncertainty of  $\pm 0.6\%$ . Such an approach shows the importance of having a reliable testing mechanism for the biomass as it directly influences the process performance and efficiency. This information helps the process designer to provide a realistic range of uncertainty to the unit operation and the process efficiency.

#### 4. Conclusions

An Aspen model was developed to simulate the conversion of biomass into sustainable aviation fuel. Optimizing the model was crucial to provide an accurate prediction of the syngas composition when using oxygen as a gasifying agent. Using different biomass types on the model proved that a slight variation in the biomass characteristics could substantially influence the SAF yield. Hydrogen is the most sensitive element in the biomass, therefore, selecting the biomass should be based on hydrogen content. Knowledge about the uncertainty of the biomass characteristics is crucial, so the process designer could provide a better estimation of the unit operation uncertainty and the final SAF yield

## Abstract

Traditionally, product design is done from within a company. From a purely economic point of view, it will focus on optimising product performance while minimising costs and waste. The optimisation uses key performance indicators, which often result from modelling the production processes and the product's properties. Increasingly, though, product design and product manufacturing involve groups of companies, each of which has its own objectives and strategies. The central idea is to couple the single company-based silo optimisation to a collaborative optimisation and decision-making to unlock hereto hidden product innovation potentials on a digital platform. This platform supports the modelling process from describing the distributed manufacturing and the involved materials to product design, which we call *Translation*. In this contribution, we discuss a joint translation ontology, capturing the translation process and the recursive business-to-business process implemented in an H2020-funded innovation platform VIPCOAT.

**Keywords:** translation ontology, optimally distributed production, innovation environment, product design.

## 1. Introduction

The European Materials Modelling Council (EMMC) has developed a Translation process performed by so-called Translators to support the industry in utilising materials modelling and facilitating innovation. The delivered Translation Guide (Hristova-Bogaerds et al. 2019) describes in detail a six-step sequential translation process: business case identification → industrial case understanding → analysis of available data space → identification (translation) to modelling workflow → model execution and validation → back-translation of modelling results to business case. An extension of this guide, in particular of its last step, establish Business Decision Support Systems (BDSS), which introduce business-related key performance indicators (KPI) into the picture (Dykeman et al. 2020) and systematise the original back-translation process. Recent developments in this area are summarised in a report on the progress of implementing the translation and BDSS concept in various running European projects, see (Klein, Konchakova, et al. 2021).

In parallel to the standardisation of translation processes, first steps in materials modelling standardisation and ontologisation have been made by the EMMC community. These attempts are documented in a CEN workshop agreement on Modelling Data, MODA CWA (CEN workshop agreement, CWA 17284:2018 (E) 2018), and Elemental

Multiperspective Material Ontology (EMMO) (Ghedini et al. 2021). An ontologisation of the MODA CWA, compatible with the EMMO, has been described for one particular industrial process in (Klein, Preisig, et al. 2021), where the development of corrosion-inhibiting coatings served as an example of a translation process initially documented in a MODA and a set of roles to automatically map this MODA description to an EMMO compatible format of materials modelling workflows. The construction principle used is now systematised in a further CEN workshop agreement, see (CEN workshop agreement, CWA 17960:2022 (E) 2022).

In this paper, we describe the basic steps for the ontologisation of the corresponding translation process suitable for coating development and take into account that the development and production processes of coatings are distributed (chained) among different actors in the industry.

## 2. Industrial challenges and requirements

In general, new innovative product designs within a company aim to optimise product performance and customer acceptance while minimising costs and waste. On top, most companies implement long-term strategies like maintaining good supplier and customer relations, technological leadership, and, nowadays, sustainable, resilient, and green production and supply. The optimisation uses key performance indicators (KPIs), often resulting from modelling the production processes and the product's properties.

Increasingly, though, product design and product manufacturing involve groups of companies, each of which has its own objectives and strategies. The central idea of this work is to couple the single company-based silo optimisation to a collaborative optimisation and decision-making process to unlock hereto hidden product innovation potentials on a digital platform. This approach necessarily calls for interoperability along the value-added chain, which is greatly supported by ontologies. In this contribution, we discuss a joint translation ontology, capturing the translation process and the recursive business-to-business (B2B) process implemented in an H2020-funded innovation platform VIPCOAT (“Virtual Open Innovation Platform for Active Protective Coatings Guided by Modelling and Optimization”) for the development of new coating systems. The best-known inhibiting pigments in metal coatings contain hexavalent chromium-based compounds, or Cr(VI) compounds for short, as pigments. Acknowledging human health and environmental issues has led these Cr(VI) compounds to be heavily regulated, so a replacement in corrosion-inhibiting coatings, to be developed by coating suppliers, is necessary.

The project involves three major production companies: a nanoscale corrosion inhibitor producer, a coating formulation producer and a large consumer with very tight and demanding specifications related to the performance of the applied coating formulations on metal surfaces. In this B2B2B innovation environment, collaborative decision support is deployed on a cloud platform with endpoints in the companies, representing our ontology's first use case. An ontologisation of the materials modelling support to be used within each company is provided in ref. (Klein, Preisig, et al. 2021).

## 3. Ontology construction principles

The first step towards ontologisation of the VIPCOAT platform was done for the modelling layer in ref (Klein, Preisig, et al. 2021), compatible with the EMMO (Ghedini et al. 2021). As an intermediate step in this works, we first construct an ontologisation of

the traditional translation process in a Translator to Business (T2B) relation, reflecting the EMMC Translation Guide (Hristova-Bogaerds et al. 2019). This ontology is consistent with a developed crosswalk from an initial VIPCOAT MODA workflow of the three industrial applications to the EMMO.

Translation as an interactive process is conceptually described in the ontology as subclasses of the translation class: partners and performance. While the Partners' subclass model basically the interaction between humans involved in a translation process, the Performance subclass models the realisation of business goals.

#### 4. T2B and T2B2B Translation ontology

This initial Translation ontology models a one-to-one relationship between the two triples (Translator, Modelling, Simulation) and (Client, Business Case, Industrial Case) - T2B relationship. In the next step, this ontology will be extended to handle a one-to-many relationship (T2B2B) between the triple (Translator, Modelling, Simulation) and a chain of (Client, Business Case, Industrial Case) triples, thus ontologically modelling a B2B2B environment.

The approach used in this works implements a somewhat different perspective on ontologies. Usually, ontologies are constructed to systematise existing knowledge. Consecutively, we use the ontology-defined syntax and semantics to construct correspondingly structured knowledge, like ontology-driven tools and knowledge graphs. This approach is our paradigm for implementing ontology-based interoperable processes and tools.

##### 4.1. Ontology for T2B Translation Processes

Translation as an interactive process using the original T2B pattern, see (Klein, Konchakova, et al. 2021), consist of two important concepts which are described as subclasses of an ontological Translation class: Partners and Performance. While the Partners model the interaction basically between humans involved in a Translation process, the Performance class models the realisation of business goals in an industrial Case or process. RDF-type data file for further processing of this ontology can be made available upon request.

One Translator- one client relationship structure has been added to the ontology and mapped into an RDF-type data file (see Figure 1).

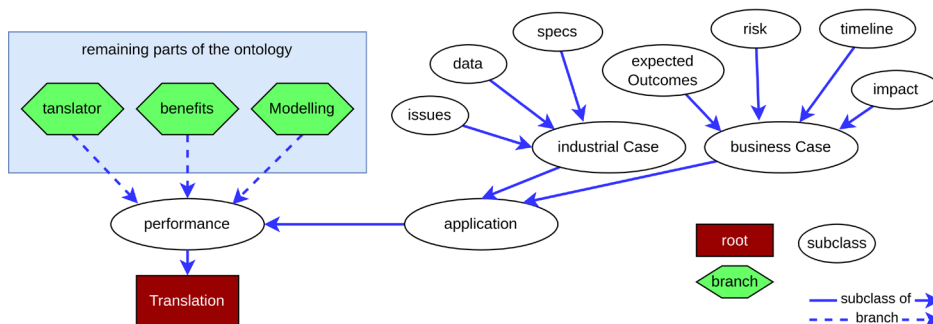

Figure 1: Section of the T2B ontology

The BDSS system deployed at the industrial partner sites may be used to visualise the results of the tasks and/or of experimental data individually at each site.

Decision Support is implemented on the VIPCOAT platform by multi-criteria optimisation and interactive explorers of the solutions of corresponding optimisation models. While multi-criteria optimisation is a well established mathematical technology used to find best balanced compromises between conflicting objectives (in the technological area usually called Key Performance Indicators), decision makers may interactively explore what-if-scenarios and add context information not modelled in the multi-criteria optimisation in order to take informed final decisions on products and processes.

#### 4.2. Ontology for one-to-many Translation Processes

Applied to the example, VIPCOAT project picks this challenge up as depicted in Figure 2.

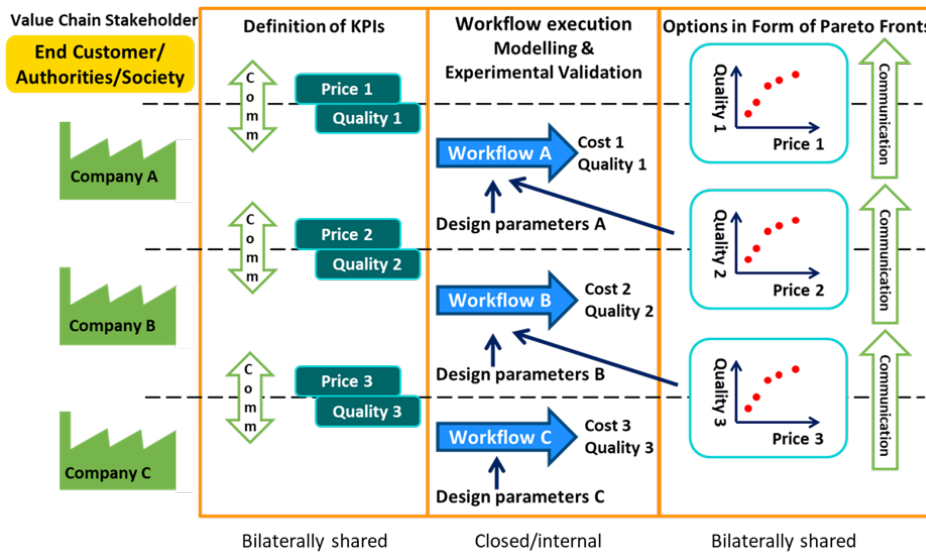

Figure 2: B2B2B environment used in VIPCOAT.

Partner C develops new pigments containing regulation-compliant inhibiting molecules. Partner B adds these pigments to formulate coatings, and Partner C applies this product on surfaces and tests their inhibiting performance to meet the End Customer's expectations. This VIPCOAT platform demonstration use case is thus structured along a value/production chain in a B2B2B environment. Typical for such environments is that the requirements flow is upstream of the production chain, starting at the End Customer. In VIPCOAT, the requirements specification on coatings is formulated to be applicable for aircraft manufacturers. The KPIs are very detailed and contain many more technical details to be fulfilled by a paint producer's coating formulation besides the corrosion-inhibiting properties. These requirements generally persist while the Cr(VI) compounds are to be replaced, a typical B2B supplier - OEM (original equipment manufacture) relation: The paint producer buys the pigments from his supplier. However, many of the requirements are not that hard specified. Also, the interaction between the different

involved materials is not fully predictable. Together this provides a certain level of freedom of choice, allowing the complete chain to choose an optimal combination satisfying the coating-applying partner's requirements.

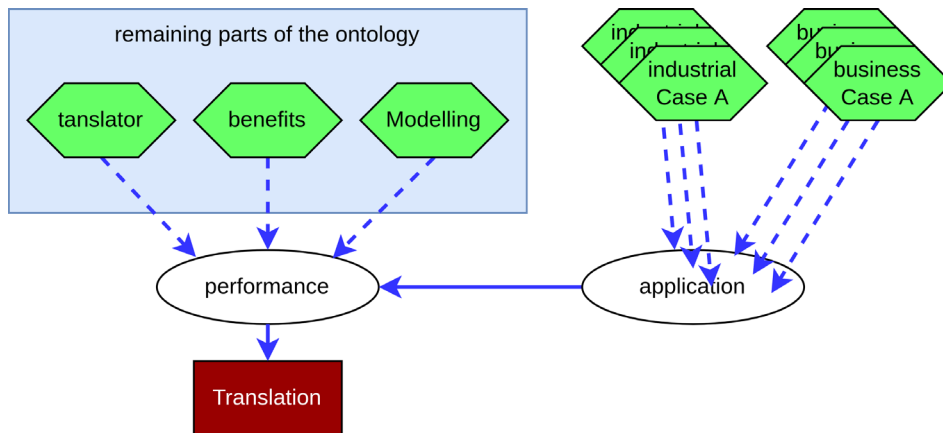

Figure 3: Sketch of the T2B2B ontology: relationship of one Translator and three industrial and business Cases (A, B, C)

VIPCOAT addresses these development challenges directly through its modelling tasks serving the most important steps in coating development by utilisation of integrated simulation and optimisation tools.

Further developments towards B2B2B collaborative decision-making, one of the VIPCOAT platform goals, call for a good understanding of B2B2B relations to implement such a new product development style. An ontology segment for the One-Translator and a B2B2B environment applied to active protective coating creation example is presented in Figure 3.

## 5. Conclusion

This contribution presents an ontological approach along a distributed production chain designed for protective coating developments. In this example, the materials modelling approach has already been ontologised, so a complete set of ontologies, including business-related ontological classes, are created. In its current implementation stage, the VIPCOAT platform takes advantage of these ontologies to support inter-company collaboration for fast innovations of corrosion-inhibiting coatings used in the aeronautic industry. The next step will be the introduction of domain ontologies to capture more general coating system formulation. These ontologies will get constructed in parallel to the VIPCOAT platform developments to support cross-fertilisation at least in the coating industry.

## Abstract

Demonstrations of pharmaceutical process modelling have been made in the literature in the pursuit of accelerated development. Modelling activities for drug substance (DS) and product (DP) manufacturing are often conducted separately, as project time constraints often require that the DS and DP processes be developed simultaneously, each with fixed decision criteria and requirements. We illustrate how connecting DS and DP process models is essential for a full process understanding and how key attributes of an isolated DS can propagate through a DP tableting line to impact the DP dissolution. We do so by performing an uncertainty analysis on a flowsheet model of a crystallization and direct compression line. The dissolution sensitivity highlights the need for end-to-end flowsheet modelling to realize the full benefits of modelling. We also discuss the key technical and regulatory obstacles that must be overcome to achieve this.

**Keywords:** Flowsheet model; Pharmaceutical manufacturing; Drug Substance; Drug Product

## 1. Introduction

The development of robust pharmaceutical manufacturing processes that ensure product quality, manufacturability and material efficiency requires a sound understanding of the impact of the process' inputs (e.g., raw material properties, process operating conditions) on product quality (e.g., purity, content uniformity, dissolution) across the operating space. Consideration of the end-to-end process in a rigorous manner can be challenging due to the large number of inputs to account for in a given process, as well as their multivariate interactions that potentially impact product quality and manufacturability.

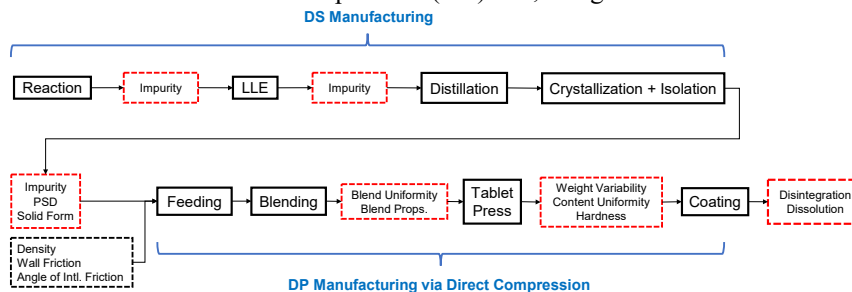

Mathematical modelling can assist this by describing the relevant physical and chemical phenomena occurring in each unit operation and connecting these sub-models into an integrated flowsheet model to assess the criticality of multiple input factors *in-silico* (Diab et al., 2022a; 2022b). In industrial practice, modelling activities for drug substance (DS) and drug product (DP) manufacturing can occur independently, as the short lifespan of a patent means that DS and DP process developments usually must occur simultaneously and risk not being perfectly harmonized, e.g., the selected DS solid form may change under certain DP process conditions. Additionally, most DP models, besides those employing physics-based methods such as Discrete Element Method (DEM) are semi-empirical and thus the benefit of connecting them to other first-principles models more commonly available in DS processes are then not as significant. This does not allow for a full consideration of the impact of DS input variability on the DP process and quality. This “disjointed” consideration of DS and DP models misses the full potential of end-to-end modelling to accelerate development.

## 2. Pharmaceutical Manufacturing Process Modelling

Various efforts have been made towards the modelling of DS system models. Examples include the use of models to predict input factor impacts on related impurity levels (Diab et al., 2022a; 2022b), avoidance of undesirable solid state forms and control of particle size distribution, PSD (Montes et al., 2018). Examples of models for DP manufacturing include wet granulation (Boukouvala et al., 2013), dry granulation (Bano et al., 2022a) and direct compression (García-Muñoz et al., 2018).

There are few literature cases of end-to-end process modelling that span the interfaces between DS, DP manufacture and *in-vitro* product performance. Benyahia et al. (2012) were the first to model an entire continuous pilot plant but did not consider product performance. Nagy et al. (2021) modelled a DS synthesis and crystallization process with *in vitro* dissolution, but without explicit modelling of the DS isolation and DP manufacturing unit operations. Most examples omit isolation, even though this can drastically impact the DS physical properties (Guo, 2009). Fig. 1 shows an example end-to-end process and how each unit operation potentially impacts a quality attribute. While many DS process models predict purity and PSD, they often do not output responses that are key inputs to DP models. For example, changes in crystallizer operation could impact the DS PSD and shape, which may then impact the powder (blend) flowability, tablet content uniformity and weight variability, etc. We now illustrate how variation in the DS properties that are DP model outputs can propagate through to the final DP quality for a tablet manufactured in a direct compression (DC) line, using a flowsheet model.

**Figure 1.** Example of an end-to-end pharmaceutical process. Black solid = Unit operation. Red = quality attribute. Black dashed = Material property not predicted from DS process model.

## 3. Case Study

The case study in this paper considers a seeded antisolvent crystallization from the final stage of a DS manufacturing process, a DC process model for DP manufacturing and subsequent *in vitro* product performance. The considered sub-models are all parameterized vs. industrial process data.

### 3.1 Drug Substance Crystallization

We consider a seeded, antisolvent DS crystallization. The supersaturated solution of DS in organic solvent is seeded at a fixed temperature and the resulting mixture is then aged. Following isothermal de-supersaturation, antisolvent is added and the suspension is further aged. The API mass balance is given by Eq. 1, where  $C_b$  = bulk solution concentration,  $\rho_c$  = crystal density,  $k_v$  = crystal volume-shape factor,  $G$  = overall growth rate,  $L$  = DS particle size,  $n$  = number size distribution. Growth contributions come from both pure API ( $G_{API}$ ) and impurity ( $G_{Imp}$ ) in Eqs. 2–4, where  $C_{sat}$  equilibrium solubility (a function of temperature,  $T$ , and antisolvent content,  $x_{AS}$ ),  $\rho$  = solvent density,  $C_{imp}$  = impurity concentration in the feed to the crystallization, and model parameters,  $k_g$ ,  $g$ ,  $s$ ,  $k_i$  and  $l$  are fit to de-supersaturation and impurity content (Taylor et al., 2021).

$$dC_b^{API}/dt = 3k_v\rho_c \int GL^2n(L)dL \quad (1) \quad dP_d/dt = \Lambda d_h^2 \varepsilon p_c / S_p \mathcal{T}_{or}^2 \mu P_d \quad (11)$$

$$G_{API} = k_g \left( \frac{C_b^{API} - C_{sat}}{\rho} \right)^g (x_{AS} + 1)^s \quad (2) \quad \frac{dM_t}{dt} = [2\rho_s(1 - \varepsilon)\Omega(t)] \frac{dP_d}{dt} \quad (12)$$

$$G_{imp} = G_{API} k_i (x + 1)^l C_{imp} \quad (3) \quad p_c = (\sigma \cos \theta_e) / d_h ; \quad d_h = [\varepsilon / (1 - \varepsilon)] (d_p / 6) \quad (13)$$

$$\frac{dL}{dt} = G = G_{API} + G_{imp} \quad (4) \quad \frac{\partial N_i}{dt} = B_i \delta(l - l_{0,i}) + R_{i,l} \frac{\partial N_i}{dl} \quad (14)$$

$$K = 1.5V_b^{1/3} F_h \omega_b t_{blend} \quad (5) \quad B_i = \frac{1}{\rho_p} \left( \frac{x_i}{S_p l_{0,i}^3} \right) \frac{dM_t}{dt} \quad (15)$$

$$sf = a_{sf} (1 + b_{sf} P) / (1 + a_{sf} b_{sf} P) \quad (6) \quad R_{i,l} = \dot{M}_l / \rho_p \quad (16)$$

$$TS = TS_0 ((1 - \beta) + \beta \exp(-\gamma K)) \quad (7) \quad \dot{M}_l = K_D (C_{sat} - C_b)^{n_{si}} \quad (17)$$

$$TS_0 = a_1 \exp(b_1 (1 - sf)) \quad (8) \quad K_D \approx 1/K_r + 1/K_d = (K_d K_r) / (K_d + K_r) \quad (18)$$

$$\beta = a_2 (1 - sf) + b_2 \quad (9) \quad C_b^{API} = x_{API} \rho_t \left( \frac{V_{t,0} - V_t}{V_t} \right) - \left( \frac{m_{API,3} \rho_p S_p}{V_m} \right) \quad (19)$$

$$V_c = (H_c - \dot{\varepsilon} t) A_t \quad (10) \quad \%LC = 100 C_b^{API} V_m / x_{API} \rho_t V_{t,0} \quad (20)$$

### 3.2 Blending and Direct Compression of Drug Product

The DC model is comprised of a blender and a tablet press. The Extended Kushner model (Nassar et al., 2021) is used to describe the tablet tensile strength ( $TS$ ) as a function of the extent of blend lubrication,  $K$ , as per Eqs. 5–9, where  $V_b$  = blender volume,  $F_h$  = fractional headspace in blender,  $\omega_b$  = blend speed,  $t_{blend}$  = blending time,  $sf$  = attained tablet solid fraction,  $P$  = pressure applied in tablet press,  $TS_0$  = tablet tensile strength at zero-porosity. Parameters  $a_{sf}$ ,  $b_{sf}$ ,  $a_1$ ,  $b_1$ ,  $a_2$ ,  $b_2$  and  $\gamma$  are estimated from experimental data.

### 3.3 In-Vitro Product Performance: Disintegration and Dissolution

Both erosion and swelling are considered in the tablet disintegration (Markl et al., 2017). Erosion is described by Eq. 10, where  $V_c$  and  $H_c$  = coating layer volume and thickness, respectively,  $A_t$  = tablet surface area,  $\dot{\varepsilon}$  = erosion rate. The penetration depth due to swelling is given by Eq. 11, where  $P_d$  = penetration depth,  $d_h$  = pore hydraulic diameter,  $\mathcal{T}_{or}$  = tablet tortuosity,  $\mu$  = liquid viscosity,  $p_c$  = capillary pressure. Model parameters  $S_p$  and  $\Lambda$  are to be estimated from experimental data (Peppas and Colombo, 1989). The change in tablet mass,  $M_t$ , is given by Eqs. 12 and 13, where  $\varepsilon$  = average porosity of the swollen product,  $\rho_s$  = solid true density,  $\sigma$  = liquid surface tension,  $\theta_e$  = solid-liquid contact angle,  $d_p$  = tablet equivalent spherical volume diameter (Kuentz and Leuenberger, 1998) from disintegration time (DT). The DT is defined when  $dP_d/dt = 0$ .

Dissolution is described by Eqs. 14–20, where  $N_i$  = number size distribution,  $B_i$  = rate of particle release,  $l$  and  $l_{0,i}$  = particle size at  $t$  and  $t = 0$ , respectively,  $\rho_p$  = particle density,  $x_i$  = mass fraction,  $M_t$  = tablet mass,  $R_{i,l}$  = particle dissolution rate,  $\dot{M}_l$  = overall mass flux,  $K_D$  = overall dissolution coefficient, which is calculated from the surface integration constant,  $K_r$ , and the diffusion mass transfer coefficient,  $k_d$  (estimated from diffusion coefficient,  $D$ , and unstirred layer thickness,  $h_l$ ),  $n_{si}$  = order of dissolution. Model parameters  $K_r$  and  $n_{si}$  are to be estimated from dynamic dissolution data for tablets with different solid fractions. The dissolution extent is defined as the percentage label content, %LC, where  $V_m$  = liquid volume in the USP <711> (2011) test vessel.

#### 4. Uncertainty Analysis

We quantify the impact of DS property variability propagation through to DP dissolution in two steps: (1) uncertainty analysis on the crystallization process model to understand the expected variance in DS properties, (2) uncertainty analysis to quantify the impacts of DS property variability propagating through the DC process to the DP dissolution using Sobol sampling in gPROMS FormulatedProducts. The input factors for the crystallization uncertainty analysis were the seeding and age temperature and age duration, seed loading, antisolvent addition duration and quantity. The responses were DS  $d_{90}$  and purity.

Fig. 2 shows the variation in DS  $d_{90}$  and purity as a function of age temperature and age duration, both of which impact the selected responses when varied over the ranges investigated. The total range of the simulated DS  $d_{90}$  was approximately  $\pm 20\%$  vs. the nominal value. The range of attained DS purity = 99.38–99.87 mol%. Even low levels of key DS impurities can be severe with respect to product quality, e.g., if they are genotoxic or mutagenic, and can also impact the crystallization kinetics and the resulting PSD, which is a direct input to the DP process. Modelling the impacts of impurities on crystallization kinetics is certainly not trivial (Capellades et al., 2022); further research in this area will be an important addition to the modelling literature.

**Figure 2.** Age temperature and duration vs. DS properties: (a)  $d_{90}$ , (b) purity.

For the DC analysis (step 2), the input was the DS  $d_{90}$  (whose range is defined from the observed responses in step 1). The considered response was the DP dissolution, whose variation is shown in Fig. 3. The extent of dissolution at 20 min varies significantly ( $\sim 90$ –95 %LC), while at 30 min the variation is slightly less ( $\sim 94.4$ –96.7 %LC) vs. DS  $d_{90}$  variation. Of course, the selection of the timepoint(s) at which dissolution extent is examined impacts how sensitive the dissolution behavior is.

**Figure 3.** (a) Variation in dissolution extent vs. time. (b) Dissolution extent at 20 and 30 min vs. DS  $d_{90}$ .

## **5. Conclusions and Discussion – Industrial and Regulatory Considerations**

The presented case study exemplifies how variation in DS properties can propagate to the final DP product performance and why modelling an end-to-end process is valuable. The modelling approach we have shown could also be used to directly inform the questions posed in the International Council for Harmonization (ICH) quality guideline Q6A (2000) Decision Tree #3, to assess whether an acceptance criterion is required for DS PSD. However, one must acknowledge that there remain certain obstacles to realizing end-to-end process modelling in general.

**Material Science:** Advancements in proven methods for DS bulk property prediction from the DS particle properties need to be made. A first principles description for this needs computational approaches to interpret and predict physical properties of crystalline solid forms incorporated into an integrated process model, including DS isolation steps – such studies are few in the literature (Destro et al., 2021).

**Blend Property Prediction:** Predicting blend properties from its composition and individual component properties is essential to describe the formulation-dependence of a process. Modelling the behavior of granular solid blends without DEM is not arbitrary. Many efforts have been made in the literature, only some of which are industrially pragmatic. Statistical approaches are limited by the range of data collated and cannot be reliably extrapolated outside of the considered calibration data space – such models that are currently available consider only a small range of flow characteristics for OSD forms. Approaches using the granular Bond number, although based more on fundamental particle behavior and interactions, require measurements that are not routinely collected in an industrial environment (e.g., particle surface energy). Bano et al. (2022b) proposed mixing rules for blend flow properties based on the van der Waals rules for fluid mixtures, while Jolliffe et al. (2022) proposed a protocol for modelling powder blend compaction properties. More efforts such as these for a wider set of blend properties are needed.

**Standardized, Systematic Model Evaluation:** Process modelling is still in its relative infancy in pharmaceutical manufacturing, and thus there can be a lack of widespread confidence and uptake of models by the pharmaceutical industry. Specifically, there may be a lack of scientists with the appropriate expertise for model development in a company, as well as resource constraints and a lack of management and stakeholder support. One component of the latter point is that there is no standardized workflow for systematic model development and evaluation that also considers uncertainty propagation. A recent publication by Braakman et al. (2021) describes a workflow for the systematic evaluation of quantitative systems pharmacology models – a similar workflow for integrated process models that is supported by both industry and regulators alike would be invaluable.

**Regulatory Guidance:** While there have been an increasing number of literature contributions from industrial research groups on modelling applications, there is not a clear consensus or guidance to what extent these approaches will be accepted by global regulatory agencies. While the ICH quality guidelines provide some guidance on model development, the level of detail that should be included in a marketing application on model usage to define a control strategy is less clear. Consequently, this leaves industrial practitioners with uncertainty on the likelihood of success; and therefore, resorting to an empirical approach based on Design of Experiments (DoE) and statistical analysis, which is a more widely applied aspect of the Quality by Design (QbD) framework, is thus the safer strategy. This highlights the need for better engagement between regulators and industry on model development and usage.

The increasing number of modelling applications by pharmaceutical companies is certainly promising. We believe that overcoming these barriers are critical to realizing the full benefits of end-to-end modelling for accelerated pharmaceutical development. Continued demonstration of successful case studies of model applications on active projects are key to move towards the systematic application of modelling by first intent for pharmaceutical process development.

## Abstract

Direct Compression (DC) is a desirable manufacturing route for pharmaceutical tablets, having fewer unit operations than granulation processes. Assessment of the impact of process operating set points and lot-to-lot raw material property variation on manufacturability and product quality attributes is essential for the development of a robust process. In this study, we describe the development of a DC process model to assess the influence of process operating parameters and material properties on *in vitro* dissolution behavior. We summarize the model equations, followed by its calibration and validation vs. industrial data. We then use Global Sensitivity Analysis to investigate the effects of process operating parameters and material properties on *in vitro* dissolution.

**Keywords:** Direct compression; Flowsheet model; Pharmaceutical manufacturing, Global Sensitivity Analysis.

## 1. Introduction

Detailed understanding of the impact of critical material attributes (CMAs) and critical process parameters (CPPs) that belong to different unit operations of the manufacturing process on tablet intermediate and/or critical quality attributes (iCQAs and CQAs, respectively) requires quantifying how their combinations and interactions of CMAs and CPPs affect product performance. This detailed understanding can be obtained by developing an integrated (flowsheet) model that links together the different unit operations of the process, often termed a “system” model in the pharmaceutical industry. Such a model is based on mechanistic and/or empirical sub-models, each simulating different unit operations of the process and can be used to enhance process understanding.

In this paper, we have developed a system model for an industrial direct compression (DC) line. We analyze the system by performing a variance-based global sensitivity analysis to identify and rank the critical process parameters, gain process understanding and support process development. The paper is structured as follows: (a) materials and methods used, (b) models used to develop the system model and validation, (c) Global Sensitivity Analysis (GSA) and input to the control strategy definition.

## 2. Materials and methods

All data presented and used in this study were performed with formulations containing a GlaxoSmithKline (GSK) proprietary active pharmaceutical ingredient (API), microcrystalline cellulose (MCC), croscarmellose sodium and lubricant. For the formulations used, another solid form, “API Form X” can be present. The levels of this

form depend on the incoming drug substance material and the tablet press operation. The software used for all modelling activities was gPROMS®.

### 3. Models

This section describes the approach used to develop the system model for the DC process, how unit operations and product performance were modelled individually and how the sub-models were connected in the validated system model.

#### 3.1. Blender and Tablet press

The purpose of the semi-empirical blender model is to calculate the extent of lubrication in the blender ( $K_b$ ). The extent of lubrication, introduced by Kushner et al. (2012), is a metric to establish the direct correlation between mixing history and the amount of lubrication observed in the system. We considered that the extent of lubrication in the feed frame ( $K_f$ ) is also significant (Ketterhagen, 2017).

The tablet press model is an empirical model which combines the Kawakita and Lüdde (1971) and the Extended-Kushner (Nassar et al., 2021) models for the calculation of the tablet porosity (i.e., solid fraction) and tensile strength, respectively, as a function of extent of lubrication. These models require calibration with data for the relevant process equipment. The tablet tensile strength can be calculated from Eq. 1:

$$TS/TS_0 \equiv (1 - \beta) + \beta \exp(-\gamma K) \quad (1)$$

where  $K$  = total extent of lubrication,  $\gamma$  = tensile strength decay rate,  $\beta$  = material lubrication extent coefficient,  $TS_0$  = tensile strength of the unlubricated blend. The total extent of lubrication,  $K = K_b + K_f$  and  $K_f = v_{tip}\tau$  where  $v_{tip}$  is the tip speed of the feed frame paddle wheel, and  $\tau$  is the mean particle residence time in the feed frame. The tablet tensile strength is then related to the hardness (the practically measured quantity) as per Pitt and Heasley (2013). The generation of API Form X in the tablet press is captured by a data-driven model whose inputs are API  $d_{90}$ , level of API form X and tablet hardness.

#### 3.2. Tablet disintegration

The tablet disintegration model includes two mechanisms: (1) liquid penetration kinetics and (2) swelling of the tablet (Markl et al., 2017). According to Desai et al. (2016), the break-up of inter-particle bonds can also be caused by strain recovery. Strain recovery is the forcing/transitioning of macromolecules (polymers/disintegrants) into a metastable configuration, e.g., due to spontaneous crystallisation during compaction. In contrast to the omni-directional enlargement of the swollen particles, strain recovery causes a unidirectional increase in the size of the particles. All the mentioned mechanisms of disintegration are interlinked and influenced strongly by the microstructure of the tablet. In this study, since water absorption leads to the particle expansion (swelling) which in turn causes the breakup of the tablet structure, we assume that the penetration rate is the

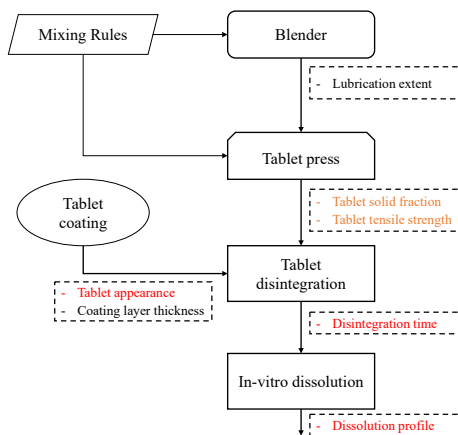

Figure 1. System model flow diagram (highlighted with orange: iCQAs, and red: CQAs).

disintegration rate-limiting step (Markl et al., 2017). The fluid flow in a tablet is described by the volume averaged velocity vector  $\mathbf{u}_p$ . This can be viewed as the volumetric flow rate per unit area. Following Bear (1988), to calculate  $\mathbf{u}_p$ , one can solve the continuity and momentum (Darcy's equation) balance equations:

$$\partial_x \mathbf{u}_p = 0 ; \mathbf{u}_p = -(\mathcal{K}/\mu_l) \partial_x p_p - \rho_l \mathbf{g} \quad (2)$$

where  $p_p$  = pressure inside the pores,  $\mathcal{K}$  = porous medium permeability,  $\mathbf{g}$  = gravitational acceleration,  $\rho_l$  and  $\mu_l$  = density and viscosity of the penetrating liquid, respectively. In Eq. 2,  $\mathcal{K}$  can be found from the Carman-Kozeny permeability equation,  $\mathcal{K} = d_h^2 \epsilon / (S_p \mathcal{T}_{or}^2)$  where  $d_h$  = pore hydraulic diameter. To account for the fact that  $\mathcal{K}$  varies within the same tablet, we introduced an empirical correction factor,  $\Lambda$ , which is fitted to tablet disintegration data. The corrected permeability is given by  $\mathcal{K}^* \equiv \Lambda \mathcal{K}$ .

To calculate average volume velocity vector, one needs to estimate the average porosity of the tablet. According to Markl et al. (2017), the latter is given by  $\epsilon = \epsilon_0 (R_c/R_{c0})^2$  where  $R_c$  and  $R_{c0}$  = wet and dry tablet region pore radius. As the tablet swells, it increases in size and this is causing the capillary radius to decrease, approximated as follows:

$$R_c = R_{c0} - \left(\frac{d_p}{2}\right) \left[ \left(\frac{\delta_0 + \lambda t}{\delta_0}\right)^{\frac{1}{3}} - 1 \right] \quad (3)$$

where  $\delta_0$  = initial dry pore length, and  $\lambda$  = swelling rate which can be calculated following Peppas and Colombo (1989). To calculate the wetting front inside the pores,  $P_d$ , the wetting front profile can be defined as  $F_p(r, z, t) \equiv P_d(r, t) - z$  (Leal, 2007). The substantial derivative of  $F_p$  is zero and this allows us to write:

$$\frac{dF_p}{dt} = 0 \Leftrightarrow \partial_t F_p + \mathbf{u}_p \partial_x F_p = 0 \Rightarrow \partial_t P_d + u_r|_{h_p} \partial_r P_d - u_z|_{h_p} = 0 \quad (4)$$

As stated above, the penetration rate is the disintegration rate-limiting step, thus, we calculate the rate of disintegration using the following expression:

$$\frac{dM_t}{dt} = [2\rho_s(1 - \epsilon)\Omega(t)] \frac{dP_d}{dt} \quad (5)$$

where  $M_t$  = mass of the tablet at time  $t$ ,  $\Omega$  = tablet cross-sectional surface area, and  $\rho_s$  = solid true density.

### 3.3. In-vitro dissolution

For the *in-vitro* dissolution model, we have used the population balance model by Wilson et al. (2012) to simulate the change in the particle size distribution during dissolution. We calculate the rate of particle release from the mass concentration and the released particles' number size distribution. The extent of dissolution is defined as the percentage Label Content (%LC) in solution, calculated as:

$$\%LC = 100 C_b^{API} V_m / x_a \rho_t V_{t0} \quad (6)$$

where  $C_b$  = mass concentration of the API in the bulk liquid,  $V_m$  = USP <711> (2011) dissolution test vessel liquid volume,  $V_t$  = volume of the tablet at  $t = 0$  and  $\rho_t$  = tablet density which is estimated from  $\rho_t \approx \rho_s(1 - \epsilon)$ . When %LC = 100% the dissolution process is complete.

### 3.4. Coating

To capture the influence of the coating layer, we used the “erosion rate” approach of Wilson et al. (2012) and Bano et al. (2022a). The main assumption of the model is that the liquid does not penetrate the coating layer, but the latter erodes with a constant erosion rate  $\hat{\epsilon}$ . The coating volume  $V_c$  on the surface of the tablet with surface area  $= A_t$  at any time is given by  $V_c(t) = [H_c(t) - \hat{\epsilon}t]A_t$  where  $H_c$  = coating thickness.

### 3.5. Mixing rules

We have also used a model-based approach to predict the fill bulk density of the blends from individual components. The model is that by Bano et al. (2022b) and used in the blender and tablet press models.

### 3.6. Calibration and validation of the models

All the above models were calibrated using experimental data from industrial DC campaigns. The system model was then validated vs. experimental data are shown in Fig. 2. The predictions and experimental data are in good agreement.

**Figure 2.** Model validation (left = nominal blend; right = different blender fill level and compaction force). Red points + error bars = experimental data; Blue curve = model predictions.

## 4. Results

Using the validated model, we performed a Global Sensitivity Analysis (GSA) to assess the impacts of different process parameters and material properties on tablet *in-vitro* dissolution. The input factors are: API particle size, form X level in API, moisture content, compaction force, MCC bulk density, lubrication time, feed frame rotational speed, tablet production rate, dissolution medium volume, blender rotational speed, paddle speed, MCC particle size, batch size and medium temperature. The output response is %LC at 30 min based on the USP <711> (2011) dissolution test.

### 4.1. Global Sensitivity Analysis

The first step on GSA is to perform the Elementary Effects (EE) method (Morris, 1991). This identified that the factors that have the biggest effect on the response of interest are the API particle size, level of API form X, the moisture content, the compaction force and the MCC bulk density. We then used the Sobol (1993) variance-based method.

There are two types of Sobol sensitivity indices: the first-order effect index ( $S_i$ ), that represents the main effect contribution of each input to the variance of the output, and the total effect index ( $S_{Ti}$ ), which measures the effect of both first- and higher-order effects

(interactions). For this study, the total effect indices for the response that the most important factors affecting the Label Content (LC)% are the API Form X and the API particle size ( $d_{90}$ ). Moreover, the interactions between MCC density, compaction force and water content (or moisture content) are expected to be important (Table 1).

**4.2. Assessment of Process Operating Space**

In this study we have used the validated model to run simulated experiments to assess the factor criticality (influential factors found in section 4.1). With this analysis we can capture scenarios in the considered process operating space where the tablet dissolution approaches or passes a threshold limit. Using the model, we can observe overall trends across the considered operating space by visualising simulated experiments as a function of different input factors. For example, in Fig. 3 we show a scatter plot that allows us to see the trend when increasing the API particle size. We also observe that some simulations are very close to the threshold limit ( $\%LC < 85\%$  at 30 min). For these cases close to the threshold, the level of form X in API and water content are high. This highlights how the model could help to highlight points in the operating space which may pose a product quality issue, which may have been challenging from experiments alone.

**Table 1.** Variance-based sensitivity analysis. Factor ranking; response: LC% @30min.

Ranking	Input Factors	$S_i$	$S_{Ti}$
1	Form X level [in API]	0.510	0.560
2	API particles X90	0.265	0.414
3	Moisture content	0.034	0.061
4	Compaction force	0.000	0.051
5	MCC density	0.000	0.026

**Figure 3.** Scatter plots of *in-silico* experiments API  $d_{90}$  effect on LC at 30min

**Figure 4.** Factor-factor interaction plots, %LC at 30min

In addition, we performed simulations to visualize factor-factors interactions. In Fig. 4, we performed simulations with high and low values of API particle size vs. high and low MCC densities. In this case, the lines are almost parallel (highlighting that factor-factor interactions are almost negligible) and the limit is not crossed. This factor-factor interaction (API particle size and MCC density) is negligible.

**5. Conclusions**

In this study, we developed a system model for a DC tableting line. The system model was calibrated and validated against data collected from industrial campaigns. At this stage, the validation showed that the model is predictive vs. *in vitro* dissolution data and has a very good prediction fidelity. Later, the model was used to perform *in-silico*

calculations of dissolution profiles under USP <711> conditions. Based on this, we identified the critical process parameters which affect tablet dissolution (main CQA). In this work, it is highlighted that the modelling approach can be used to provide actionable insight into control strategy definition discussions and to help industrial practitioners develop robust pharmaceutical manufacturing processes.

### Abstract

Lignocellulosic biomass potentially represents a great feedstock for biofuel production, but its' pretreatment needs to be enhanced in order to make biorefineries competitive with fossil fuel based alternatives. One way to make biorefineries more economically viable is to recover and valorize all generated by-products during the biomass pretreatment step. The main goal of this original research is to design an optimal process for recovering valuable by-products after hot-liquid water pretreatment of poplar biomass. Rigorous models for all operations included in the recovery process are developed using Aspen Plus as a CAPE tool. An optimal downstream processing sequence, consisting of multiple distillation steps, is designed to recover several valuable components, such as acetic acid, formic acid, furfural and 5-hydroxymethyl-furfural (HMF).

**Keywords:** biorefineries, lignocellulosic biomass, valorization, distillation

### 1. Introduction

The increasing concerns on environmental pollution and reduction of available fossil carbon sources lead to a need for a transition towards biofuels and bio-based chemicals from renewable sources. Technologies for the production of the first generation biofuels are already well established. On the other hand, their implementation directly competes with global food production as the first generation biomass can also be used for food supply. The potential solution is usage of lignocellulosic biomass as a source for biorefineries. As the second generation feedstock, it is a non-food crop that can be easily grown on land not suitable for food production. Therefore, the production of biofuel and biochemicals from lignocellulosic biomass does not threaten the food production process (Chiaramonti et al., 2013).

However, technologies and markets for conversion of the second generation feedstocks are still not well established. In order to become competitive with fossil-based production, biorefineries need to be more economically viable (Kiss & Infante Ferreira, 2016). Due to the complexity of the lignocellulosic biomass structure, the pretreatment step is needed to facilitate further conversion of lignocellulosic components to fermentable sugars. Since this process step significantly contributes to the total costs (up to 30-40%) (Ramaswamy et al., 2013), its' enhancement can drastically increase the viability of biorefineries. One way to improve the competitiveness of biorefineries is to recover and valorize valuable by-products generated during the biomass pretreatment step, which has not been the subject of many studies so far. This research gap is covered in this study.

## 2. Problem statement

### 2.1. Enhanced biomass pretreatment step

A common problem with different pretreatment methods is usage of additional chemicals. These chemicals might facilitate the pretreatment step but complicate downstream processing, as well as valorization of generated by-products. In that context, hot-liquid water pretreatment potentially presents an eco-friendly solution due to relatively mild process conditions, lack of additional chemicals, low process costs and a possibility to recover and valorize formed by-products (Chen et al., 2022).

### 2.2. Recovery of valuable by-products from the pretreatment step

After the biomass pretreatment step by hot-liquid water, the solid fraction is sent to enzymatic hydrolysis while the potential value of the liquid fraction is usually neglected. This research focuses on downstream processing of the liquid fraction after hot-liquid water pretreatment of poplar biomass. The main goal is to fully recover valuable by-products (e.g. acetic acid, formic acid, furfural, HMF). These components are not only economically valuable, but they can also inhibit fermentation reactions. Therefore, their removal will result in higher bioethanol yields. A crucial problem regarding by-product recovery is a very dilute solution after the pretreatment step (Kiss et al., 2016). Consequently, improved fluid separation processes are needed in order to recover by-products in a high-purity form that can be valorized on the market.

## 3. Methodology/Approach

The main objective of this research is to develop an optimal way to recover by-products from the liquid obtained after hot-liquid water pretreatment. The composition of the liquid, which is the feed stream for the designed downstream processing sequence, is obtained from literature (Jiminez-Gutierrez, 2023) and is presented in Table 1. This stream is diluted solution of different products generated by pretreatment of poplar biomass. Acetic acid is formed by hydrolysis of acetyl groups in the hemicellulose chain. C-5 sugars (mainly xylose and arabinose) from hemicellulose can degrade to furfural, while C-6 sugars (mainly glucose, mannose and galactose) from both cellulose and hemicellulose can degrade to HMF. Formic acid can be generated from both furfural and HMF, while levulinic acid can be formed by degradation of HMF. Rigorous Aspen Plus simulations are developed for every process operation. Components are defined in Aspen Plus according to the literature (Aspen Technology, 2021). Due to presence of different carboxylic acids in the initial mixture, NRTL property method coupled with Hayden-O'Connell model with correction for vapor phase association of carboxylic acids is used (Aspen Technology, 2020). Properties of the components and possible formation of azeotropes (Gmehling et al., 2004) are given in Table 2.

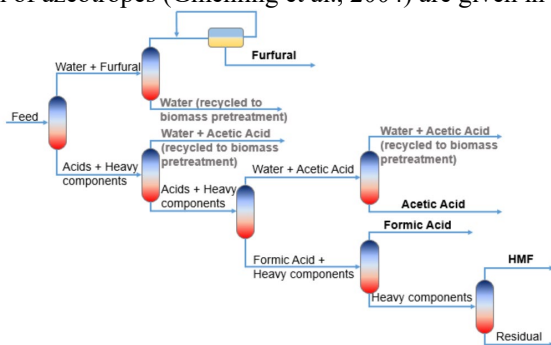

Figure 1. Simplified process flow scheme of the by-products recovery process

Table 1. Feed stream

Component	%wt
Water	96.568
Acetic acid	1.747
Formic acid	0.427
Furfural	0.297
HMF	0.128
Levulinic acid	0.005
Glucose and xylose	0.097
Other heavy components	0.730

Table 2. Components and azeotropes (1 atm)

Pure components		Azeotropes		
Component	T <sub>b</sub> (°C)	Component	Molar fraction	T (°C) / type
Water	100.02	Water	0.9066	97.79
Formic acid	100.55	Furfural	0.0934	/heterogeneous
Acetic acid	118.01	Water	0.3607	106.50
Furfural	161.35	Formic acid	0.4998	/homogenous
Levulinic acid	256.98	Acetic acid	0.1395	
HMF	281.85	Water	0.4566	106.81
Glucose	343.85	Formic acid	0.5434	/homogenous

Different methods for recovery of present components from diluted solutions are proposed in the literature (Li et al., 2016), but recovery yields are usually insufficient and the usage of additional chemicals complicates downstream processing. Research is often done on lab-scale and scale-up is not considered. To avoid adding extra chemicals, distillation is chosen and component separation is proposed in a defined order (Figure 1). Since the feed is very diluted, the first step is to concentrate it by separating as much water as possible. Due to the formation of light heterogeneous azeotrope (Figure 2), furfural is separated together with water. It can further be recovered by simple phase separation in a decanter. Recovery of acetic and formic acids from an aqueous solution is complex due to existence of four distillation areas and two azeotropes (Figure 3). As acetic acid concentration is the highest of all by-products in the feed, its' recovery is crucial. Therefore, most of acetic acid and water are separated from formic acid and heavier components (HMF, levulinic acid, dissolved sugars and solubilized lignin components) at temperature lower than needed for ternary azeotrope formation. Further recovery of acetic acid is complex due to the tangent pinch at high water concentrations. Formic acid, plus the remaining water and acetic acid, can be separated from HMF and other high boiler components by distillation. The obtained mixture can be further treated in order to obtain a high-purity formic acid product. HMF can be recovered in a high-purity form, while other components can be sent to the fermentation step.

## 4. Results and discussion

### 4.1. By products recovery process design

The proposed optimal process design for recovery of valuable by-products after biomass pretreatment by hot-liquid water recovers acetic acid, furfural, HMF and formic acid. This process (Figure 4) consists of seven distillation columns and one decanter. Light azeotrope water-furfural is separated in column C-1, after which furfural is purified by additional distillation in column C-2 and phase separation in decanter DEC-1. This results in 100% furfural recovery, while purity of product stream is 97.9%wt. After separation of the water – furfural azeotrope, the solution is still very dilute and is further concentrated in column C-3. Some acetic acid is separated together with water, resulting in top product from this column with 0.5%wt of acetic acid (13.8% from acetic acid present in the feed stream). Since addition of acetic acid in pretreatment step improves digestibility of biomass by decreasing pH to mild-low values (Jiminez-Gutierrez, 2023), this stream can be recycled back to the biomass pretreatment step. Bottom product from column C-3 is further distilled in column C-4. Acetic acid, together with most of the water, is separated as a top product, while formic acid, levulinic acid, HMF and other heavy components are obtained in the bottom stream. Acetic acid is purified in column C-5 and obtained in a high purity form (99.8%wt), with total recovery of 78.8 %. HMF and heavier components are separated from formic acid, levulinic acid and remains of acetic acid and water in column C-6. HMF is further purified in column C-7 and obtained as high-purity (100%wt) top product with total recovery of 99.6 %, while heavy components that are obtained at the bottom can be recycled back to the fermentation step. Top product from column C-6 is stream with 73.6%wt of formic acid. Since composition of this stream is in distillation region 3 in Figure 3, high recovery of pure formic acid cannot be obtained by simple distillation due to the thermodynamic limitations of the water – formic acid azeotrope formation. Therefore, reactive distillation with methanol could be applied to completely recover formic acid (Painer et al., 2015). Moreover, additional purification of formic acid might not be necessary as there are applications of 70% formic acid solution (Singhal et al., 2015). Condition and composition of feed stream and product streams are given in Table 3.

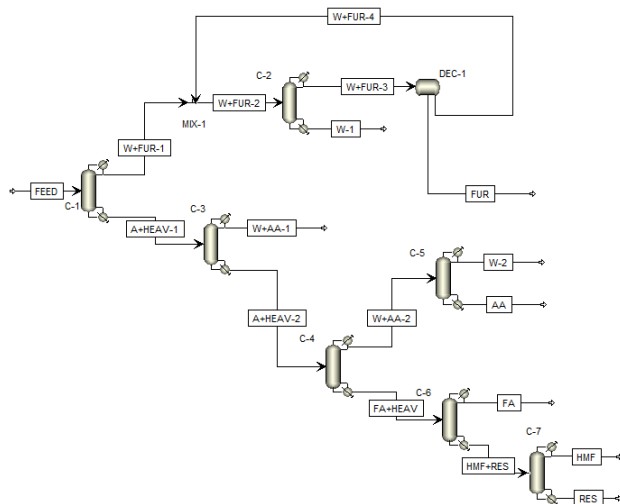

Figure 4. Flowsheet of by-products recovery process

Figure 5. MVR heat pump design

Table 3. Condition and composition of feed stream and product streams for by-products recovery process

Stream	FEED	FUR	AA	FA	HMF
Temperature [°C]	99.70	27.36	26.00	34.82	26.00
Pressure [bar]	1	1	1	0.05	0.01
Mass Flow [kg/h]	110000	333.89	1517.00	635.11	140.70

Table 4. Design parameters of distillation columns in by-products recovery process

Column	C-1	C-2	C-3	C-4	C-5	C-6	C-7
No. Stages	52	30	60	48	66	20	20
Feed Stage	35	12	40	36	33	10	13
Pressure [bar]	1	1	1	1	1	0.05	0.01

#### 4.2. Distillation columns design

Design parameters (number of stages, feed stage and column pressure) for each of the columns are given in Table 4. As the feed stream is very dilute, large amounts of water need to be evaporated in C-1, C-3, C-4 and C-5. Hence these columns have larger number of stages and higher reboiler duties than the other columns. However, the top vapor from these columns can be used to evaporate bottom liquid by implementing mechanical vapor recompression as heat pump. Columns C-6 and C-7 operate at lower pressure to reduce temperatures and avoid thermal degradation.

#### 4.3. Energy analysis

Mechanical vapor recompression (MVR) and heat integration (HI) are implemented to enhance base process design. MVR is a heat pump design that can be applied to decrease energy use when separating close boiling components (Kiss & Infante Ferreira, 2016). This implies compressing top vapor and using it to evaporate bottom liquid (Figure 5). In the designed optimal recovery process, MVR is applied to the columns C-1, C-3, C-4 and C-5. Comparison of key performance indicators for processes before and after enhancing process design is given in Table 5. The inefficiencies in power generation are taken into account for calculation of the total energy requirements through an electric to thermal conversion factor of 2.5. Total investment cost (TIC), total operating cost (TOC) and total annual cost (TAC) are calculated according to a published procedure (Kiss, 2013), with a payback time of 10 years. A Marshall and Swift cost index of 1638.2 (end of 2018) is used (Mantingh & Kiss, 2021). Emissions of CO<sub>2</sub> are calculated using the equations from the literature (Mantingh & Kiss, 2021).

Table 5. Key performance indicators for processes with and without MVR

Performance indicator	Base case	Enhanced case	Savings (%)
Thermal energy requirements (kW <sub>th</sub> h/kg <sub>product</sub> )	75.13	0.18	99.8
Electrical energy requirements (kW <sub>e</sub> h/kg <sub>product</sub> )	n/a	3.53	n/a
Primary energy requirements (kW <sub>th</sub> h/kg <sub>product</sub> )	75.13	8.99	88.0
Total Investment Cost (k\$)	24923	48284	n/a
Total Operating Cost (\$/kg <sub>product</sub> )	2.29	0.33	85.5
Total Annual Cost (\$/kg <sub>product</sub> )	2.41	0.56	76.6
CO <sub>2</sub> emissions (kg <sub>CO2</sub> /kg <sub>product</sub> )	10.84	1.88/ 0.03*	82.7/ 99.7*

\*electricity from non-renewable sources / green electricity

## 5. Conclusions

This original work proposes an optimal process design for recovering by-products after biomass pretreatment by hot-liquid water. Improved fluid separation processes are used to obtain valuable products from very dilute feed stream (>96%wt water). Several biomass pretreatment products are effectively recovered, including: acetic acid, formic acid, furfural and HMF, with recoveries of around 78.8%, 99.5%, 100% and 99.6% respectively. Acetic acid, furfural and HMF are obtained in high-purity forms (99.8%wt, 97.9%wt and 100%wt respectively), while formic acid is recovered as a 73.6wt% solution. MVR and HI are efficiently implemented to further decrease the energy usage. Due to the use of additional compressors, TIC after implementation of MVR and HI is about 93.7% higher, but TOC and TAC are decreased for 85.5% and 76.6% (from 2.29 to 0.33 \$/kg<sub>product</sub> and from 2.41 to 0.56 \$/kg<sub>product</sub> respectively). Moreover, usage of MVR resulted in 88.0% energy savings and significantly lower CO<sub>2</sub> emission leading to a more environmentally friendly process.

## Abstract

In this paper, a deep learning-based group contribution approach has been developed to identify the optimum structure for ionic liquids (ILs) and to maximize the CO<sub>2</sub> absorption capacity. The suggested methodology demonstrates the steps required to build two deep-learning-based group contribution models, DNN-GC and ANN-GC, separately for IL viscosity and CO<sub>2</sub> solubility in the programming language ‘Python’ by using the two widely used modules, ‘Scikit-Learn’ and ‘TensorFlow’. The CO<sub>2</sub> solubility of IL candidates may not result in the best CO<sub>2</sub> absorption process performance because many other properties of IL, such as viscosity, may affect process performance. To resolve this issue, the two developed models were merged to increase the model accuracy and to predict CO<sub>2</sub> solubility and IL viscosity at the same operating pressure and temperature. Based on the latter steps, an illustrative post-combustion CO<sub>2</sub> capture case study was performed to assess the applicability of the model to select the best IL candidate. With this method, a trade-off between CO<sub>2</sub> solubility and viscosity of ILs can be explicitly studied.

**Keywords:** Deep learning, Group contribution, Ionic liquids, Physiochemical properties

## 1. Introduction

Recently, ionic liquids (ILs) have been the subject of intensive research due to their tunability to fit the needs of a certain application. Also, these solvents possess several advantages including low energy required for energy regeneration, low vapor pressure, and non-corrosive (Nath & Henni, 2020). Despite these merits, their tunability also makes it difficult to identify the optimum candidate for CO<sub>2</sub> capture from the thousands of potential candidates. The number of novel ILs is on the rise and yet the experimental data on these novel ILs are scarce or not readily available in the open literature. Therefore, a robust and less time-consuming computational method such as predictive models, especially deep learning (DL) algorithms is needed for the optimal design of ILs and to accurately understand the dynamics of their physiochemical properties (Jian et al., 2022). Deep neural networks (DNNs) have a greater depth in terms of network layers and a larger number of network parameters compared to

conventional shallow neural networks (Deng et al., 2020). Deep learning (DL) is the primary machine-learning model for predicting structure properties and is composed of deep neural networks (DNN) and artificial neural networks (ANN) (Schmidhuber, 2015). DL which is a subset of Machine learning (ML) are empirical models that apply multiple structures of a neural network to significantly enhance the computing efficiency leading to an increase in neuronal complexity (Pezhman et al., 2022). Artificial neural networks (ANNs), employ most DL algorithms, consisting of an input layer, an output layer, and one hidden layer (Pezhman et al., 2022). Both the DNN and ANN model receives inputs as artificial features from raw data, where they get correlated between layers until they reach the property prediction at the final layer. However, in DNN the hidden layer comprises a multi-layer to allow the neural network to reach deeper levels and to have more network parameters. Moreover, they are computationally advanced in terms of finding non-linear correlations (Deng et al., 2020). The chief objective of this work is to develop two deep learning-based group contribution (GC) models in python to predict ILs viscosity and their CO<sub>2</sub> absorption capacity at different pressure and temperature based on their cation-anion skeletons and functional groups. Furthermore, the two models are merged to optimize new IL molecule structure based on viscosity, cation-anion skeleton, and cation-substituents to achieve maximum CO<sub>2</sub> solubility in a post-combustion carbon capture case study.

## 2. Methodology

### 2.1 Data collection

In this study, a total of 3466 data points on viscosity and CO<sub>2</sub> solubility for 48 ILs, 1733 data points each, as well as their critical properties ( $T_c$ ,  $P_c$ , and  $\omega$ ) were collected from Ionic liquids Database-ILThermo (v2.0) (*Ionic Liquids Database - ILThermo*, n.d.) at different temperature and pressure. The classifications of the cations in the selected ILs are Imidazolium (41%), Ammonium (15%), Phosphonium (15%), and Pryridinium (29%).

### 2.2 DL-GC model development

GC model is widely used in IL solvent design and predicting their thermophysical properties, and for many various decomposition approaches of IL molecules (Chen et al., 2022). A total of 28 different functional groups were obtained from IL molecular structure consisting of 4 cations, 13 anions, and 11 cation substituents (e.g. organic and inorganic groups) as shown in Table 1. So far, many DL-based non-linear GC models have been suggested for property estimation, and the results show that these non-linear models have higher prediction accuracy compared to linear models. Therefore, here the aim is to incorporate DNN and ANN with the GC model to construct a predictive model for the IL viscosity and CO<sub>2</sub> solubility. DNN was selected to predict IL viscosity due to better performance over ANN during model development. The optimum DL-GC architecture and hyperparameters will be identified through the grid search method in TensorFlow for DNN and ANN to determine the optimum number of neurons in each hidden layer.

### 2.3 Data pre-processing

As a first step, the collected data need to go through the pre-processing step to remove anomalies within the data such as outliers or missing data values. After that, feature selection was applied to select the independent variables for model inputs. In the DNN-GC model, certain features were dropped to improve the performance of the model. In total, 39 and 46 independent variables including the group contribution parameters (see Table 1) for DNN-GC and ANN-GC models, respectively, were identified to predict both dependent variables, the viscosity and the  $\text{CO}_2$  solubility at different temperatures and pressure, resulting in 39 and 46 input nodes in the input layer and one output node in the output layers in both models. The following step is splitting the acquired dataset into two sets, the training set (90%) and the test set (10%), by using an in-built function in the Scikit-learn python library called `train_test_split` function.

### 2.4 Building and training the DL model

To continue with DL model development, both DNN and ANN were constructed and trained separately. A general structure for DNN-GC consists of multiple hidden layers and each layer comprises several neural elements. ANN-GC model consists of only one hidden layer that contains many neural elements. Both models were built using the Keras-Dense layer available in the TensorFlow package. A commonly used activation function named Rectified linear unit (ReLU) was selected for this study because this function acts as an excellent predictor that activates all neurons at the same time (Zarra et al., 2019). To speed up the optimization process during the training stage, the adaptive moment estimation (Adam) optimizer of TensorFlow was used. The loss function 'mean\_absolute\_error' (MAE) was used during training to identify the best regression based on the value of MAE. To assess the predictive performance of both models, three standard metrics were chosen namely Mean Absolute Error (MAE), Root Mean Square Error (RMSE), and coefficient of correlation ( $R^2$ ).

### 3. Results and discussion

#### 3.1 Identifying the optimum structure for DNN and ANN

To increase the accuracy of the two models, the grid search hyperparameters tuning method was applied to search for the optimum number of hidden layers, neurons, and epochs. When the grid search was used for the DNN-GC model, it was observed that 2 hidden layers with 30 and 256 neurons each, with a number of epochs 10,000, and activation function ReLU and sigmoid for the hidden layer and the output layer, respectively, were required to increase the model accuracy. Also, MAE is used for training and validation loss function as stated earlier to validate the accuracy of the model. Furthermore, regularization and dropout methods were also used to avoid overfitting or underfitting during the training. A similar approach was followed for the ANN-GC model, only one hidden layer with 40 neurons was enough to increase the accuracy of the model and neither regularization nor dropout was required for the ANN-GC model. After training both models for nearly an hour, and based on the optimum structures, both models were validated graphically and statistically. Figure 1 depicts the correlated viscosity and CO<sub>2</sub> solubility values for both models versus the corresponding experimental data. Both predicted values for both models are accumulated around the 45° line which indicates a good fit. As for the statistical evaluation, the results have shown high R<sup>2</sup> of 95% and 96%, RMSE of 0.052 and 0.065, and MAE of 0.042 and 0.021 for DNN-GC and ANN-GC, respectively.

Figure 1: Cross-plot of true values versus predictions for Viscosity using DNN (Left) and CO<sub>2</sub> solubility using ANN (Right)

#### 3.2 Illustrative case study

To explicitly study the trade-off between the CO<sub>2</sub> solubility and viscosity of ILs, both trained models were merged by making the output of the DNN-GC model (viscosity) as an input feature to the ANN-GC model to simultaneously understand the behavior of the viscosity of the ILs and their CO<sub>2</sub> solubility capacity by varying temperature and pressure. The ‘Keras.Model’ option available in TensorFlow was used to merge both models. To find the optimum parameters (activation function and epochs), a grid search was applied.

Optimizers ReLU and sigmoid for hidden and output layers, respectively, gave better performance, and an epoch of 8000 improved model accuracy (training time = 25 minutes). The previously used metrics were also applied to the merged model. As for graphical validation, a good fit is depicted and almost all predicted data are accumulated around the 45° line as shown in Figure 2. For statistical validation, results showed that the merged model has better accuracy with an R<sup>2</sup> of 97%. RMSE and MAE are 0.041 and 0.022, respectively. This indicates that by merging models, the performance of the model is enhanced.

Figure 2: Cross-plot of true values versus predictions for CO<sub>2</sub> solubility using the merged model – DNN-ANN

In this illustrative study, the objective is to demonstrate the capability of the developed models to find the optimum structure of IL with maximal CO<sub>2</sub> absorption capacity using the given functional group in Table 1. Two constraints were set for the feasibility of ILs: (1) the maximum number of cation substituents [CH<sub>2</sub>] was set to be 8 and (2) viscosity less than 0.1 Pa.s. Also, only cation core [Im<sub>13</sub>]<sup>+</sup> and [Im<sub>123</sub>]<sup>+</sup> were considered in this example. To illustrate a post-combustion CO<sub>2</sub> capture, absorption conditions were pre-specified as 293.15 K and 1.5 MPa. A python code was developed to predict the optimum combination of a functional group to obtain an IL with high CO<sub>2</sub> capacity and low viscosity. Table 2 presents the best IL candidates, with the following IL structure cation [Im<sub>13</sub>]<sup>+</sup> anion [Tf<sub>2</sub>N]<sup>-</sup>, 1OH, 8CH<sub>2</sub>, 1 aN-CH<sub>3</sub>, 1aN-CH<sub>2</sub> having the highest CO<sub>2</sub> removal and low value of viscosity (< 0.1 Pa.s). However, IL with anion [PF<sub>6</sub>]<sup>-</sup> might not be a viable option for the CO<sub>2</sub> capture process due to its high viscosity.

Table 2: Merged model results of the optimal ILs

Optimal IL group combination	IL Viscosity (Pa.s)	CO <sub>2</sub> Solubility
1OH, 8CH <sub>2</sub> , 1[Im13] <sup>+</sup> , 1 aN-CH <sub>3</sub> , 1aN-CH <sub>2</sub> , [Tf <sub>2</sub> N] <sup>-</sup>	0.0111	0.642
1OH, 8CH <sub>2</sub> , 1[Im13] <sup>+</sup> , 1 aN-CH <sub>3</sub> , 1aN-CH <sub>2</sub> , [PF <sub>6</sub> ] <sup>-</sup>	0.553	0.543
1CH <sub>3</sub> , 7CH <sub>2</sub> , 1[Im123] <sup>+</sup> , 1 aN-CH <sub>3</sub> , 1aN-CH <sub>2</sub> , [AC] <sup>-</sup>	0.080	0.647

#### 4. Conclusion

This paper presents a new modeling framework for the design of the optimal molecular structure of IL for CO<sub>2</sub> solubility, from a given set of functional groups. One important target property considered in this study is viscosity since it affects the pumping power required and ultimately the operating cost. To achieve this, two predictive deep learning models, DNN and ANN, were built and trained separately for IL viscosity and CO<sub>2</sub> solubility, respectively. The grid search method for hyperparameters tuning was employed to find the optimum DL-GC structure with regularization and dropout applied to avoid overfitting and underfitting. Results of validation metrics R<sup>2</sup> were found to be 95% and 96% for DNN and ANN, respectively. Then, both models were merged, with the output of the DNN model (viscosity) used as an input feature to the ANN model (CO<sub>2</sub> solubility). This improved the performance of the model (R<sup>2</sup> = 97%). Furthermore, to investigate the applicability of the merged model, a case study was carried out to design optimum ILs based on a set of structural and viscosity constraints. Results showed that IL with [Im<sub>13</sub>]<sup>+</sup>, [Tf<sub>2</sub>N]<sup>-</sup>, and cation substituents (1OH) is a good candidate in terms of viscosity and CO<sub>2</sub> solubility.

## Abstract

Plastics are present in many products and nearly every commercial sector. However, the management of plastic waste is still an open challenge. This work proposes a mixed integer linear programming optimization model of the Northern Italian supply chain for mixed plastic waste treatment. The model aims at maximizing the economic performance of the overall supply chain, taking into account both the selection of the treatment technologies (i.e. incineration, gasification and pyrolysis) and finding the optimal distribution of the material flows. The best economic scenario is achieved by a supply chain where only incineration plants are selected, yielding a gross profit of 31.8 M€/y for the overall supply chain. However, by varying oil price and specific treatment costs both pyrolysis and incineration plants are selected, showing that pyrolysis could be an economically competitive technology for chemical recycle of the mixed plastic waste, leading to a gross profit of 21.6 M€/y (- 32 % w.r.t. base case scenario).

**Keywords:** mixed plastic waste, plastic recycling, optimization, supply chain.

## 1. Introduction

Plastics are key and ubiquitous materials whose increasing consumption poses a challenge with regard to the management of plastic waste, as significant fractions of plastics still end up in landfills or leak into the ocean (Li et al., 2022). The largest fraction of plastic waste is made of plastic packaging; unfortunately, only a limited fraction can be mechanically recycled. The residual fraction, called mixed plastic waste (MPW), is either used as an ingredient for secondary solid fuel production, or directly incinerated or landfilled. The challenges in managing MPW are due to the variability in its composition, and incineration, which is an industrially well-established pathway, can help reducing the amount of waste that needs to be landfilled, and recover electric energy as well. Pyrolysis and gasification represent potentially attractive emerging technologies for MPW management; however, pyrolysis only preserves some molecular complexity and can be considered the first step of a chemical recycle path. Pyrolysis and gasification were indeed identified as the most mature and commercially viable chemical recycling technologies suitable for MPW treatment, according to the Threshold Readiness Level (TRL) assessment of Solis and Silveira (2020).

Supply Chain (SC) optimization raises as an important research topic in achieving an efficient plastic circular economy, and it allows assessing both the optimal selection of

MPW treatment technologies and an optimal distribution of the material flows among the different stages of the SC. The combinatorial complexity of the MPW SC is given by its multi-stage, spatially-explicit nature, and mixed integer linear programming (MILP) models are regarded as powerful mathematical optimization tools that can deal with such systems (Kallrath, 2000). This study aims at proposing a spatially explicit MILP framework for the economic optimization (in terms of maximizing the annual gross profit [€/y]) of MPW SCs, focusing on the Northern Italian region and considering multiple technological options.

## 2. Modelling framework

This section will describe the stages of the optimized MPW SC in terms of key model input parameters. The problem is formulated as an annualized spatially-explicit MILP modelling framework based on the location (in terms of latitude and longitude) of Italian provinces, sorting centres, incineration plants and oil refineries. The model optimization outcomes provide quantitative information on the SC in terms of economic results and technology selection under different scenarios. Both waste-to-energy (i.e. incineration) and chemical recycling technologies (i.e. pyrolysis and gasification) are considered as treatment options. The block diagram of the MPW SC is represented in Figure 1.

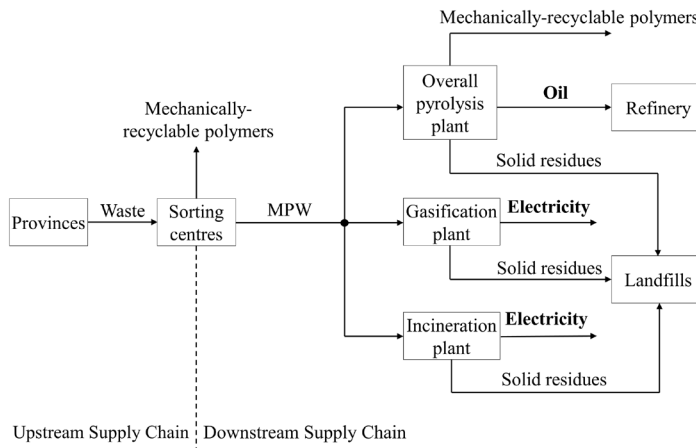

Figure 1. Block diagram of the MPW Supply Chain.

The stages of the MPW SC are divided into upstream SC and downstream SC. The upstream SC deals with the transport of plastic packaging waste (PPW) from provinces to sorting centres, separating the PPW share that can be mechanically recycled from the remaining part, i.e. the MPW. The downstream SC contains the MPW treatment options (incineration, gasification, pyrolysis), whose outputs are: electric power in the case of incineration and gasification, and oil in the case of pyrolysis plants, to be transported to a refinery for further processing (the system boundary is at the gate of the refinery in the case of pyrolysis oil). MPW is a heterogeneous mixture, and, to comply with the quality requirements for the pyrolysis oil produced, an additional sorting step is coupled with the pyrolysis plant; its costs and sorting performance are taken into account together with those of pyrolysis. Two options of pyrolysis technology are implemented: *Po. Pyrolysis* – the reactor feed consists of the polyolefin fraction, producing an oil similar to Brent oil. *PoPs. Pyrolysis* – using polyolefin and polystyrene fractions, producing an oil similar to

that of Western Canadian Select (WCS) (Mastellone, 2020). Road transport is considered as the only transport option since it reflects current practice for plastic waste.

### 2.1. Modelling assumptions and inputs

The spatially-explicit nodes are described in the model through a set  $n = \{n_{1-86}\}$  comprising 47 provinces, 12 sorting centres, 24 incinerators and 3 refineries. Each node is characterized by its exact geographic coordinates. The incineration plants are the plants currently available in Northern Italy (Utilitalia, 2019). It is assumed that gasification plants can be installed only in proximity of incineration plants; similarly, pyrolysis plants can be sited either by incineration plants or by refineries. The yearly PPW flowrate of each province are taken from COREPLA (2020) and are referred to 2019. Sorting centres are characterized in terms of plant capacity and sorting performances (their PPW-to-MPW conversion factor). All treatment plants generate solid residues that are sent to nearby landfills. For each technology (except incineration) three plant sizes have been considered (*Small, Medium and Large*). Each technology has been characterized in terms of relevant mass balances, energy balances, and each plant size and each incinerator has been characterized by its Specific Treatment Costs (*STC* [€/kt]) defined as:

$$STC = \frac{CAPEX + OPEX}{C} \quad (1)$$

where  $C$  is the annual plant capacity [kt/y],  $OPEX$  is the Operational Expenditure [M€/y] and  $CAPEX$  is the annualized Capital Expenditure [M€/y] calculated as:

$$CAPEX = TCI \cdot \frac{i \cdot (1 + i)^N}{(1 + i)^N - 1} \quad (2)$$

$TCI$  [M€] is the Total Capital Investment (updated using CEPCI, 2019),  $i$  is the interest rate, and  $N$  is the plant life. For all technologies and plant sizes, it is assumed that  $i = 15\%$  and  $N = 15$  years.

The decision variables in the optimization problem are:

- the PPW flowrates distribution from the provinces to the sorting centres;
- the MPW flowrates distribution from the sorting centres to the treatment plants;
- the selection of technology, plant size and location of the treatment plants.

### 2.2. Mathematical Formulation

The objective function of the MILP aims at maximizing the SC annual gross profit:

$$Objective = \max\{GP\} \quad (3)$$

Gross profit  $GP$  [€/y] is defined as the difference between the total annual revenues ( $TR$  [€/y]) and total annual costs ( $TC$  [€/y]):

$$GP = TR - TC \quad (4)$$

Total revenues  $TR$  [€/y] of Eq.(4) sums up revenues from gate tariffs cashed in  $Rev^{T,tot}$  [€/y], and from selling mechanically-recyclable polymers sorted out in the SC  $Rev^{Mech}$  [€/y], pyrolysis oil  $Rev^{Oil}$  [€/y], and electric power produced  $Rev^{El}$  [€/y].

$$TR = Rev^{T,tot} + Rev^{Mech} + Rev^{Oil} + Rev^{El} \quad (5)$$

A gate tariff value of 210 €/t of treated MPW is considered. Revenues from selling the mechanically-recyclable polymers from pyrolysis plants are computed based on 2019 market price 378 €/t. To calculate the revenues from the pyrolysis oil, the oil market price

is referring to 2019 average prices, and based on the choice of pyrolysis, either only from polyolefin fraction producing an oil similar to Brent oil (64.3 US\$/bbl) or from polyolefin and polystyrene fractions producing an oil similar to WCS (44.3 US\$/bbl). Revenues from electric power consider a market price of 52346 €/GWh, which is the average 2019 selling price in the Italian Power Exchange trading market.

The total cost  $TC$  [€/y] of Eq. (4) is defined as the sum of total MPW treatment cost ( $TPTC$  [€/y]), total landfilling cost ( $TLC$  [€/y]) and total transport cost ( $TTC$  [€/y]):

$$TC = TPTC + TLC + TTC \quad (6)$$

Total MPW treatment cost ( $TPTC$  [€/t]) is calculated as the sum between the overall plant specific treatment cost ( $STC$  [€/kt]) and incineration costs for remaining MPW  $PTC$  [€/y]:

$$TPTC = \sum m_{k,s}^{MPW} \cdot STC_{k,s} \cdot c_{k,s} + PTC \quad (7)$$

where  $m_{k,s}^{MPW}$  [kt/y] is the MPW flowrate treated in a plant  $k$  of size  $s$ , while  $c_{k,s}$  is a factor accounting for cost saving in the case a pyrolysis plant co-exists with a refinery.

The total landfilling cost ( $TLC$  [€/y]) is computed from the total residues produced in the SC ( $m^R$  [kt/y]) and landfill gate tariff  $T^l$  that equals 210 €/t of residues:

$$TLC = m^R \cdot T^l \quad (8)$$

Total transport cost ( $TTC$  [€/y]) is the sum of transporting waste, MPW, remaining MPW, oil and residues ( $TC^w$ ,  $TC^{MPW}$ ,  $TC^{RMPW}$ ,  $TC^{Oil}$ ,  $TC^R$ , respectively, all in [€/y]).

$$TTC = TC^w + TC^{MPW} + TC^{RMPW} + TC^{Oil} + TC^R \quad (9)$$

Each term is computed based on Unitary Transportation Cost ( $UTC$  [€/kt/km]) specific to the transported material (for solids:  $UTC^{MPW}$ , and for oil:  $UTC^{Oil}$ ), and the matrix of linear distances between nodes calculated with the spherical law of cosines (d'Amore and Bezzo, 2017).

### 3. Results

The model has been implemented in GAMS software and optimized by means of CPLEX solver. Two different scenarios are considered: a base case scenario containing all treatment options, and an alternative scenario excluding incineration.

The economic performance of the MPW SC for the different scenarios, and a cost breakdown showing are presented in Table 1.

Table 1. Total supply chain cost  $TC$  [M€/y] and the contribution of each component into the total cost: total MPW treatment cost  $TPTC$  [M€/y], total landfilling cost  $TLC$  [M€/y], total transport cost  $TTC$  [M€/y]. Annual gross profit  $GR$  [M€/y] are also presented.

Scenario	$TC$	$TPTC$		$TLC$		$TTC$		$GP$
	[M€/y]	[M€/y]	[%]	[M€/y]	[%]	[M€/y]	[%]	[M€/y]
Base Case	59.1	38.6	65.3	5.4	9.1	15.1	25.5	31.8
1-Pyro	68.2	45.5	66.7	7.1	10.4	15.6	22.9	
Alternative	99.4	66.0	66.4	11.7	11.8	21.7	21.8	21.6

### 3.1. Base Case Scenario Results

The base case scenario considers all MPW treatment technologies discussed for the economic optimization of the supply chain. It is characterized by a gross profit for the overall SC of 31.8 M€/y. Electric power contributes to about 21 % of total revenues. However, electricity revenues do not compensate for the total treatment costs. The largest contribution to total revenues (79 %) is given by the gate tariff received by treatment plants for treating MPW. The supply chain configurations are shown in Figure 2, for both the upstream and downstream sections.

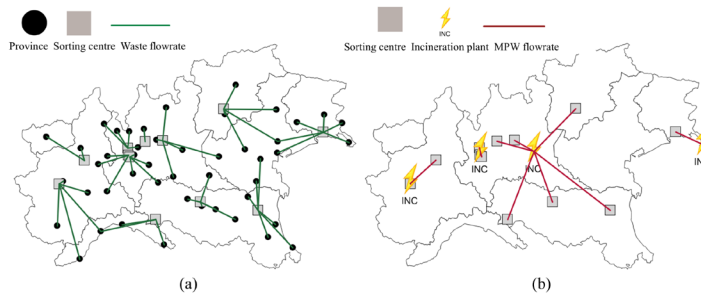

Figure 2. Base case supply chain configuration: (a) upstream SC, (b) downstream SC.

From Figure 2(a) it can be observed that the waste flowrate of each province is sent to the nearest sorting centre. This result suggests that whatever the advantages of sending the waste flowrates to sorting centres that are close to the final treatment plants, they are outmatched by the waste flowrates transport costs. From Figure 2(b), only the Northern Italian incineration plants are selected while no pyrolysis nor gasification plants are selected.

We verified that for the solver to select a different technology the oil price should be increased to a value of 72.7\$/bbl for Brent oil and to 50.1\$/bbl for WCS oil. The resulting configuration is shown in Figure 3, and it can be observed that both a pyrolysis plant and incineration plants are selected. The selected pyrolysis plant is of the largest plant size (benefiting from economies of scale) and it is located where a refinery exists, suggesting that the cost savings due to the coexistence of an oil refinery play a significant role.

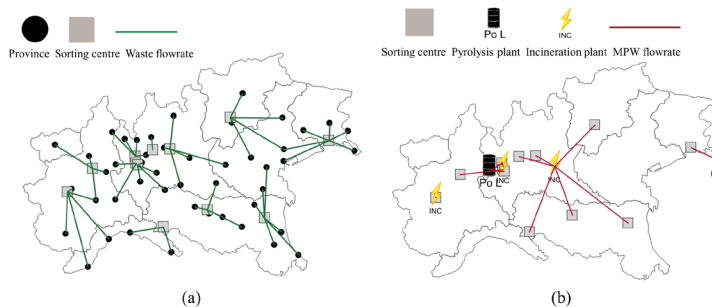

Figure 3. 1-Pyro Scenario MPW SC configuration: (a) upstream SC, (b) downstream SC.

### 3.2. Alternative Scenario Results

The alternative scenario excludes incineration (except for treating the remaining MPW from pyrolysis). The MPW SC configuration is shown in Figure 4, and it can be observed that only pyrolysis plants are selected, while gasification appears to not be economically

competitive w.r.t to the other technologies. From Table 1, the gross profit related to the alternative scenario is 21.6 M€/y, i.e. about 32 % lower w.r.t. the base case scenario.

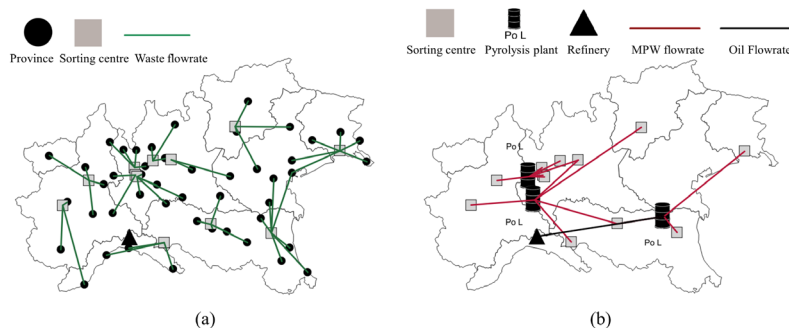

Figure 4. Alternative scenario MPW SC configuration: (a) upstream SC, (b) downstream SC

From Table 1 it can be observed that the total MPW treatment cost (*TPTC*) has the largest contribution representing more than 65 % of the to the total cost (*TC*) in all analysed scenarios. It can be observed that all cost components increase when pyrolysis plants are selected. In particular, the total landfilling cost (*TLC*) increases due to increasing flowrate of total solid residue generated by the pyrolysis in the SC.

#### 4. Conclusions

This study presented a MILP framework for the optimal design of an MPW supply chain in Northern Italy. Both waste-to-energy (i.e. direct incineration) and chemical recycling technologies (i.e. pyrolysis and gasification) were considered as possible MPW treatment options. The economic optimization of the base case scenario gives a configuration in which only incineration is selected, exhibiting an annual gross profit of 31.8 M€/y. However, it was proven for a higher oil price (comparable to 2022 oil prices), pyrolysis becomes economically competitive. Gasification plants are never a viable alternative. If incineration is excluded, only pyrolysis is selected, giving a gross profit of 21.6 M€/y (- 32 % w.r.t. base case scenario). Future work will address a multi-objective optimization accounting for both economic and environmental performances.

## Abstract

Recently circular economy has attracted a lot of attention in its ability to handle global challenges related to resource scarcity, sustainability and supply chain unpredictability. Designing circular products is probably one of the most critical factors that manufacturers need to consider when it comes to implementing a closed-loop production strategy. In continuation to our in-progress research related to circular economy applications in the manufacturing and process industry, the present work focuses in the development of optimisation models for the circular economy activities in the industry that will assist substantially in the decision making for implementing the most efficient and sustainable activities. The model development for such complex processes has very significant added value for the evaluation of the economic, environmental and technical circular economy options available. In this context, optimisation models are presented as well as the main problem variables and parameters are identified and the problem constraints are developed. Furthermore, the optimisation criteria for different industrial systems are also described. The results and conclusions of the work highlight the characteristics of the complex circular economy alternatives and develop the basis for the continuation and the expansion of the work in different industrial units.

**Keywords:** Circular economy modelling, Optimisation, industrial activities.

## 1. Introduction

The notion of circular economy (CE) the last few years has been widely accepted from manufacturing industries in order to transform their products processing and consumption to more sustainable throughout their supply chain. A transition from linear to a closed loop or circular system requires a shift away from the traditional model of producing products. Manufacturing industries have a significant impact on engineering process that must be adaptable, sustainable and efficient while maintaining high quality and low cost. Nonetheless, the big market demand for a long period of time is resulting in depleting natural resources and making products less sustainable. Over the past few decades efforts have been initiated to reduce our environmental impact through clean manufacturing and life cycle management initiatives (Stylianopoulou et al., 2021). Thus, this necessitates an innovative approach in researching the challenges and limitations of traditional linear economy to circular economy by making products and the supply chain of products more sustainable. One of the activities and focus is extending to a second life products by remanufacturing/recycling used products which are discarded by end-users when they are no longer needed. Advances towards CE mean efforts to improve the circulation of resources, materials and energies by closing loops. Thus, the objective of the present work is to highlight the relevance of CE with optimisation and make a concise review of the

current status in optimisation CE models, also, indicating the problem parameters and variables.

## 2. Tools for Circular Economy

Industries play an important role in implementing the CE notion. Product innovation, redesign, remanufacture, or value chain reconfiguration, can have a significant impact on how resources are managed and consumed. A remanufacturing industry must increase its quantity to effectively control variation in its supply chain and reduce the processing times required to intelligently incorporate remanufactured materials into new ones, such as the use of Industry 4.0 (I4.0). As a result, remanufacturing should be planned in such a way that allows high quantity content in the shortest amount of time when the products are produced (Baratsas et al., 2021, Nascimento et al., 2019). The use of harmonized CE standards and tools can be critical in the implementation of CE. This section presents selected CE tools which promote circularity in industries. Following, selective tools are presented which main goal is to promote circularity in industrial business.

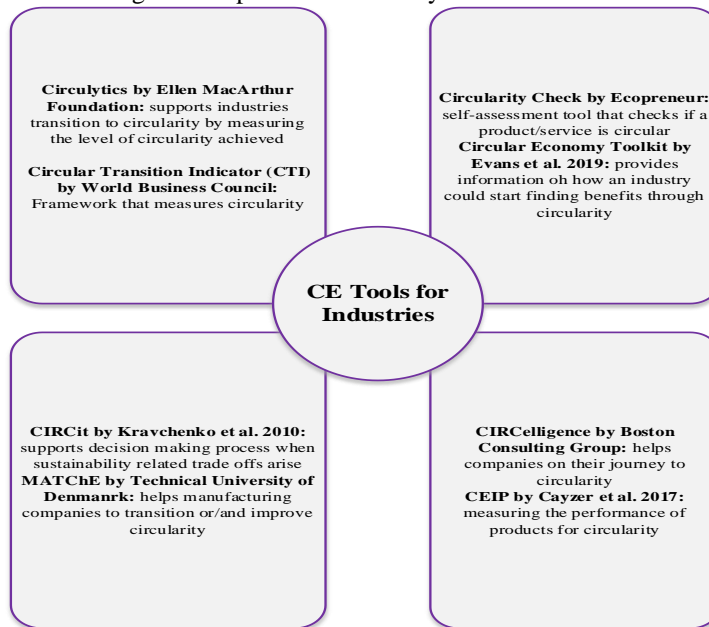

Figure 1: Existing CE Tools for Industries

However, these tools fail to give a quantitative solution in the CE approach by making them more of a framework than quantitative tool. Their approach is on a small amount of product life cycle without giving solution to the entire product lifecycle. Thus, there is a need for more accurate methodologies such as mathematical optimisation to begin implementing CE in industries.

## 3. Optimisation Models in CE

Circular economy in industries has been gaining interest from researchers and the industries themselves in view of transitioning from linear to circular economy. However, how an industry can approach circularity depends on the framework available to each country and how they can implement circularity.

Table 1: Selected literature review of CE optimisation

For instance the EU supports recycling and recovery targets where in the US there is no relevant framework (Saidani et al., 2019, Bjørnbet et al., 2021). Performance indicators are also required in order to monitor targets in CE models in the manufacturing sector. Our research was conducted in over 100 articles relevant to CE implementation in manufacturing, food and electronic industries. However, only a few of them are related

to the optimisation models development in CE. In the context of our focus in developing optimisation models expressing CE strategies for the industry, we have completed a detailed review in the suggested CE relevant optimisation models. The analysis presented in Table 1 is mainly focused in the structure of the optimisation models, its criterion and constraints. Through this research it was identified that Industry 4.0 (I4.0) with CE enables a sustainable innovation model that improves end-of-life activities, reduces waste and tracks production and consumption operations. On the other hand, publications that are not using I4.0 are either generally referring to optimisation models or are not giving solutions across the entire product lifecycle from manufacturing to use/reuse to end of life. What has been discovered is that product design optimisation is a rather unexplored area. Some publications proposed frameworks so as to analyse trade-offs between profit, environmental impact and circular performances but without optimizing the physical parameters of a product.

#### 4. Mathematical Model to be developed

The problem considered here is to approach CE and cleaner production with a mathematical model. In the publications reviewed, there are plenty of quantitative models which are focusing in I4.0, smart manufacturing, Industrial Internet of Things (IIoT), but its integration with the optimisation models focusing on CE and cleaner production is attempted by only a few researchers.

<i>Parameters</i>	<i>Variables</i>
Demand for new product	Qty of product
Demand of new & refurbished product	Qty of product shipped from plant to warehouse to market
Demand for used products	Qty of returned product of least reusable
Demand for remanufacturing products	Qty of new products to be produced
Capacity for processing/production	Qty of remanufactured products to be produced
Energy consumption	Qty of products to be recycled
Production time	Qty of products to be refurbished
Number of returned products	Qty of products to be disposed
Cost of remanufactured products	<b>Constraints</b>
Cost of used products	Warehouse for returned product
Cost for new products	Qty of used products allocated from least reusable level
Setup Cost for production	Warehouse for products
Waste disposal cost	<b>Sets</b>
Warehouse cost	Set of products
Returned products to warehouse cost	Set of plant
Transportation Cost	Set of warehouses
Cost of disassembling & inspecting returned products	Set of market
Cost of products to be manufactured, cost of refurbished products	Set for time period
Collection and logistics costs	

Table 2: Description of proposed mathematical model parameters, variables and sets

Thus, there is a need of more focused and advanced optimisation models modelling circularity to fulfill demand, clean production and zero waste. Table 2 presents model assumptions, sets, parameters, and variables to formulate a mathematical optimisation model for industries to implement CE.

Currently there are three dimensions that the circularity in industry is approached in our work.

1. Feasibility models are developed to investigate in detail all the investment and operational costs of potential remanufacturing/ reuse investments. The feasibility model is generic; however specific case study is implemented for the chemical recycle of plastics.
2. Environmental performance software is being implemented to provide various performance indices that are exploited then as inputs in the optimisation models.
3. Optimisation models are currently developed for various CE alternatives in specific industrial cases.

## **5. Conclusion**

The industrial / manufacturing sector plays an important role in transitioning from linear to circular economy. Industries can influence the way resources are consumed and managed through implementing circular economy in their supply chains. Most researchers use the 4Rs strategies, reduce reuse recycle and recover, to approach this topic, however the 10Rs (refuse, rethink, reduce, reuse, repair, refurbish, remanufacture, repurpose, recycle and recover) of CE is more preferable solution in waste scale so as to prevent waste to landfill and achieve zero waste. In order to achieve this there is a must of implementing strategies for product and supply chain design and material selection. However, there are several barriers that backtrack such a transition to a more circular model. Those barriers are the lacking of a unifying definition of CE and a common understanding of the concept, lack of technological innovations in the supply chains of industries that are focusing in CE. In addition, optimisation models presented in the publications are more general and they are not giving solutions across the entire product lifecycle and supply chain of a product. Thus, more research is needed for better understanding of how CE industries can contribute to sustainable production and consumption. Furthermore, the optimisation models for CE product design needs to aim to more pertinent analysis for the whole product life cycle of an industry and comprehend the CE strategies. For this the use of harmonized CE standards and tools can play an important role. Further research needs to be done for optimisation models in material section from larger material databases which are going to benefit the CE product life cycle.

## Abstract

Nutrients play a major role in several microalgal industrial processes and their efficient exploitation has an impact on environmental sustainability. The Droop model is suitable for the description of nutrients effect on microalgal growth but presents challenges in parameter identification for the high experimental effort required. In this work, a Model-Based Design of Experiments (MBDoE) was employed to plan information-rich experiments for precise parameter estimation. An initial dynamic sensitivity analysis showed that parameters of the Droop model can be practically identified with measurements of biomass and nitrogen content of the medium only. Finally, MBDoE was employed to plan *in silico* experiments, proving that two optimal experiments are sufficient to achieve accurate parameters estimation.

**Keywords:** Model Based Design of experiments; Droop model; microalgae; continuous photobioreactors; parameter estimation.

## Introduction

Microalgae are a wide variety of photosynthetic microorganisms, both prokaryotic and eukaryotic, that can be found in all ecosystems. Thanks to their ability to exploit photosynthesis to fix CO<sub>2</sub> and consume nutrients as inorganic nitrogen and phosphorus from wastewater, they represent a sustainable alternative for multiple industrial applications (Kumar et al., 2020; Olaiwola, 2003). Modelling the effect of nutrients on microalgal growth is of particular interest due to their strong relevance in different microalgal industrial processes and their impact on environmental sustainability. Even though Monod equations are conventionally used to describe microalgal growth, the Droop model better describes the growth rate as a function of the internal quota of the limiting nutrient, since microalgae still exhibit growth when dissolved nutrients are exhausted (Bernard, 2011). The main hurdle when working with the Droop model is related to the high number of measurements and experiments needed to reliably determine the kinetic parameters, resulting in long and time-consuming experimental campaigns (Turetta et al., 2022). In addition, working in steady state continuous cultures, which are more suitable for microalgal production, is even more time intensive, up to 11 weeks for each nutrient.

Based on those reasons, in this work, we propose a Model-Based Design of Experiments (MBDoE) approach to optimize the quality of experimental data while minimizing time and resources consumption (Franceschini and Macchietto, 2008). Accordingly, the objective is to exploit MBDoE to design experiments for maximising the information

required for accurate parameter estimation of the Droop model for continuous microalgal cultivation from measurements of biomass and nitrogen concentrations only. After the introduction of the Droop model and the definition of the mathematical foundation of MBDoE, a dynamic sensitivity analysis will be presented to highlight possible issues in parameter estimation. To show the capability of MBDoE of designing experiments for accurate parameter estimation, iterative *in silico* experiments were performed, according to the MBDoE procedure.

## 1. Model and methodology

### 1.1. The Droop model

In the Droop model, the specific biomass growth rate  $\mu$  ( $\text{d}^{-1}$ ) is a function of both light intensity  $I$  ( $\mu\text{mol m}^{-2} \text{s}^{-1}$ ) and the internal quota  $q$  ( $\text{g}_\text{N} \text{g}_\text{x}^{-1}$ ) of the limiting nutrient: in this work, nitrogen is considered as the limiting nutrient. Thus, the specific biomass growth can be expressed as (Bernard 2011):

$$\mu = \mu_{max} \frac{I}{I + K_I \left( \frac{I}{I_{opt}} - 1 \right)^2} \left( 1 - \frac{q_{min}}{q} \right) - k_d \quad , \quad (1)$$

where  $\mu_{max}$  ( $\text{d}^{-1}$ ) is the maximum specific growth rate of the microorganism,  $K_I$  ( $\mu\text{mol m}^{-2} \text{s}^{-1}$ ) is the half saturation constant of light response curve,  $I_{opt}$  ( $\mu\text{mol m}^{-2} \text{s}^{-1}$ ) is the optimal light intensity for growth,  $k_d$  ( $\text{d}^{-1}$ ) is the specific decay rate and  $q_{min}$  ( $\text{g}_\text{N} \text{g}_\text{x}^{-1}$ ) is the minimum internal cell quota. Light intensity varies along the depth of the reactor and for a flat plate reactor it can be expressed through the Lambert-Beer law:

$$I = I_0 \exp(-k_a c_x z) \quad , \quad (2)$$

where  $I_0$  ( $\mu\text{mol m}^{-2} \text{s}^{-1}$ ) is the incident light intensity,  $k_a$  ( $\text{m}^{-2} \text{g}_\text{x}^{-1}$ ) is the biomass light absorption coefficient,  $c_x$  ( $\text{g}_\text{x} \text{m}^{-3}$ ) is biomass concentration, and  $z$  (m) is the spatial coordinate along the thickness of the reactor. The biomass growth rate  $r_x$  ( $\text{g}_\text{x} \text{m}^{-3} \text{day}^{-1}$ ) can be expressed as

$$r_x = \mu c_x \quad , \quad (3)$$

and the average biomass growth rate  $r_x^{avg}$  ( $\text{g}_\text{x} \text{m}^{-3} \text{day}^{-1}$ ) along the culture depth  $W$  (m) is calculated as:

$$r_x^{avg} = \frac{1}{W} \int_0^W r_x dz \quad . \quad (4)$$

The nutrient uptake rate  $\rho$  ( $\text{g}_\text{N} \text{g}_\text{x}^{-1} \text{d}^{-1}$ ) depends both on the external dissolved nutrient concentration  $c_N$  ( $\text{g}_\text{N} \text{m}^{-3}$ ) and on its internal quota (Turetta et al., 2022):

$$\rho = \rho_N \frac{c_N}{K_N + c_N} \left( 1 - \frac{q}{q_{max}} \right) \quad , \quad (5)$$

with  $\rho_N$  ( $\text{g}_\text{N} \text{g}_\text{x}^{-1} \text{d}^{-1}$ ) as the maximum nutrient uptake,  $K_N$  ( $\text{g}_\text{N} \text{m}^{-3}$ ) as the nutrient half saturation constant and  $q_{max}$  ( $\text{g}_\text{N} \text{g}_\text{x}^{-1}$ ) as the maximum nutrient quota in the biomass. For a continuous photobioreactor material balances for biomass are:

$$\frac{dc_x}{dt} = \mu(q)c_x - Dc_x \quad , \quad (6)$$

$$\frac{dc_N}{dt} = -\rho(c_N)c_x - Dc_N + Dc_{N,in} \quad , \quad (7)$$

where  $D$  ( $\text{d}^{-1}$ ) is the dilution rate and  $c_{N,in}$  ( $\text{g}_\text{N} \text{m}^{-3}$ ) the inlet nitrogen concentration. The internal quota is maintained by nutrient uptake from external medium and consumed by cells duplication and thus its material balance can be expressed as:

$$\frac{dq}{dt} = \rho(c_N) - \mu(q)q \quad . \quad (8)$$

In this work a MBDoE was implemented for planning of experiments to estimate Droop parameters  $K_N$ ,  $q_{max}$ ,  $q_{min}$ ,  $\rho_N$ , while values of light parameters  $\mu_{max}$ ,  $K_I$ ,  $I_{opt}$ ,  $k_d$ ,  $k_a$  were retrieved from Saccorda et al. (2022).

### 1.2. MBDoE

MBDoE is a mathematical technique that, building on *a priori* knowledge embedded in a mechanistic mathematical model, aims at obtaining the maximum information from an experimental apparatus that will yield the most informative data for modelling activity, in a statistical sense, avoiding waste of time and resources (Franceschini and Macchietto, 2008). This approach consists of exploiting the model equations and current parameter values to estimate the information content of the experiment by evaluating a certain objective function. An optimisation framework is then applied to the solution of the resulting numerical problem. The methodology was successfully applied in several fields, including model identification in microalgae systems (Bernardi et al., 2016).

For MBDoE application, Equations 1-8 can be rearranged in a compact form:

$$\begin{cases} \mathbf{f}(\dot{\mathbf{x}}(t), \mathbf{x}(t), \mathbf{u}(t), \boldsymbol{\theta}, \mathbf{k}, t) = 0 \\ \hat{\mathbf{y}}(t) = \mathbf{h}(\mathbf{x}(t)) \end{cases} \quad (9)$$

where  $\mathbf{x}$  is the  $N_x$ -dimensional vector of all the model state variables and,  $\hat{\mathbf{y}} = [c_x, c_N]^T$  is the  $N_y$ -dimensional vector of the measured response variables,  $\mathbf{u} = [D, c_{N,in}]^T$  is the  $N_u$ -dimensional set of time-varying inputs to the process,  $\boldsymbol{\theta} = [K_N, q_{max}, q_{min}, \rho_N]^T$  is the  $N_\theta$ -dimensional vector of parameters to be determined, determined,  $\mathbf{k} = [\mu_{max}, K_I, k_d, k_a, I, W]^T$  the  $N_k$ -dimensional vector of constants of the model and  $0 < t < \tau$  is time, with  $\tau$  as the duration of the experiment. The symbol  $\hat{\cdot}$  is used to define the estimate of a variable (e.g.  $\hat{\boldsymbol{\theta}}$  contains the best available parameters estimation). Variable measurements are collected at time instant defined in the  $N_{sp}$ -dimensional vector  $\mathbf{t}_{sp}$ . Each experiment is defined by the experiment design vector  $\boldsymbol{\phi} = [\mathbf{u}(t), \mathbf{t}_{sp}, \tau]^T$ .

A key point of MBDoE is the formulation of a metric for the measurement of experimental information content. In mathematical terms, decreasing the size of the inference regions of the model parameters allows to improve parameter precision. This is equal to decrease the value of the elements of the parameter variance-covariance matrix  $\mathbf{V}$  defined as (Franceschini and Macchietto, 2008):

$$\mathbf{V}(\hat{\boldsymbol{\theta}}, \boldsymbol{\phi}) = \left[ \sum_r^{N_y} \sum_s^{N_y} \tilde{\sigma}_{rs} \mathbf{Q}_r^T \mathbf{Q}_s \right]^{-1}, \quad (10)$$

with

$$\mathbf{Q}_r = \left. \frac{\partial \hat{y}_r}{\partial \theta_m} \right|_{t_l} \quad l = 1, \dots, n_{sp} \quad m = 1, \dots, N_\theta \quad (11)$$

$\mathbf{Q}_r$  is the  $(n_{sp} \times N_\theta)$  dynamic sensitivity matrix of the  $r^{th}$  response. The term  $\tilde{\sigma}_{rs}$  in Equation 10 is the  $(r, s)$  element of the inverse of variance-covariance matrix of the experimental error. The final designed experiment  $\boldsymbol{\phi}^{opt}$  is the solution the following minimisation/maximisation problem:

$$\boldsymbol{\phi}^{opt} = \operatorname{argmin} \{ \det[\mathbf{V}(\hat{\boldsymbol{\theta}}, \boldsymbol{\phi})] \} = \operatorname{argmin} \{ \det[\mathbf{V}^{-1}(\hat{\boldsymbol{\theta}}, \boldsymbol{\phi})] \} \quad (12)$$

defined with the so-called D-criterion (Franceschini and Macchietto, 2008). In other words, the optimum experiment is the one that minimises the parametric uncertainty or maximises the experimental information content.

## 2. Results

### 2.1. Sensitivity analysis

A local dynamic sensitivity analysis was performed to highlight possible parameter identifiability issues. The dynamic trajectories of measured variables were perturbed by one-at-a-time variations of the parameters to be estimated. Nominal values of the parameters to be estimated are shown in Table 1. Additional parameters and constants (fixed light parameters from Saccardo et al. (2022), light intensity and reactor thickness)

are shown in Table 2. The dynamic sensitivity  $s_{i,p}(t)$  for the  $i^{th}$  variable perturbed by the  $p^{th}$  parameter at time  $t$  was computed as:

$$s_{i,p}(t) = \frac{\hat{y}_i(t) - \hat{y}_{i,p}^{pert}(t)}{\Delta\% \hat{y}_{i,REF}} \quad (13)$$

where  $\hat{y}_i(t)$  is the value calculated with the nominal set of parameters,  $\hat{y}_{i,p}^{pert}(t)$  the perturbed value calculated with the variation in the  $p^{th}$  parameter,  $\Delta\%$  is the percentage perturbation of the parameter (equal to 1% for all parameters) and  $\hat{y}_{i,REF}$  is a reference value for the normalisation. Results of the sensitivity analysis are shown in Figure 1, where the effects of step wise changes in the inputs for all the perturbed parameters on the biomass and nitrogen concentrations are reported. Figure 1(a) highlights that  $q_{min}$  is the parameter with the highest impact on the biomass concentration and thus its estimation is expected to be linked to this measurement. Even though  $K_N$ ,  $q_{max}$ ,  $\rho_N$  have a minor impact on biomass concentration, Figure 1(b), shows that their main effect is on the nitrogen concentration and thus this variable is expected to be mainly responsible for their estimation. Figure 1(b) also evidences that some degree of correlation between  $q_{max}$  and  $\rho_N$  exists as well as anticorrelation between  $K_N$  and  $q_{max}$ , thus suggesting possible issues in the estimation of those parameters. However, Figure 1 also suggests that measurements of biomass and nitrogen concentration alone are sufficient for precise estimation of all Droop parameters if experiments are planned adequately.

**Figure 1:** Dynamic sensitivity analysis: sensitivities of model parameters on biomass (a) and nitrogen concentration (b).

**Table 1:** Reference values of parameters of Droop model.

Parameter	Value
$K_N$	14.23 g <sub>N</sub> m <sup>-3</sup>
$q_{max}$	0.90 g <sub>N</sub> g <sub>x</sub> <sup>-1</sup>
$q_{min}$	0.005 g <sub>N</sub> g <sub>x</sub> <sup>-1</sup>
$\rho_N$	0.62 g <sub>N</sub> g <sub>x</sub> <sup>-1</sup> d <sup>-1</sup>

## 2.2. In silico experiments

*In silico* iterative experiments have been performed to inspect the capability of MBDoE to plan experiments for precise parameter estimation.

**Table 2:** Fixed light parameters (Saccardo et al., 2022). and constants for simulations

Name	Value
$\mu_{max}$	2 d <sup>-1</sup>
$K_I$	110 $\mu\text{mol m}^{-2} \text{s}^{-1}$
$I_{opt}$	405 $\mu\text{mol m}^{-2} \text{s}^{-1}$
$k_d$	0.45 d <sup>-1</sup>
$k_a$	0.09 m <sup>2</sup> g <sub>x</sub> <sup>-1</sup>
$I$	222 $\mu\text{mol m}^{-2} \text{s}^{-1}$
$W$	0.035 m

Reference parameter values of Table 1 have been perturbed by 50% and used to plan a first MBDoE. Then, a simulation using the “true” parameters of Table 1 has been performed with the input trajectories planned by the MBDoE. White noise has been then applied on these simulation results to obtain *in silico* data, employed for a subsequent parameter estimation. If the estimation was not precise the last parametric set was then used for a new MBDoE and the entire procedure was repeated until a precise estimation was achieved. It was found that two planned experiments of 5 and 9 days respectively are sufficient for a precise parameter estimation. Dynamic profiles of the first and second experiment are shown in Figure 2. Notice that in the first experiment input variables were allowed with impulse profiles. Moreover, all the input variables were allowed to vary from 9 AM to 5 PM to reflect real working conditions. Table 3 shows the initial perturbed parameters, parameters fitted after the first and second *in silico* experiment and the corresponding 95% *t*-values. All parameters from the second fit are close to those in Table 1 and have *t*-values above the reference one all above the reference *t*-value, showing high parametric accuracy. Results of the second fitting are shown in Figure 3 for both experiment I and II.

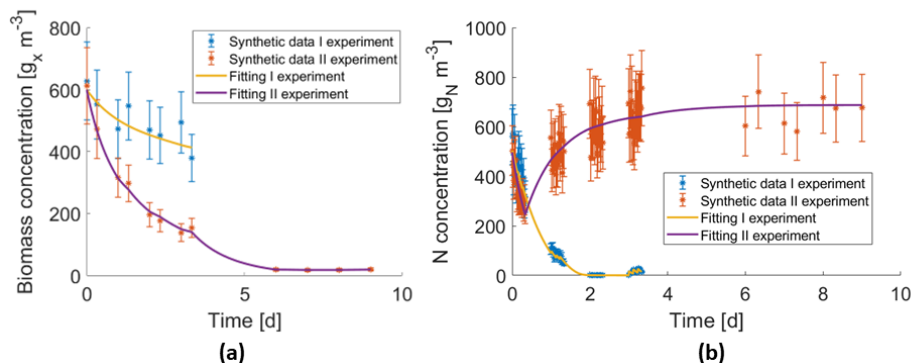

**Table 3:** Model parameters for *in silico* experiments. Reference *t*-value is equal to 1.67.

Parameter	Perturbed value	First fit	First fit 95% <i>t</i> -value	Second fit	Second fit 95% <i>t</i> -value
$K_N$ [g <sub>N</sub> m <sup>-3</sup> ]	7.115	14.74	4.9	14.73	5.01
$q_{max}$ [g <sub>N</sub> g <sub>x</sub> <sup>-1</sup> ]	0.45	0.8662	2.5	0.83	2.95
$q_{min}$ [g <sub>N</sub> g <sub>x</sub> <sup>-1</sup> ]	0.0075	0.00285	0.15	0.0055	1.72
$\rho_N$ [g <sub>N</sub> g <sub>x</sub> <sup>-1</sup> d <sup>-1</sup> ]	0.93	0.64	3.29	0.67	3.73

**Figure 2:** Dynamic profiles of input variables in the optimally designed experiments: dilution rate (a), inlet nitrogen concentration (b).

**Figure 3:** Second fitting results of synthetic data from the two optimal *in silico* experiment: biomass (a) and nitrogen concentration (b).

## Conclusions

In this work, the effectiveness of MBDoE techniques for precise parameter estimation of the Droop model was assessed. An initial local sensitivity analysis showed that the biomass concentration is mainly affected by  $q_{min}$  and the nitrogen concentration by  $K_N, q_{max}, \rho_N$ . Although some degree of correlation (between  $q_{max}$  and  $\rho_N$ ) and anticorrelation (between  $K_N$  and  $q_{max}$ ) exists, parameters are expected to be practically identifiable from measurements of biomass and nitrogen concentrations only. MBDoE was iteratively employed to plan *in silico* experiments, showing that two optimal experiments (of 5 and 9 days) can be sufficient to estimate all the parameters with accuracy. Moreover, MBDoE allowed to reduce the experimental time by over 80%, from about 77 days to 14 days for both experiments. Future work will aim at assessing the effectiveness of the proposed methodology experimentally.

## Abstract

A comprehensive waste composition analysis was undertaken in 2021, covering ten municipal waste companies in Central Norway. The results are used in a multiple linear regression model to explore factors influencing the municipal solid waste sorting behaviour. The aim of the study is to better understand what affects waste sorting, to aid in the progress of achieving circular economy targets. The share of food waste and mixed waste in the mixed waste bin is analysed considering three variables: Food waste collection system, glass and metal packaging waste collection system and type of settlement. The waste collection systems are found to have a significant effect on the sorting behaviour, where the *possibility* for sorting and the *user-friendliness* and *transparency* of the sorting system are important factors. Type of settlement is not found to have a significant effect on the sorting behaviour. We recommend further in-depth studies to confirm and expand on the findings in this study, and to better utilise the potential of waste composition analyses to enhance understanding of waste sorting behaviour. This understanding is crucial to reach a more circular waste system.

**Keywords:** Municipal solid waste, sorting behaviour, waste management, regression analysis, circular economy.

## 1. Introduction

To achieve a more circular future, municipal solid waste (MSW) management plays a key role, as large quantities of materials with great potential for reuse and recycling are handled. The 2021 Norwegian material recovery rate for MSW was 43 % (Statistics Norway 2022), far from the 2025 target in line with the EU of 55 % (Directive (EU) 2018/851 2018). Effective sorting at source is vital to increase material recovery, and there is room for improvement as more than 60 % of the waste in the mixed waste bin is recyclable materials (Fagerheim et al 2021). Effective waste strategy planning relies on good data (Thomas 2004), and this paper aims to contribute by studying the effects of various factors on the sorting behaviour.

This work was initiated to test an assumption that there is a difference in MSW sorting behaviour between different size settlements, i.e., cities versus more sparsely populated areas. To test this assumption, consistent and comparable data was needed. In 2021 the largest waste composition analysis in Norway to date was carried out, for the circular waste cluster CIVAC (Fagerheim et al 2021). The analysis was carried out for eight MSW companies in Central Norway, further including results from waste composition analyses performed in the same time period by two other MSW companies in the region. The resulting analysis covers an area of more than 750 000 inhabitants, and more than ten tonnes of waste was analysed. This data set made it possible to compare variations

between cities and villages/towns, as well as variations between different sorting systems, on a sample area basis.

## 2. Methodology

Using the results from the waste composition analysis, a multiple linear regression analysis was carried out, to study what significantly affects waste sorting.

The waste composition analysis investigated the contents of the mixed waste (MW) bin, identifying the share (weight percentage) of the 11 fractions shown in Table 1. The share of the fraction was used as dependent variable, and the regression was run for each fraction. Using a 5 % significance level, significant results were found for five fractions (in italic in Table 1). The focus of this study is the two largest fractions: Food waste including paper towel (FW) and MW which comprises the correctly sorted MW.

Table 1 Overview of dependent variables: waste fractions in the mixed waste bin.

Waste fractions
Paper and cardboard
<i>Food waste incl. paper towel</i>
Garden waste
Bags for waste
<i>Plastic packaging</i>
<i>Glass packaging</i>
<i>Metal packaging</i>
Other metal
Recyclable textiles
Hazardous waste and WEEE
<i>Mixed waste</i>

Twenty distinct sample areas were analysed, nine in cities and 11 in smaller settlements. 15 of the areas have separate collection of FW, and nine have kerbside collection of glass and metal packaging waste (G&M). One of the two additional MSW companies included reported only the totals, which cover eight sample areas, but in our analysis only counts as one sample area: a city without separate FW and kerbside G&M collection. See Table 2 for an overview of the MSW companies' solutions for sorting at source. This methodology made it possible to isolate three independent variables for the regression analysis, shown in Table 3. As the independent variables are categorical, they were all initially coded as dummy variables (Wooldridge 2009).

Table 3 Overview of MSW companies' source sorting solutions: basis for independent variables.

	MSW 1	MSW 2	MSW 3	MSW 4	MSW 5	MSW 6	MSW 7	MSW 8	MSW 9	MSW 10
Mixed waste	Green	Green	Green	Green	Green	Green	Green	Green	Green	Green
Food waste	Green	Red X	Green	Green	Green	Green	Green	Green	Red X	Red X
Paper/cardboard	Green	Green	Green	Green	Green	Green	Green	Green	Green	Green
Plastic	Green	Green	Green	Green	Green	Green	Green	Green	Green	Green
Glass/metal	Green	Yellow	Green	Yellow	Green	Yellow	Yellow	Yellow	Green	Yellow
Kerbside collection	Central coll./recycling point									
Optibag	No separate collection: X									

Table 2 Overview of independent variables and their coding in the model.

Independent variables	Short name	Values		
		-1	0	1
Separate FW collection	sepFW	No separate collection	Optibag	Separate FW bin
Kerbside G&M collection	kerbG&M		Central recycling point or civic amenity site	Kerbside G&M collection
Settlement			Town/village	City

For separate FW collection, two systems were represented in the sample areas: A separate bin, and the optibag system. In the optibag system, several waste fractions are sorted in colour-coded bags and collected in the same bin, to be machine sorted centrally. Using a

scatter plot, in Figure 1, we found that the results from the optibag system lie between no separate collection and a separate FW bin. To corroborate this finding, the share of FW in the MW bin for a city which also uses the optibag system, is included in the figure as *Alt. optibag*. The coding of the dummy variable was changed to linear, increasing the explanatory power of the model ( $R^2$ ) by 10 percentage points.

This study has a small number of observations for a multiple regression analysis, which can increase uncertainty. This is because it was carried out at a sample area level rather than a household level. A sample area is however aggregated waste from typically 30-40 households, and we expect that the analysis represents around 600-800 households. Each bin collected is a snapshot in time, which may not be representative of the households' average waste composition. Aggregating into sample areas may thus make a more representative waste composition, but for an area rather than a household. As we do not have any information about each household, the additional resolution would give limited value, as variations cannot be explained. On the other hand, using data from only one analysis will ensure consistent data collection, reducing other sources of uncertainty. Differences between waste composition analyses can include analysis methods, such as sample size and location, or types and number of waste components (Dahlén & Lagerkvist 2008). In conclusion, the consistent data collection was considered to compensate for the small number of observations, and the study deemed a good contribution to advance the understanding of how external factors can affect MSW source-sorting results. To strengthen the findings and increase generalisability, similar studies should be carried out.

Figure 1 Actual shares of FW in the MW bin, by source sorting solution.

### 3. Results and discussion

The results from the linear regression model for FW are shown in Table 4. The model explains ( $R^2$ ) 85 % of the variation in the fraction, but only separate FW collection has a significant impact ( $p < 0.01$ ) on the amount of FW in the MW

Table 4 Results for food waste fraction regression model.

Dependent variable: Food waste					
$R^2$	85 %			95 % confidence intervals	
Obs.	20	Coeff.	P-value		
(Intercept)		35 %	< 0.01	32 %	39 %
sepFW		-9.7 %	< 0.01	-12.5 %	-7.0 %
kerbG&M		-3.3 %	0.13	-7.6 %	1.1 %
Settlement		1.7 %	0.45	-3.0 %	6.5 %

bin. With each increment in the separate FW collection variable, i.e. from no collection to optibag, or from optibag to dedicated FW bin, the share of FW in the MW bin is reduced by almost 10 percentage points. Due to how the sepFW variable is coded, this means the FW share goes from 45 % with no collection, to 35 % with optibag, to 25 % with dedicated bin, which amounts to an average 25 % reduction per step. The confidence intervals indicate a 95 % likelihood that the real reduction is between 7 and 12.5 percentage points. Kerbside collection of glass and metal packaging waste and the settlement type do not show any significant effects on the amount of FW in the MW bin.

The results from the linear regression model for correctly sorted MW are shown in Table 5. The model explains 82 % of the variation in the fraction, and both separate FW collection and kerbside G&M collection have significant effects ( $p < 0.01$ ) on the dependent variable. With each increment in the separate FW collection variable, the share of correctly sorted MW increases by almost 7 percentage points, going from 24 % with no collection, to 31 % with optibag, to 37 % with dedicated FW bin. This amounts to an increase of about 25 % per step on average. The confidence intervals indicate an increase between 4 and 9.5 percentage points. For kerbside collection of G&M, the share of correctly sorted MW increases by 7.5 percentage points, from 31 % to 38.5 %, which amounts to a 24 % increase. There is a 95 % probability that the increase is between 3 and 12 percentage points.

Table 5 Results for mixed waste fraction regression model.

Dependent variable: <b>Mixed waste</b>					
R <sup>2</sup>	82 %			95 % confidence intervals	
Obs.	20	Coeff.	P-value		
(Intercept)		31 %	< 0.01	27 %	34 %
sepFW		6.7 %	< 0.01	3.9 %	9.4 %
kerbG&M		7.5 %	< 0.01	3.1 %	11.8 %
Settlement		-4.4 %	0.07	-9.1 %	0.3 %

The increase in the share of correctly sorted MW from kerbside collection of G&M is larger than can be explained by a reduction in G&M alone, as G&M are small weight fractions. This suggests that other factors may be at play, and indeed we found a significant effect on the share of plastic packaging waste in the MW bin: When there is kerbside G&M collection there is less plastic packaging waste in the MW bin. This interrelation cannot be explained by our dataset, but Mikkelsen (2017) also found a connection between sorting of different waste fractions, where better sorting in one fraction coincides with better sorting in other fractions. He points at communication and information as important factors behind this, further discussed below for other variables.

Despite size of settlement not having a statistically significant effect on the share of correctly sorted MW, it is not far off, with a p-value of 0.07. Mikkelsen (2017) showed that typical city traits, such as limited indoor and outdoor space, more households likely to have small children (citizens in 20s and 30s age groups), more citizens with foreign background and more lower income households, are related to a lower degree of source sorting. The results from Mikkelsen (2017) were further analysed in Fagernæs (2018), and better communication differentiated by target group is presented as a key measure to improve poor source sorting. One could hypothesize that targeted communication is easier and social control stronger in a smaller community. The insignificant effect of settlement type on correctly sorted MW indicates better sorting in smaller communities.

Based on the results we see that two factors are important for improved MSW sorting at source: (1) The possibility to sort at source. For FW, we see that having separate FW collection reduces the amount of FW in the MW bin with both systems. This is in many ways obvious, as the only option if there is no separate FW sorting, is to dispose of FW in the MW bin (or home composting). (2) The convenience of the sorting system. We see that kerbside pickup of G&M reduces the amount of G&M in the MW bin, with significant reductions of the glass and metal packaging waste fractions, as well as a significant increase in correctly sorted MW. The easier it is for the consumer to sort at source, and the less transport required to use the correct waste bin, the more likely it is that they sort better at source.

However, while a more convenient sorting system means more of the fraction is collected separately, studies have shown that it also leads to more missorting in the case of glass and metal packaging. Syversen et al (2019) show that while the amount of sorted G&M waste collected with a kerbside system is more than 25 % higher, the share of waste that is missorted more than doubles, from 4 % to almost 10 %. This means that the quality of the sorted fraction is worse, and it will need more processing before recycling.

A third factor, which was outside the scope of this study, is the transparency of the waste system and the perceived fate of the waste. For FW, we see that the optibag system gives inferior results compared to a dedicated bin collected separately. Based on discussions with industry partners in the CircWtE project, we believe the main reason for this is that the inhabitants do not know enough about how the waste is further treated downstream. When several waste fractions are collected in one bin, they believe all the waste goes to the same place, most likely to incineration, hence perceiving it as less important to sort correctly. Industry partners reported that they see the same effect when several bins are collected with the same multi-compartment truck (CircWtE workshop, 31 May 2022, Trondheim, Norway). It is however worth noting that the optibag system is a space saving solution, requiring a single bin for four separate fractions. In densely populated areas where space is limited, this can enable source sorting of more fractions. This does not apply to indoor space limitations though, where multiple bins are still needed. The optibag system also enables collection of four fractions with one single-compartment truck, which can be beneficial in sparsely populated areas with long transport distances.

The type of settlement was not found to be a significant factor for the MSW sorting at source in this study. This may be rooted in how the type of settlement was determined. As we did not have detailed knowledge about where the waste was collected, sample areas were defined as city or town/village based on the name of the settlement. Most Norwegian cities are small and not densely populated, implying that the differences between a city and a town may be minor. Demographic traits also vary between neighbourhoods and different degrees of urbanization, meaning the sample areas from cities may not represent typical city traits. Without detailed knowledge about the locations, we were not able to analyse this further.

Despite interesting findings, a limited number of variables were available for analysis. Demographic variables are found to have significant effects on degrees of sorting at source (Mikkelsen 2017), but the dataset did not allow for such variables. With only two sample areas per MSW company, quantitative analysis of differences between companies was impossible, despite anecdotal indications that e.g. communication strategies can affect results significantly. In the presentation of the waste composition analysis, one MSW company was highlighted for outstanding FW sorting results, despite launching separate sorting only recently. This was explained by an active communication strategy, combined with a strict policy of not collecting wrongly sorted waste. Bad sorting is photodocumented, and the documentation including an explanation of why the waste is not collected is sent to the customer immediately. According to the MSW company, this active communication led to good sorting results as well as high customer satisfaction, which was validated in that they have the two highest shares of correctly sorted MW of all 20 sample areas (CIVAC: Presentation of results from waste composition analysis, 7 December 2021, Stjørdal, Norway). In summary, many variables other than sorting systems affect the results of MSW sorting, and these should be considered when

designing systems to enable effective sorting at source. As for the effect of the sorting systems, comparable results have been found in a similar study by the authors (Grytli & Birgen 2023), strengthening the findings of this study.

#### 4. Conclusions

The results from our regression analyses show that the possibility to sort at source, as well as the user-friendliness and transparency of the waste system, are significant factors impacting MSW sorting behaviour. We recommend further in-depth studies of waste composition analyses to confirm and expand on these findings.

Despite no significant effects from type of settlement in this study, demographic variables have been found to have an effect in other studies. Targeted communication and sanction systems also appear to impact sorting results. These types of variables should be studied further, to aid MSW companies in developing strategies for increased sorting.

This study intends to better utilise the potential of waste composition analyses and the results obtained contribute to a deeper understanding of sorting behaviour and its drivers. The study can help MSW companies better design and select effective collection systems and policymakers in implementing measures to improve sorting and increase circularity.

## Abstract

This paper presents regression analysis results on time series data of waste composition analyses from a municipal waste company in Norway, with a discussion on methodological challenges. The aim is to investigate what affects municipal solid waste (MSW) source-sorting results, to facilitate achieving circular economy targets. The share of four MSW fractions in the mixed waste bin are studied considering five independent variables: Collection/sorting systems for food waste, glass and metal packaging waste, and mixed waste; year of analysis, and pre/post covid-19. We find that only the source sorting systems have significant impacts on the waste composition, and that user-friendliness matters. We recommend more in-depth studies to increase data quality to better utilise the potential of waste composition analyses for a more circular waste system.

**Keywords:** Municipal solid waste, sorting behaviour, waste management, regression analysis, circular economy.

## 1. Introduction

To improve circularity, recycling, and reuse, we need to improve municipal solid waste (MSW) management systems, where large quantities of materials have the potential to be recovered. The 2021 material recovery rate in Norway was 43 %, well below the 55 % target for 2025 (Statistics Norway 2020, Directive (EU) 2018/851 2018). More than 60 % of the waste in the mixed waste (MW) bin is recyclable, so understanding how households sort their waste is vital, and good data is key for effective waste strategy planning (Grytli & Birgen 2023). The aim of this study is to increase the insight into what affects sorting behaviour, to enable increased circularity in the waste treatment system.

This study is based on waste composition analysis data from a municipal waste company in Norway that serves more than 100 000 inhabitants. Waste composition analyses of the MW bin were carried out in 2016, 2017, 2019 and 2021, comprising a time series where in total almost 4 000 kg waste has been physically analysed.

## 2. Methodology

To better understand what affects waste sorting at source, the results from the waste composition analyses were investigated using multiple linear regression analysis. The number of sample areas analysed per year were two (2016-2017), three (2019) and four (2021), giving a total of 11 observations.

The waste composition analyses examine the contents of the MW bin, estimating the share, in weight percentage, of ten different waste fractions. Table 1 shows the sample area average share per fraction. A regression analysis was run for each fraction, with the

share of the fraction in the bin as the dependent variable. Significant effects were found for five fractions, and this study focuses on four of them: Food waste (FW), glass packaging waste (GW), metal packaging waste (MeW), and MW which is the correctly sorted MW.

To identify independent variables, the differences between the 11 observations were assessed. Two sample areas have separate FW collection. Kerbside glass and metal packaging waste (G&M) collection was rolled out between 2017 and 2019, and five observations took place after this roll-out.

Three sample areas have underground MW collection, where the waste is discarded in a large underground container via a waste inlet aboveground. The other eight have regular rolling bins for MW. Four observations were from late fall of 2021, i.e. after Covid-19. These differences gave rise to five potential independent variables, described in Table 2. As all independent variables (except year) are categorical, they were coded as dummy variables (Wooldridge 2009).

Table 2 Overview and coding of independent variables.

Independent variables	Short name	Values			
		0	1	2	3
Separate FW collection	<i>sepFW</i>	No separate collection	Separate FW bin		
Kerbside G&M collection	<i>kerbG&amp;M</i>	G&M to central recycling point or civic amenity site	Kerbside G&M collection		
Underground waste collection	<i>Undergr.</i>	Aboveground MW bin	Underground MW system		
Post Covid-19	<i>Covid19</i>	Before Covid-19	After Covid-19		
		1	2	4	6
Year	<i>Year</i>	2016	2017	2019	2021

There were some challenges with the identified independent variables. Most had some correlation with the time variable, as they either happened at a certain time (kerbside G&M collection and Covid-19) or were included only in later years (underground waste collection). This can cause a multicollinearity problem, as discussed later. The next challenge was a very small number of observations for a regression analysis. Each observation is however the aggregated waste from 30-40 bins. This means that the 11 sample areas represent more than 330 bins, and almost 400 households. For practical reasons this study was done on a sample area level. It is unlikely that additional resolution would have added much value, as we had no information about each household, thus could not have explained any additional variation. As each bin is a snapshot in time and may not be representative of the household's average waste composition, an average of a sample area may be considered more representative of an average waste composition. In general, a small number of observations increases uncertainty and means that the results should be interpreted carefully and may not be generalisable.

During analysis, unexpected results emerged. Close inspection of the data revealed large increases in one fraction, that could not be explained even after communication with the

Table 1 Overview and average share of waste fractions in the mixed waste bin.

Waste fractions with average shares	
Paper and cardboard	7.65 %
Food waste incl. paper towel	43.6 %
Garden waste	4.83 %
Plastic packaging	9.43 %
Glass packaging	2.94 %
Metal packaging	1.43 %
Other metal	0.98 %
Recyclable textiles	3.03 %
Hazardous waste and WEEE	1.35 %
Mixed waste	24.8 %

MSW company. Thorough debugging revealed a summation error for a subtraction of the fraction in a spreadsheet, causing a hard to spot error that had significant impacts on the results. Data from waste composition analyses is registered on paper and punched manually into a spreadsheet template. As a copy of the template was used, the mistake spread to five sample areas over two years, causing a systematic error. Left undiscovered, this systematic error would have impacted the accuracy of the model significantly. Several random errors were also discovered, where numbers were punched incorrectly. Although most random errors were too small to affect overall results, they would have reduced the model’s precision.

Due to Norway’s sparse and spread population and complex geography, MSW companies are often small, which induces several of the methodological complications discussed. Small companies have limited resources for carrying out waste composition analyses, resulting in fewer observations, and for quality assuring results. The uncovered systematic error gave a faulty picture of the company’s performance in collection, sorting and recycling, ultimately giving an incorrect base for their strategic development. This shows the benefit provided by research, as in addition to giving insight into effects of measures implemented, the MSW company’s data is improved and quality assured.

### 3. Results and discussion

The results from the linear regression model for the FW fraction are shown in Table 3. The model explains ( $R^2$ ) 91 % of the variation in the fraction, but the only variable with a significant effect ( $p < 0.01$ ) is separate FW collection. The model finds that the share of FW is reduced by 25 percentage points (pp) when there is separate FW collection, from 53 % to 28 % FW in the MW bin, amounting to a 48 % reduction. The confidence intervals indicate that there is a 95 % likelihood that the reduction is between 10 and 40 pp. None of the other variables were found to have a significant effect on the share of FW in the MW bin.

Table 3 Results for food waste fraction regression model.

Dependent variable: <b>Food waste</b>					
$R^2$	91 %	Adj. $R^2$	82 %	95 % confidence	
Obs.	11	<i>Coeff.</i>	<i>P-value</i>	<i>intervals</i>

sepFW		-25 %	< 0.01	-40 %	-10 %
kerbG&M		7.4 %	0.37	-12 %	27 %
Undergr.		0.3 %	0.95	-10 %	11 %
Covid19		-6.7 %	0.40	-25 %	12 %
Year		-1.5 %	0.40	-6 %	3 %

Multicollinearity (a correlation between several of the independent variables) may give unreliable results in a regression analysis. To assess whether multicollinearity was a problem in the model, the variance inflation factors (VIF) for the independent variables were analysed (Wooldridge 2009). There is no agreed-upon threshold for when multicollinearity becomes problematic, but threshold values of 5 or 10 are commonly used. The VIFs for the independent variables are never over 10, but for kerbside G&M collection, year and Covid-19, the VIF is over 5. This became a problem for the GW and MeW fractions, where results were significantly affected. The collection system for G&M has been shown to impact the sorting behaviour in other studies (Grytli & Birgen 2023, Syversen et al 2019), and it is therefore assumed to be more important than development over time, or the effect of a pandemic. To avoid the multicollinearity problem, the variables Post Covid-19 and Year were excluded from the models for the GW and MeW fractions, and a simplified model is presented.

The results for the simplified regression models are shown in Table 4 for GW and Table 5 for MeW. For GW we found that the adjusted  $R^2$  increased when running the model with only kerbside G&M collection as independent variable, indicating that the simplified model may be overfitted. Results from both runs are thus included in Table 4, and the discussion will focus on the *Only G&M* model for GW. The underlying reasons will be discussed later.

Table 4 Results for glass packaging waste fraction regression models.

Dep. variable:		Simplified model				Only G&M			
<b>Glass pack. waste</b>		R <sup>2</sup>	54 %	Adj. R <sup>2</sup>	34 %	R <sup>2</sup>	50 %	Adj. R <sup>2</sup>	45 %
Obs.	11	<i>Coeff.</i>	<i>P</i>	95 % <i>CI</i>		<i>Coeff.</i>	<i>P</i>	95 % <i>CI</i>	
(Intercept)		3.7 %	< 0.01	2.6 %	4.8 %	3.7 %	< 0.01	2.8 %	4.7 %
sepFW		0.8 %	0.51	-1.9 %	3.5 %				
kerbG&M		-2.2 %	0.04	-4.3 %	-0.1 %	-1.8 %	0.01	-3.1 %	-0.4 %
Undergr.		0.4 %	0.65	-1.6 %	2.5 %				

For GW the model explains ( $R^2$ ) 50 % of the variation in the fraction, while the MeW model explains more of the variation, with an  $R^2$  of 66 %. Only the kerbside G&M collection affects the share of G&M waste in the MW bin significantly in any of the models. For MeW the effect is more clearly significant ( $p < 0.01$ ) than for GW ( $p = 0.01$ ). The estimated reduction in MeW is 0.9 pp, from 1.6 % to 0.7 % MeW in the MW bin, amounting to a 55 % reduction. The confidence intervals indicate a true reduction between 0.3 and 1.5 pp. For GW the reduction is 1.8 pp, from 3.7 % to 1.9 % GW in the MW bin, or a 48 % reduction, with a true reduction estimated between 0.4 and 3.1 pp. The findings are in line with Syversen et al (2019), where the increase in collected metal is larger than the increase in collected glass when introducing a kerbside G&M collection. They found an increase in the amounts sorted at source of 11 % for glass and 157 % for metal. As metal packaging is lighter than glass packaging, we can assume that a smaller reduction in the share of metal in the MW can account for a larger increase in the amount collected from sorting at source.

For the MW, the results from the full regression model are shown in Table 6. The model explains ( $R^2$ ) 90 % of the variation in correctly sorted MW in the MW bin. The only significant effect is

Table 5 Results for simplified metal packaging waste fraction regression model.

separate FW collection ( $p=0.01$ ), which leads to an increase in the share of correctly sorted waste in the MW bin of 18 pp, from 21 % to 39 %, or an 83 % increase. The confidence intervals indicate a real increase in correctly sorted MW with separate FW collection of 6 - 29 pp.

We see high explanatory powers ( $R^2$ ) and large effects for both the FW and MW fractions, when separate FW collection is the significant variable. Two factors help explain this: (1) FW is heavy, constituting by far the largest fraction in the MW bin for households without separate FW collection, as shown in Figure 1. With separate FW collection, the correctly sorted MW is the largest fraction. (2) If there is no separate FW collection, the only option is to dispose of FW in the MW bin (or home composting). This implies that

when we say *correctly sorted MW*, it does not mean that households without separate FW collection are doing anything wrong by discarding their FW in the MW bin, but rather that there should be separate FW collection, so this fraction can be recycled.

On the other hand, we saw how kerbside G&M collection did significantly affect the shares of GW and MeW in the MW bin, but not the share of correctly sorted MW. This is likely due to GW and MeW being small fractions in the MW bin. Effects may thus be obscured by variations in the larger fractions, such as food, plastic, and paper/cardboard. This shows the importance of looking at each fraction separately, to catch individual variations also in the smaller fractions.

Due to the weight of FW, we expected separate FW collection to impact the results of the shares of GW and MeW in the MW bin. As the heavy fraction is removed, the relative shares of all other fractions should increase. For MeW we saw this effect be close to significant, but we did not observe this for GW in the simplified model. The effect of the kerbside G&M collection was also less significant for GW in the simplified model. Through in-depth analysis of the background data, the reason for these results was found to be one outlier data point in a sample area after the rollout of kerbside G&M collection. The outlier lifts the sample area average above the lowest value before the rollout, and above the average of the areas with separate FW collection. This shows how the small number of sample areas can inflate the impact of noise from outliers. It is also a challenge when working with waste composition rather than absolute amounts. We found that by subtracting the FW from the waste composition, the problematic sample area's GW share falls below the lowest value before the rollout. This is because the earlier sample area had a very large share of FW, and the later (problematic) sample area a share below average, thus affecting the relative share of GW in the opposite direction. Both of these problems caused noise that made the simplified GW model seem overfitted, and as a consequence the choice to further simplify the model was made.

As discussed, the small number of observations caused some difficulties. However, using data from only one MSW company yields consistent data collection, which reduces other sources of uncertainty. Different methods for the waste composition analysis, in terms of for example sample size and location, or types and number of waste components, are good

Figure 1 Shares of the two largest fractions in the mixed waste bin.

examples of such sources (Dahlén & Lagerkvist 2008). We assessed that the benefits from the data collection consistency outweigh the disadvantages of few observations and consider this study a good contribution to understanding the effects of external factors on the results of MSW sorting at source. To strengthen findings and make them more generalisable, similar analyses should be carried out for other MSW companies.

#### 4. Conclusions

The regressions show that it is mainly separate sorting and user-friendly systems that influence the sorting results in the MW bin. The more fractions it is possible and easy to sort, the better the sorting results. We found no significant impacts over time, post covid-19 or from a different type of MW bin.

There are many factors that can influence sorting at source that we were not able to analyse in this study, such as demographic variables, communication, and information, which is further discussed in Grytli & Birgen (2023). To optimize the design of MSW systems for a circular future, it is crucial to identify and understand all relevant factors, and more research should be carried out to this effect.

This study has revealed challenges related to waste composition analyses due to manual data registration. As most MSW companies in Norway are small, the capacity for quality assurance is limited, increasing the risk of errors. Through this work we were able to provide debugging and data quality improvements for the MSW company. Improving the waste composition statistics will help the company better understand how their implemented measures are working and which new ones to consider.

Besides helping the specific MSW company, this study can help similar companies better understand and design their collection systems to increase circularity. We also aim to contribute to the necessary high-quality information and data needed for effective waste strategy planning by policymakers.

## Abstract

Waste of multiple categories such as agricultural, municipal, and industrial waste are the most abundant biomass sources worldwide. The mismanagement of such waste results in severe impacts on the environment, human health, and resources availability for future generations. However, waste can be utilised within energy, water and food sectors. As such, evaluating the optimal processing pathway, in addition to the optimal supply chain is crucial to fulfilling an adequate balance in the Energy-Water-Food (EWF) Nexus considering national priorities. In this study, 10 waste biomass categories were located over 35 locations across the Qatar using the geographic information systems (GIS), while their quantities, calorific values, and possible associated product yields were defined. Meanwhile, three biomass processing plants representing the EWF industries have been considered, including: biorefinery, desalination plant, and livestock feed developer. An optimisation model was then developed to select optimal biomass and minimise the overall transportation costs for all three industries. Three scenarios were introduced to ensure an EWF Nexus balance throughout the biomass allocation process. The scenarios included: a) equal biomass-based production amongst EWF industries, b) equal biomass distribution, and c) equal biomass-based sales. The model was able to allocate biomass resources from almost all sites at different utilisation percentages. Biomass transportation cost was minimised to 1.98 \$/t in scenario (b), where 0.48 M t/y of biomass were utilised, 49.8 M t/y of products were generated and sold at 82.5 M \$/y. However, scenario (c) achieved higher utilisation rate of biomass at 1.49 M t/y, transported at a minimised cost of 4.33 \$/t. The established model provides an insight on advanced decision-making approaches for optimal waste biomass valorisation to meet the growing demand on EWF resources.

**Keywords:** EWF nexus; Optimisation; GIS; Decision-making; Supply chain; Qatar.

## 1. Introduction

The Energy-Water-Food (EWF) Nexus is an emerging approach that supports the security of these three vital sectors and the adequate management of their resources (Namany et al. 2019). The importance of this approach lies in its capability to trace the interlinkages between the EWF systems and subsystems and alert any possible nexus imbalances (Al-Ansari et al. 2015). Biomass presents itself as a crucial aspect of EWF Nexus systems, where the resource is mainly utilised for clean energy production, while it may significantly occupy lands and consume water at the expense of food and water sectors. Several EWF models have been presented earlier for biomass and biofuel industry.

López-Díaz et al. (2018) developed a framework to enhance the EWF resources' management efficiency for biodiesel-bioethanol industry in Mexico. The model targeted the generation of biofuel to fulfill the market demand at a high profit, while minimising water consumption. Whereas Moioli et al. (2018) developed a "Nexus Index" to examine different EWF resources needed for the production of 1 unit of energy. Moreover, Alherbawi et al. (2021) evaluated 11 processing pathways of biomass to select an optimal route that maximises profit and energy, while minimising emissions, lands and water consumption via genetic algorithm.

In this study, a novel framework was developed to ensure an EWF Nexus balance. A hybrid techno-geospatial approach was developed to allocate local biomass resources for different EWF industries, maximise the production and minimise the gate-cost of biomass. ArcGIS was utilised to map the biomass supplying sites and EWF representative industries and to define the distances amongst them.

A mathematical optimisation model was then developed to optimally allocate biomass supplying sites for each industry, given their location, quantity, calorific values, and possible processing pathways. Three EWF balancing scenarios were studied: a) equal EWF production, b) equal biomass distribution, and c) equal biomass-driven sales.

## 2. Methodology

### 2.1 Data Collection and Mapping

The required data was adapted from authors' earlier study (Alherbawi et al. 2022), where geospatial, quantitative, and qualitative data (i.e., heating value) for 10 different waste categories in Qatar were re-mapped at 35 sites in ArcGIS (10.7.1) using Universal Transverse Mercator (UTM) coordinates system.

In addition, three industries representing energy, water and food sectors were selected and located on the map, including an earlier proposed biorefinery site (Alherbawi et al. 2022), a desalination plant, and a livestock feed developing industry.

The biorefinery was assumed to produce syngas via gasification of biomass at a yield of 65% (Alherbawi et al. 2020). Whereas the desalination plant was assumed to be equipped with a biomass-based combined heat and power plant (CHP) at 34% net efficiency (IEA 2007) and consumes 11.4 MJ/m<sup>3</sup> (Rayburn 2012). Nevertheless, the feed developer was assumed to utilise food waste and agro-waste only for the manufacturing of livestock feed with a 75% nutrients recovery. All three plants operate for 8000 hours a year with a biomass feed capacity of 30 tonnes per hour. Moreover, the distances between the 35 biomass supply sites and the 3 industries were calculated in ArcGIS along with the corresponding transportation costs.

### 2.2 Optimisation Model Development

The optimisation model aims at minimising the overall biomass transportation costs to the 3 industries, while achieving an EWF Nexus balance via optimal biomass allocation. A summary of the mathematical model is presented in Table 1. Three constraints scenarios were introduced to restrict the model for the achievement of EWF Nexus balance. Scenario (a) leads to the production of equal quantities (i.e., syngas, water, and livestock feed) in (tonnes/y). While scenario (b) distributes biomass equally between the EWF industries, within the given capacities. Finally, scenario (c) achieves equal gross product sales, given that the maximum possible biomass quantity is valorised. The problem was solved using Microsoft Excel solver.

**Table 1:** Mathematical optimisation model for optimal biomass allocation.

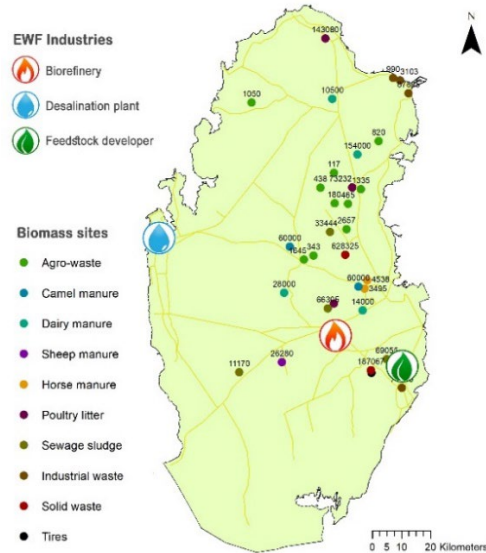

Function	Description
<b>Objective function:</b>	
$MIN TransCost = C * \sum_{i=1}^3 \sum_{j=1}^{35} D_{ij} * \frac{Q_j}{L} * A_{ij}$ <p>C: Cost of transportation (\$/km).                      D<sub>ij</sub>: Distance (km) between biomass site (j) to industry site (i).                      Q<sub>j</sub>: Total quantity (t) of biomass at site (j).                      L: Freight load (t/y).</p>	Minimising the total biomass transportation cost.
<b>Decision variable:</b>	
A <sub>ij</sub> : Allocated biomass (t/y) from supply site (j) to industry (i).	
$Distance (D_{ij}) = \sum_{i=1}^3 \sum_{j=1}^{35} \sqrt{(X_i - X_j)^2 + (Y_i - Y_j)^2}$ <p>(X<sub>i</sub>, Y<sub>i</sub>): Coordinates of industry (i).                      (X<sub>j</sub>, Y<sub>j</sub>): Coordinates of biomass site (j).</p>	Distance between biomass supplying site (j) to industry (i) based on UTM coordinates.
$Gross Biomass (B_{ij}) = \sum_{i=1}^3 \sum_{j=1}^{35} Q_j * A_{ij}$	Total biomass utilised (t/y)
$Gross Generation (G_{ij}) = \sum_{i=1}^3 \sum_{j=1}^{35} B_{ij} * R_{ij}$ <p>(R<sub>ij</sub>): Rate of production (t/t) at industry (j) using biomass (i).</p>	Total products generated (t/y)
$Gross Sales (S_{ij}) = \sum_{i=1}^3 \sum_{j=1}^{35} G_{ij} * P_{ij}$ <p>(P<sub>ij</sub>): Price of product at industry (j) using biomass (i).</p>	Total products sales (\$/y)
<b>Constraints:</b>	
$\sum_{j=1}^{35} A_j \leq 1 \quad \forall i$	Biomass consumed at site (j) should not be more than its capacity.
$A_{2,13}, A_{2,14}, \dots, A_{2,35} = 0$	Biomass from sites (13-35) is not suitable for industry (2).
$A_{i,1}, A_{i,2} \leq 0.578$	Only non-recycable biomass can be utilised from sites (1,2).
$A_{2,1}, A_{2,2} \leq 0.427$	Only food waste can be utilised from these sites for industry (2).
$G_{ij} \leq CP_{ij}$	Gross production at industry (i) should not exceed its capacity (CP <sub>ij</sub> )
<b>EFW Balancing Constraints:</b>	
$\sum_{j=1}^{35} G_{1,j} = \sum_{j=1}^{35} G_{2,j} = \sum_{j=1}^{35} G_{3,j}$	Scenario (a): Equal products generation.
$\sum_{j=1}^{35} B_{1,j} = \sum_{j=1}^{35} B_{2,j} = \sum_{j=1}^{35} B_{3,j}$	Scenario (b): Equal biomass utilisation.
$\sum_{j=1}^{35} S_{1,j} = \sum_{j=1}^{35} S_{2,j} = \sum_{j=1}^{35} S_{3,j}$	Scenario (c): Equal products sales.

### 3. Results and Discussion

#### 3.1 Data Mapping

The mapped sites of biomass resources and the three targeted EWF industries are presented in Figure 1. Most of the sites exist along the eastern coast towards the middle of the map, while the industries are distributed in the southern and western sides.

**Figure 1:** Quantities (t/y) and geospatial distribution of waste in Qatar.

#### 3.2 Biomass Allocation

The Excel solver yielded the optimal biomass allocation shown in Table 2 and Figure 2. In scenario (a), given equal production for the three industries (at 0.24 M tonne/y), 1.15 M tonne of biomass were utilised at an average transportation cost of 2.45 \$/t. While in scenario (b), equal biomass quantities were allocated for all industries (total: 0.48 M tonne/y), with the lowest biomass transportation cost attained at 1.98 \$/t and highest gross production and sales at 49.8 M t/y and 82.5 M \$/y, respectively. Whereas in scenario (c), equal products sales were achieved at 24 M \$/y, where 1.49 M tonne of biomass were utilised at an average transportation cost of 4.33 \$/t.

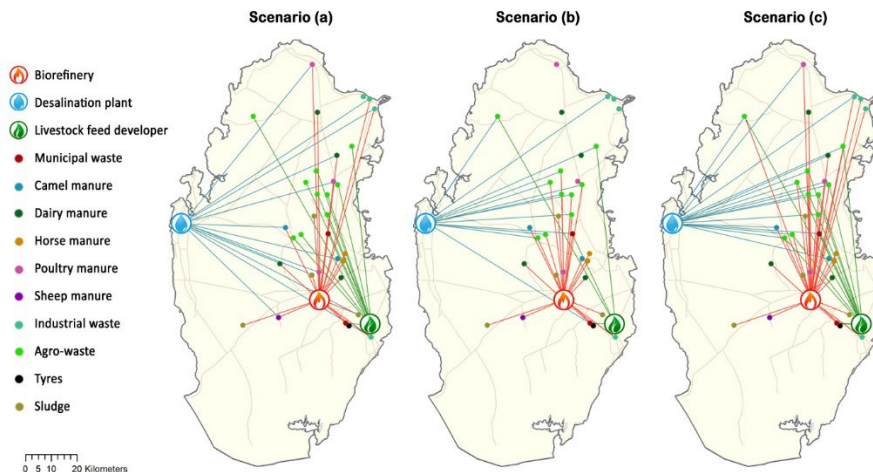

Figure 2: Representation of optimal biomass allocation over EWF industries.

#### 4. Conclusion

An EWF Nexus balancing framework was developed in this study to optimally allocate local waste biomass over EWF industries using ArcGIS and Excel tools. The framework has considered geospatial, quantitative, and qualitative aspects of biomass supplying sites and the receiving EWF industries. The model aimed at selecting optimal biomass resources and minimising their overall transportation costs. Moreover, three scenarios to achieve a Nexus balance were evaluated: a) equal biomass-based production, b) equal biomass distribution, and c) equal biomass-based sales. Scenario (b) achieved the lowest biomass transportation costs at 1.98 \$/t, however, lower biomass quantity has been utilised (0.48 M t/y). Whereas the maximum biomass utilisation was attained in scenario (c), with 1.49 M t/y of biomass transported at a minimised cost of 4.33 \$/t. This model provides insights on possible means to optimally utilise biomass resources at lower costs, while ensuring an EWF Nexus balance.

## Abstract

The Energy-Water-Food (EWF) Nexus approach has recently become an important tool to ensure efficient and optimum management of the three vital resources by considering the inter-dependencies amongst them. However, EWF optimisation complexity increases at times when resources are prioritised during trade off-driven decision-making, coupled with differences between the three resources in terms of measurement units. Therefore, this study presents a novel ‘Levelised-EWF indicator’ (LEWF) which merges the net value of energy, water and food requirement for a system or a product into a single value in (Megajoule equivalent “MJ-e”) unit. This tool enables a convenient comparison between biomass sources and processing technologies in the light of the EWF Nexus by converting multi-objective problems into single objective. Moreover, the study proposed a 10-level EWF resilience chart, to evaluate the system resilience to the changes in EWF resources supplies based on the obtained LEWF value. As a case study, the proposed LEWF tool is used to evaluate the various processing routes for *Jatropha curcas*’ seedcake to produce various energy products. Required data are obtained via earlier Aspen Plus<sup>®</sup> simulations of potential processes including gasification, pyrolysis, hydrothermal liquefaction, incineration, fermentation, and anaerobic digestion. The results demonstrated that pyrolysis is the optimal processing route for *Jatropha* seedcake with the lowest LEWF value of 0.23 MJ-e/MJ (product), with an EWF Resilience Level of 9 out of 10. The importance of this tool lies in its ability to ensure an adequate management of EWF resources within biomass systems and ensure system resilience against possible changes in supply chains.

**Keywords:** LEWF; Resilience; Biomass; Optimisation; Simulation; *Jatropha*.

## 1. Introduction

Energy, water, and food are the three essential resources for human existence and nations development. The increasing demand on these resources has raised the need to efficiently manage their consumption in a balanced manner. However, efficient management becomes more pushing at times when complicated interlinkages between these resources exist. Such a relationship was officially introduced in the Rio+20 Summit as “EWF Nexus” (Galmés et al. 2014).

The EWF Nexus concept has emerged as a key tool to evaluate the EWF resources’ synergies and tradeoff to ensure an adequate consumption balance. Several EWF Nexus frameworks have then been developed based on existing quantitative and qualitative approaches.

Al-Ansari et al. (2015) presented a Nexus framework based on lifecycle assessment (LCA) concept to study the possible tradeoffs amongst EWF systems and sub-systems. Meanwhile, Daher and Mohtar (2015) developed a scenario-based framework (WEF Tool 2.0) to trace the flow of EWF resources for different case studies towards reaching a self-sufficiency scenario. In addition, Alherbawi et al. (2021) developed a technology-based optimisation framework to evaluate the key biomass processing technologies and their interventions with EWF resources. Whereas Flammini et al. (2014) introduced a “Nexus Rapid Appraisal” method as a decision-making tool, through which the systems’ associated EWF resources are plotted in spider charts against standard values. The chart’s polygon area is considered a rapid visual representation of the possible intervention between the three resources. Moreover, Moioli et al. (Moioli et al. 2018) developed a “Nexus Index” as reference to evaluate the system’s EWF requirement to produce one energy unit.

In this study, a new concept is introduced, named “The Levelised Energy, Water, Food Nexus (LEWF Indicator)” for biomass-biofuel systems. The indicator merges the system’s associated EWF resources input into a single value, with energy equivalent unit (E-eq) based on the concept of resource payback that was introduced earlier by the authors (Alherbawi et al. 2020, Alherbawi et al. 2021). Merging the EWF into a single value facilitates a convenient comparison between the various biomass resources and the different processing technologies.

## 2. Methodology

### 2.1. Data Collection

Required data for the establishment of the LEWF concept and the development of its formulation have been collected from literature as displayed in Table 1. The table includes information on the interlinked requirements amongst the EWF resources and sectors.

**Table 1:** Data collected to assist the formulation of the LEWF Indicator.

Scope	Detailed item	Value*	Unit
Energy to water	Water requirement for coal-power generation	0.0790	(m <sup>3</sup> /GJ)
	Water requirement for NG-power generation	0.0760	(m <sup>3</sup> /GJ)
	Water requirement for nuclear-power generation	0.0180	(m <sup>3</sup> /GJ)
	Water requirement for solar-power generation	0.0064	(m <sup>3</sup> /GJ)
	Water requirement for wind-power generation	0.0002	(m <sup>3</sup> /GJ)
	Water requirement for hydro-power generation	0.3000	(m <sup>3</sup> /GJ)
	Water requirement for diesel fuel production	5.3000	(m <sup>3</sup> /GJ)
Water to Energy	Energy requirement for rainfed irrigation	0.0000	(GJ/m <sup>3</sup> )
	Energy requirement for groundwater provision	0.0013	(GJ/m <sup>3</sup> )
	Energy requirement for FO desalination	0.0029	(GJ/m <sup>3</sup> )
	Energy requirement for RO desalination	0.0108	(GJ/m <sup>3</sup> )
	Energy requirement for MED desalination	0.0130	(GJ/m <sup>3</sup> )
	Energy requirement for MSF desalination	0.0114	(GJ/m <sup>3</sup> )
	Energy requirement for wastewater treatment	0.0022	(GJ/m <sup>3</sup> )
Food to Energy	Energy requirement for cereal production	3.5600	(GJ/t)
	Energy requirement for beef production	44.7500	(GJ/t)

Land to Energy	Land requirement for coal-power generation	37.6040	(m <sup>2</sup> /GJ)
	Land requirement for NG-power generation	38.2200	(m <sup>2</sup> /GJ)
	Land requirement for nuclear-power generation	39.1440	(m <sup>2</sup> /GJ)
	Land requirement for solar-power generation	133.971	(m <sup>2</sup> /GJ)
	Land requirement for wind-power generation	217.557	(m <sup>2</sup> /GJ)
	Land requirement for hydro-power generation	970.815	(m <sup>2</sup> /GJ)
	Land requirement for diesel fuel production	0.2400	(m <sup>2</sup> /GJ)
Land to Food	Land requirement for cereal production	0.00023	(m <sup>2</sup> /t)
Fertilisers to Food	N-fertiliser requirement for cereal production	0.014	(t/t)
LS Feed to Food	Protein-feed requirement for beef production	0.13	(t/t)

## 2.2. LEWF Indicator Development

The LEWF indicator is formulated as given in Equation 1. The mathematical formula translates the water consumed or produced in a system into an equivalent energy amount, that is the amount of energy required to generate an equivalent quantity of water. Similarly, the formula converts the amount of food consumed into energy equivalent value based on the amount of energy required to produce similar amount of food. Nevertheless, the formula considers the embodied water and land of 7 energy systems to comprehensively account for all EWF resources' consumption throughout the lifecycle of a biomass-based process. Meanwhile, the different conversion factors (CF) required for the conversion are calculated and reported in the results section based on the data collected in Table 1.

$$LEWF = 1 - \left[ \frac{\left( \sum_{e=1}^{e'} E_e \cdot CF_e + \sum_{w=1}^{w'} W_w \cdot CF_w + \sum_{f=1}^{f'} F_f \cdot CF_f \right)}{\left( \sum_{p=1}^{p'} Q_p \cdot HV_p \right)} \right] \quad (1)$$

Where:

**LEWF**: Levelised Energy-Water-Food indicator (GJ-e<sub>in</sub>/GJ<sub>out</sub>).

**E**: Total energy consumed throughout the process' lifecycle via different energy supplies (e).

**W**: Net water consumed throughout the process' lifecycle via different water supplies (w).

**F**: Net food consumed throughout the process' lifecycle via different food supplies (f).

**CF**: Conversion factor into energy equivalent value.

**Q**: Gross mass quantity of different energy products generated (p).

**HV**: Heating value of product (p).

The LEWF obtained value may offer an indication of how resilient the system is. Where LEWF values of less than 1 (MJ-e/MJ product) indicate that the biomass-based system can generate sufficient energy to payback for the water and food consumed, while the resource payback is performed using an energy currency rather than money. Thus, the system hedges towards the worst-case scenarios, where in case of EWF supply chain disturbance, the system must be able to generate the required resources based on the extent of energy generated. Therefore, a 10-step EWF Resilience Chart is formulated based on the LEWF values, with a step size of 0.2, as illustrated in Figure 1.

**Figure 1:** Proposed EWF Resilience Chart.

### 2.3. Case Study

To evaluate the proposed LEWF tool and Resilience chart, a case study from author's previous work has been considered (Alherbawi et al. 2021), in which *Jatropha curcas* seedcake biomass was processed into multiple energy-producing technologies as illustrated in Figure 2. Energy, water and food-related data (Table 2) were adapted and plugged into the LEWF formula (Equation 1).

**Figure 2:** *Jatropha* seedcake's processing technologies within EWF boundaries.

**Table 2:** Case study's data on EWF systems consumption and generation.

Technology	Energy Generated (GJ/y)	Energy consumed (GJ/y)	Net water consumed ( $10^3 \text{ m}^3/\text{y}$ )	land used ( $10^3 \text{ m}^2/\text{y}$ )	By-products credit (Fertilisers) (tonne/y)
Gasification	1,039,967	291,924	38,557	25,000	0
Pyrolysis	1,645,898	291,735	38,431	25,000	0
Liquefaction	1,072,398	292,112	38,552	25,000	0
Fermentation	180,661	292,559	38,533	25,000	21,712 (N: 5%)
Digestion	664,308	291,782	38,398	25,000	2,778 (N: 5%)
Incineration	475,820	293,154	38,375	25,000	0

## 3. Results and Discussion

### 3.1. LEWF Indicator's Database

Utilising the data collected in Section 2, a set of conversion factors from different EWF resources into an energy equivalent value is provided in Table 3. The database comprises 7 energy supply resources and 7 water supply resources, in addition to food-related resources as energy crops or lands that are diverted from food cultivation towards energy production.

Nevertheless, food-related by-products (i.e., fertilisers, livestock feed) were taken into consideration, and were associated with a negative conversion factor as they represent a credit to the system, which cuts from its net resources consumption.

**Table 3:** LEWF Indicator’s conversion factor.

Source	Description	Energy equivalent conversion factor (GJ-e)
<b>Energy (GJ)</b>	Coal-Power	1.0313
	Natural Gas-Power	1.0317
	Nuclear- Power	1.0322
	Solar-Power	1.1097
	Wind- Power	1.1781
	Hydro- Power	1.7967
	Diesel fuel	1.0317
<b>Water (m<sup>3</sup>)</b>	Average	1.1731
	Rainfed	0.0000
	Groundwater	1.3E-03
	Forward osmosis	2.9E-03
	Reverse osmosis	1.1E-02
	Multi-effect distillation	1.3E-02
	Multi-stage flash	1.1E-02
	Wastewater treatment	2.2E-03
	Average	5.9E-03
<b>Food-related (tonne)</b>	Energy Crops	3.5600
	Land (m <sup>2</sup> )	8.2E-04
	By- products credit	-0.0498
	Fertilisers (N content) Animal feed (Protein content)	-5.8175

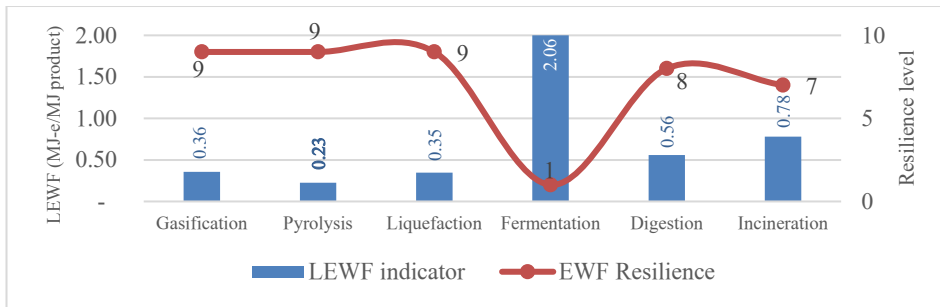

### 3.2. Model Application

The proposed LEWF Indicator has been applied to a *Jatropha* seedcake case study. The breakdown of total equivalent energy requirement for the different processing pathways is plotted in Figure 3. Whereas the final LEWF values and the corresponding EWF Resilience levels are illustrated in Figure 4.

**Figure 3:** Energy equivalent analysis of *Jatropha* seedcake processing technologies.

**Figure 4:** LEWFs and Resilience levels of *Jatropha* seedcake processing systems.

Pyrolysis achieved the lowest LEWF value (0.23 MJ-e/MJ) and highest EWF Resilience level (9/10), therefore, it is selected as an optimal processing technology. Similar conclusion has been reached through an EWF multi-objective optimisation conducted in MATLAB earlier (Alherbawi et al. 2021), which further validate the proposed LEWF Indicator.

#### 4. Conclusion

A novel LEWF Indicator is introduced for the evaluation of EWF resources requirement for energy systems. The indicator merges the three EWF input values into a single figure in energy equivalent unit (E-eq), which enables a convenient evaluation of EWF interlinkages in a system and facilitates the comparison with other systems. The indicator was implemented in a case study to select optimal processing pathway of *Jatropha* seedcake, where pyrolysis achieved the lowest LEWF at 23 (MJ-e/MJ product).

## Abstract

Controlled environment agriculture (CEA) has some clear advantages over traditional farming, such as: reliable and consistent production capability; efficiency in water and space use; reducing the use and runoff of fertiliser and pesticides; etc. As such CEA can greatly benefit from the CAPE (computer-aided process engineering) approach – cross-fertilization of these two apparently distinct areas may result in new methods and applications to improve CEA and process engineering, with potentially significant contribution to circular economy. In this paper, we discuss several important aspects of CEA drawing from our own experiences in aquaculture and aeroponics, including product development, process design and process operation, and the potential contribution of CAPE. Finally, we postulate a systems platform for CEA, aiming to foster a long-lasting partnership between the two scientific communities.

**Keywords:** Controlled environment agriculture; Computer-aided process engineering; Digital twin; Optimisation; Process control; Process modelling.

## 1. Introduction

A recent breaking news is that the global population has exceeded 8 billion people, (United Nations, 2022). This means that more and more agricultural products and raw materials are required in future. The traditional production methods face a tremendous challenge to meet the ever-increasing demand whilst aiming to achieve net zero and minimal environmental impact (Hemathilake et al., 2022). Thus, advanced agricultural systems with high efficiency, high production capacity and low emission need to be developed.

Controlled environment agriculture (CEA) refers to the production of food (e.g., crops, aquatic and livestock) and non-food (e.g., biomass, fur) agricultural products under conditions that are more controllable than traditional farming in the open field/ponds. It uses adjustable production environment and facility conditions to optimal and correct the growth system over real-time (Benke et al., 2017), provides a high-efficiency, high-yield, potentially low carbon and sustainable production. At scale, CEA can spare the use of land and water bodies with significant ecological benefits. However, CEA faces the challenges of high capital investment and operating costs, the need for crop/animal to

adapt to the indoor environment, and complex cultural and political resistance. Some of these issues can be addressed by technological advancement including the use of systems engineering thinking and methods.

CEA encompasses a wide range of primary production methods, ranging from loosely controllable environment in polytunnel greenhouses, aquaculture pens, to totally controlled production systems in plant factories and recirculating aquaculture systems. Like any emerging and rapidly developing subject, this field has been given many names which often overlap in their connotation but have different focuses, such as plant factory, vertical farming, urban farming, facility agriculture, to name a few. We choose CEA to emphasise its key difference from traditional, uncontrolled farming.

In this paper, we discuss from the perspective of systems engineering the three tasks in CEA: product development, process design and process operation, with a focus on the latter. The narrative will mainly draw from our own experiences in aquaculture, aquaponics and aeroponics (Li et al., 2021; 2022; Guo et al., 2022; Zhou et al., 2021), supplemented by work reported in the open literature. Figure 1 illustrates two examples of CEA production systems. Other crop and livestock production systems, such as indoor poultry and insect farming, have their own special requirements in terms of product development, process design and operation. However, they share the same conceptual framework of using systems engineering approach to enable more sustainable production.

Figure 1. CEA examples: (a) Aeroponic cultivation of bioenergy willows in a greenhouse; (b) Industrialised aquaponics to produce fish and vegetables.

## 2. Systems engineering techniques for product and process design

### 2.1. Computer aided product design

Products play an important role on the production system. In CEA, product design / redesign is often needed to adapt to the spatiotemporal characteristics and the constraints of resources. For example, the willows growing in an indoor, aeroponic environment (Figure 1(a)) should ideally be dwarf, fast-growing, comfortable with aeroponic irrigation and nutrition, and resistant to disease. The same idea is also used in aquaponics factories, where the high-density production environment requires fish species with fast growth and disease resistance. Such controlled environment and the adapted crops or animals may also require new formulations of the feed.

Computer aided breeding is a well-established concept. Statistical design of experiments has been widely used in decades. Advanced machine learning / artificial intelligence methods, incorporating multi-faceted data such as imaging, genomics and phenomics, have shown promises (Harfouche et al., 2019; Marsh et al., 2021). More fundamental,

systems biology models, such as gene regulatory networks, have been applied to obtain the favourable traits with mechanistic understanding of why and how (Lavarenne et al., 2018). Notably, these computational methods have the maximum potential when they are integrated with high-throughput experiments – CEA can provide such high-throughput facilities with close control of the environmental parameters.

## *2.2. Computer aided process design*

CEA at industrial scale is analogous to biomanufacturing processes. The centrepiece is the “bioreactor” to produce the biomass (animal or plant). A wide range of facilities, equipment and devices are needed to support the microclimate environment, water quality, nutrient supply, disease control, downstream processing of products and/or wastes, etc. These decisions mirror process design in CAPE. For most facilities, the key design considerations are to do with HVAC (heating, ventilation and air conditioning), water supply, and power supply, to provide required temperature, humidity, ventilation, supplementary light, irrigation, etc.

Specific requirements are needed beyond the above general principle. For example, recirculating aquaculture systems (RAS) require design of not just the fish tanks, but also aeration, sterilisation, water quality adjustment, multi-stage filtration (physical and biological), etc. For soilless plant production, the design of nutrient supply and recycle units (Bittsánszky et al., 2016), supplementary lighting / shading facilities, etc., will be required in addition to HVAC.

It is necessary to fully consider the integration between product design (breeding) and process design, as opposed to treating them as two separate tasks. Computer aided process design in CEA is emerging (Guo et al., 2022; Holzworth et al., 2015), though its full potential is yet to materialise, especially in whole-process simulation and design.

Energy consumption has always been a major factor in agricultural production. The requirement for heating during winter has restricted the use of many agricultural technologies in high latitude regions. This is particularly an issue for CEA. A potential solution is the use of a multitude of energy sources, including solar, wind energy, biomass, geothermal and tidal energy. In high latitude regions, distributed energy systems for combined heat and power hold promise to reduce reliance on the grid, reduce cost and reduce emission. We conducted large-scale aquaponics production experiments by integrating solar, geothermal and biomass energy in Northern China (Le et al., 2021), supported by computational fluid dynamic simulations (Le et al., 2020).

## **3. Systems engineering methods for process operation**

Similar to chemical manufacturing, the operation of CEA processes can be organized in a hierarchy from regulatory control, optimisation to scheduling, planning and supply chain management. Agricultural production is inherently slow and in batch mode. Slow dynamics in biomass production suggests some level of tolerance to operation disturbances. For example, although the desired temperature for Salmon growth is around 12 °C, a short exposure to temperature moderately outside this range is usually tolerable, creating degrees of freedom for optimisation. On the other hand, the nutrient dynamics can be fast, such as nitrification in a fish tank, so is the dynamics of microclimate parameters. This disparity in dynamics may pose challenges to process monitoring, control, optimisation and scheduling.

### *3.1. Soft sensor for process monitoring*

Effective process operation requires reliable measurement. In traditional agriculture, a key consideration is the cost and maintainability because of the often harsh environment in the open field. These challenges are alleviated to some extent in CEA. Nevertheless, since agricultural products are relatively low value, cost and maintainability are still big drivers. For example, many commercial ammonia sensors need to be calibrated once a month – this might be an affordable, standard practice in a wastewater processing plant in the UK (private communication) but impractical for agriculture.

Therefore, software based sensor self-calibration has been proposed as a solution (Yuri et al., 2015), for temperature, dissolved oxygen (DO) and ammonia (Yu et al., 2020). Liu et al. (2013) developed a multi-source heterogeneous data preprocessing technologies to improve the measurement accuracy. Li et al. (2021) applied a moving horizon estimation approach, widely used in CAPE, with a mechanistic nitrogen cycle model as a state estimator to improve the resolution and reliability of total nitrogen monitoring from infrequent sensor readings.

### *3.2. Process control & optimisation*

Process control in CEA normally refers to the control of the microclimate parameters, i.e., temperature, humidity, water quality, nutrient supply, light intensity, CO<sub>2</sub> concentration (if CO<sub>2</sub> enrichment is possible in a totally controlled environment), etc. In the context of aquaculture DO control has been the primary focus, because fish health and viability is very sensitive to DO. Aeration is an effective manipulated variable to control DO, but it associates with significant energy cost. DO's importance has warranted a large number of reports of controller design, such as adaptive PID control enhanced by evolutionary algorithms (Zhou et al., 2021). In principle, model predictive control (MPC) should give improved results as shown in controlling DO in wastewater processing (O'Brien et al., 2011), though the application of MPC in agriculture is still under-explored. In addition, due to the difficulties in real-time measurement of other water quality indices, e.g. ammonia nitrogen, their feedback control is less common in practice.

Direct control and/or optimisation of the biomass growth has been less reported in the literature. In principle these are similar to batch process control/optimisation problems. The challenges are two-fold: the limitation on measurement and the incredibly long batch duration. Direct measurement of biomass growth could be achieved by manual sampling or using imaging based techniques, but the latter itself is an open research area. Long batch duration, from weeks to months, renders run-to-run control impractical. There have been reports of reference tracking using MPC (Chahid et al., 2021) and direct use of a mechanistic model in growth optimisation (Li et al., 2022). If computer models are developed to incorporate the prediction of both production and environmental parameters, they could be used to formulate economic indices and thus cast into an economic MPC framework for dynamic, direct optimisation of the economic measures. Currently such methods are limited to simulations and have a long way to be taken up in practice.

### *3.3. Scheduling, planning & supply chain*

Due to the long lead time of agriculture produces, scheduling, planning and supply chain integration is key to commercial viability and success. At the process level, scheduling models could be developed at steady state to mixed integer linear programs (MILP) or even nonlinear ones, similar to those in the vast CAPE literature, and solved accordingly. With distributed energy systems, the objective is typically to maximise capacity

utilisation with minimal energy costs, considering variable energy inputs/costs due to the use of renewables. Alternatively economic MPC, as mentioned above, might be useful to make dynamic decisions enclosing both the scheduling and optimisation levels. The key enabler is digitalisation throughout the production, and integrated with pre-production to post-production for optimising the fresh/cold supply chain. An especially interesting case is aquaponics, where the production of fish and crops should be scheduled in a staggered manner to meet variable market demand.

### *3.4. Big data, IoT and AI*

Agriculture is traditionally data poor but has seen rapid transition to big data, enabled by massive connectedness, industrial internet-of-things (IoT), and data processing platforms such as the Apache Spark and Storm. Big data has allowed the application of advanced AI for the intelligent perception, prediction, and decision making in agrifood production (Wang et al., 2021). A particularly important application of big data AI in CEA is disease control. AI is well suited to integrating data from low-cost camera with environment data, and by using machine learning algorithms to providing early warning of pathogens (Wen et al., 2012; Zhang et al., 2020). We recently demonstrated a proof-of-concept of using acoustic signal to determine fish feeding intensity (Cui et al., 2022).

## **4. Concluding remarks**

In this paper we provided an overview of CEA as an emerging method for efficient and sustainable agrifood production. Whether CEA can fulfill its perceived benefits is likely to depend on how the products are processes are designed, and how the processes are operated, all in a holistic approach encompassing commercial viability, energy consumption, environmental impact, and circularity. There is a strong case for adapting CAPE methods to the application in CEA, as shown in increasing research reported in the literature. However, challenges abound. Agriculture produces are of relatively low value per kg produced compared with many chemical products familiar to the CAPE community. Most processes are slow with a long time delay / time constant between input and output. Measurement of key process parameters, especially those to do with the biomass properties (e.g., growth and health of the animal/crop), is difficult. On the flip side, the live biomass being produced are often tolerant to minor environment changes, providing more space for optimisation. We foresee a fruitful and long-lasting partnership between CAPE and CEA to address these and emerging challenges in the near future.

## Abstract

The concentration of carbon dioxide in the atmosphere has reached an alarming level. CO<sub>2</sub> can be captured using the traditional amine absorption process. However, this process is an energy-intensive and environmentally unfriendly. Thus, we have developed in this work a novel adsorbent using magnesium oxide (MgO) that has been functionalized with 3-aminopropyl-triethoxysilane (APTES). This CO<sub>2</sub> adsorbent (APTES-MgO) is reported for the first time in this work to the best of our knowledge. APTES-MgO can significantly adsorb CO<sub>2</sub> at ambient conditions. It is fully regenerable and the regeneration process can be carried out at mild conditions (120°C and atmospheric pressure) under a nitrogen environment. This low regeneration temperature indicates that the energy consumption of CO<sub>2</sub> capture process using APTES-MgO could be low. The adsorption capacity of APTES-MgO is more than 1.5 mmol/g at 30 °C and 1 atm. The regeneration process of APTES-MgO can fully restore its CO<sub>2</sub> adsorption capacity. The adsorption process has been modelled using a first order adsorption model. The mathematical model can track the experimental data quite well, allowing the estimation of the key adsorption parameters. The effectiveness of APTES-MgO in adsorbing CO<sub>2</sub> at ambient conditions and its regenerability and stability suggest its potential commercial application in CO<sub>2</sub> capture industry.

**Keywords:** Amine-functionalized magnesium oxide, Adsorption, Regeneration, Ambient conditions, Carbon dioxide (CO<sub>2</sub>) capture, Mathematical modelling

## 1. Introduction

Next paragraphs should start with heading as given in below example. The emission of CO<sub>2</sub> to the atmosphere is steadily increasing. One of the serious impacts of increasing CO<sub>2</sub>, and other greenhouse gases, level in the atmosphere is global warming, which has several negative consequences. One of such negative consequence is the significant increase in the water level of oceans and seas and, thus, the submerging of some islands and coastal cities. Thus, CO<sub>2</sub> has to be captured and managed in a proper way. The current main process for CO<sub>2</sub> capture is the absorption using aqueous solutions of some amines such as methyldiethanolamine (MDEA) and monoethanolamine (MEA). In addition to environmental concerns on the utilization of these organic solvents (i.e., amines), amine absorption process is corrosive and the regeneration of the spent amine is energy intensive (i.e., expensive) [1-3]. Thus, alternative processes have been (and are still) actively sought by academia and relevant industries.

One of the attractive alternatives is adsorption. Nonetheless, several adsorbents reported in the literature are either not regenerable or/and require relatively high regeneration energy. Furthermore, some adsorbents are only effective at high pressures or sub-zero temperatures. Accordingly, there is a pressing need for developing CO<sub>2</sub> adsorbents that

are effective at (or near) ambient conditions. Besides their effectiveness at ambient conditions, these adsorbents should be stable and fully regenerable under mild conditions. Thus, MgO has been synthesized in this work and used for CO<sub>2</sub> capture. To enhance the CO<sub>2</sub> adsorption capacity, MgO was functionalized with APTES. The kinetics of CO<sub>2</sub> adsorption on both MgO and the APTES-modified MgO was fitted using three different adsorption kinetics models (pseudo-first order, pseudo-second order and Avrami), enabling the extraction of the values of the adsorption parameters.

## 2. Methodology

### 2.1. Preparation of adsorbents

MgO was synthesized using the following protocol. First, an aqueous solution (270 mM) of magnesium nitrate hexahydrate was prepared. After obtaining a homogenous solution of this magnesium salt via stirring at room temperature for 10 min, a certain volume of 30% ammonium hydroxide (NH<sub>4</sub>OH) was added to make the molar ratio of Mg: NH<sub>4</sub>OH as 1:5. The new mixture was stirred for few minutes to thoroughly mix its ingredients. After that, the glass bottle containing the mixture was closed and incubated in a hot water bath (60 °C) for 6 h. The mixture was stirred while incubated in the hot water bath. Then, the mixture was removed from the hot water bath, the bottle cap was removed (to allow some liquid to evaporate) and the bottle content was stirred for additional 24 h at room temperature, leading to the formation of a thick paste (consists of Mg(OH)<sub>2</sub> and NH<sub>4</sub>NO<sub>3</sub>) [4]. To remove the formed NH<sub>4</sub>NO<sub>3</sub>, which is water-soluble, the thick paste was washed extensively with distilled water. Such an extensive wash is expected to also remove any unreacted magnesium precursor. After drying at 60 °C, the material was ground and calcinated (under an air environment) at 400 °C for 10 h to yield MgO. The synthesized MgO was characterized using BET and energy-dispersive X-ray spectroscopy (EDX).

After the synthesis of MgO, it was functionalized with APTES according to the following procedure. An aqueous dispersion of MgO containing 0.83 g/L was prepared by vigorously stirring the MgO solution for 5 min. After that a certain amount of APTES (MgO/APTES mass ratio = 1/2) was added to the MgO suspension. Then, the resultant solution was heated at 80 °C and refluxed for one day. Following this step, the obtained amine-functionalized MgO was rinsed thoroughly with distilled water. The produced APTES-MgO was collected via centrifugation and then it was dried at 60 °C overnight. The synthesized APTES-MgO was also characterized using BET and EDX.

### 2.2. Adsorption kinetics of CO<sub>2</sub>

The CO<sub>2</sub> adsorption kinetics on the bare and the APTES-modified MgO was monitored using a thermogravimetric analysis (TGA) technique. In each experiment, the TGA pan (made from alumina) was thoroughly cleaned and dried and then a certain amount (roughly 20 mg) of either MgO or APTES was placed in the TGA pan. To remove moisture, the adsorbent was degassed at 100 °C using a stream of nitrogen. The mass of the adsorbent was continuously monitored while degassing until it reached a steady value and remained constant for at least 30 min. After that, the temperature was dropped to the desired adsorption temperature (i.e., 30 °C). The temperature was continuously monitored until it stabilized at 30 °C and remained stable. Then, nitrogen gas valve was closed and the carbon dioxide (> 99.9% pure) valve was opened. CO<sub>2</sub> flowrate was kept constant at 100 mL/min. To ensure the attainment of adsorption equilibrium, the

adsorption of CO<sub>2</sub> was monitored in time until no significant change in the sample mass (adsorbent + adsorbate) was observed.

### 2.3. Regeneration of spent amine-functionalized adsorbent

The regeneration of APTES-MgO (given the effectiveness of this adsorbent relative to the unmodified MgO as will be presented and discussed in the subsequent section) was studied. The regeneration was carried out using nitrogen gas flowing at 100 mL/min. The protocol of APTES-MgO regeneration is as follows. APTES-MgO was contacted with CO<sub>2</sub> until adsorption equilibrium was approached. Then, CO<sub>2</sub> flow (100 mL/min) was halted and N<sub>2</sub> valve was opened. Once, the adsorbent was fully regenerated (i.e., the mass of APTES-MgO returned to its original value before CO<sub>2</sub> injection), the flow of N<sub>2</sub> was stopped and CO<sub>2</sub> valve was opened. Four cycles of adsorption-regeneration were conducted. In each of these cycles, CO<sub>2</sub> adsorption took place at 30 °C while the regeneration temperature was set to 120 °C. The pressure of adsorption and regeneration processes was fixed at 1 atm.

## 3. Results and discussion

### 3.1. Characterization of the synthesized MgO and APTES-MgO

After the synthesis of MgO and its modification with APTES, elemental analysis of the composition of these two adsorbents was carried out using EDX. The results obtained from the elemental analysis are summarized in Table 1. The MgO sample contains about 53.61 atomic% magnesium and 46.39 atomic% oxygen, indicating the formation of magnesium oxide. The hypothetical chemical formulas of the formed magnesium oxide is MgO<sub>0.87</sub>, which is reasonably close to the chemical formula of magnesium oxide (MgO). Upon the modification of MgO with APTES, other elements (N, C, and Si) appeared in the elemental analysis results. These elements originate from the APTES molecules (molecular formula: C<sub>9</sub>H<sub>23</sub>NO<sub>3</sub>Si). The atomic ratios of N, C and Si in the APTES-MgO adsorbent are close to their atomic ratios in the APTES molecules. The increase in the oxygen content of the amine-modified MgO relative to MgO stems from the presence of oxygen in the APTES molecules.

Table 1: Elemental compositions of the synthesized MgO-based adsorbents.

Sample	Mg atomic%	O atomic%	C atomic%	N atomic%	Si atomic%
MgO	53.61	46.39	–	–	–
APTES-MgO-A	15.85	44.75	31.83	3.01	4.56

Besides the elemental analysis, textural properties (i.e., BET surface area, pore volume and pore diameter) of MgO and APTES-MgO were studied. The textural properties of the synthesized MgO and the amine-modified MgO are shown in Table 2. The BET surface area and pore volume of MgO were about 246 m<sup>2</sup>/g and 0.086 cm<sup>3</sup>/g, respectively. Upon the functionalization of MgO with APTES, the BET surface area and the pore volume of the modified MgO dropped by a factor of ~5. Such a reduction in the BET surface area of MgO and its pore volume upon the functionalization with APTES is expected since the amine molecules are likely to fill some of MgO pores [5, 6]. Unlike the drop in the BET

surface area and pore volume of APTES-MgO relative to the unmodified MgO, the pore size has increased by about 20% upon the attachment of APTES to MgO. The attachment of APTES to MgO-A was carried out at 80 °C under continuous stirring and refluxing for 24 h. Such a thermal treatment, despite being mild, coupled with APTES attachment to MgO-A might have assisted in expanding the size of the pores of the APTES-MgO-A sample [7]. The expansion in the pore size upon the functionalization of MgO with APTES does not contradict the observed reduction in pore volume and surface area. However, despite having higher pore size, the number of pores in the APTES-MgO sample is likely much lower than that in the unmodified MgO due to the blockage of some pores by APTES molecules.

Table 2: BET surface area, average pore size and average pore volume of the synthesized MgO-based adsorbents.

Samples	BET Surface area (m <sup>2</sup> /g)	Pore volume (cm <sup>3</sup> /g)	Pore size (nm)
MgO	246.421	0.086	1.389
APTES-MgO	48.651	0.020	1.644

### 3.2. Adsorption kinetics of CO<sub>2</sub>

CO<sub>2</sub> adsorption on MgO and APTES-MgO was studied at ambient conditions (i.e., 30 °C and 1 atm). Before contacting CO<sub>2</sub> with these two adsorbents, they were degassed using nitrogen gas as described in the previous section. Figure 1 shows the kinetics of CO<sub>2</sub> adsorption on the unmodified MgO. The adsorption capacity approached about 0.68 mmol/g when the adsorption process approached equilibrium. The adsorption data were fitted to pseudo-first order, pseudo-second order and Avrami kinetics model as shown in Figure 1. Among these three models, the pseudo-second order kinetics model provides the best fit to the experimental data ( $R^2 = 0.9996$ ). The estimated parameter values of the CO<sub>2</sub> adsorption kinetics using these models are presented in Table 3.

Figure 1: Adsorption kinetics of CO<sub>2</sub> on MgO and APTES-MgO. The solid curves represent the calculated values using the adsorption kinetics models.

The adsorption of CO<sub>2</sub> on APTES-MgO was also studied and modeled using the above adsorption kinetics models (see Figure 1). The estimated values of the adsorption parameters are shown in Table 3. The results displayed in Figure 1 and Table 3 (particularly the R<sup>2</sup> values) clearly demonstrate the superiority of the pseudo-second order in tracking the experimental data relative to the other two models. However, unlike the case of MgO where Avrami kinetics model provided a good data fitting, the fitting of CO<sub>2</sub> adsorption on APTES-MgO using this model is relatively poor. Nonetheless, Avrami model still provides a better data fitting for CO<sub>2</sub> adsorption on both MgO and APTES-MgO compare to the pseud-first order model.

Table 3: Values of the fitting parameters of CO<sub>2</sub> adsorption kinetics.

MgO					
Model	Model Equation	Adsorption rate constant (k)	Adsorption capacity at equilibrium (qe)	Avrami exponent (n)	R <sup>2</sup>
Pseudo-first order	$q_t = q_e(1 - e^{-kt})$	0.131 min <sup>-1</sup>	0.643 mmol.g <sup>-1</sup>	-----	0.9849
Pseudo-second order	$q_t = kq_e^2 t / (1 + kq_e t)$	0.241 g.mmol <sup>-1</sup> .min <sup>-1</sup>	0.725 mmol.g <sup>-1</sup>	-----	0.9996
Avrami	$q_t = q_e(1 - e^{-(kt)^n})$	0.117 min <sup>-0.706</sup>	0.675 mmol.g <sup>-1</sup>	0.706	0.9980
APTES-MgO					
Model	Model Equation	Adsorption rate constant (k)	Adsorption capacity at equilibrium (qe)	Avrami exponent (n)	R <sup>2</sup>
Pseudo-first order	$q_t = q_e(1 - e^{-kt})$	0.089 min <sup>-1</sup>	1.414 mmol.g <sup>-1</sup>	-----	0.9879
Pseudo-second order	$q_t = kq_e^2 t / (1 + kq_e t)$	0.064 g.mmol <sup>-1</sup> .min <sup>-1</sup>	1.647 mmol.g <sup>-1</sup>	-----	0.9951
Avrami	$q_t = q_e(1 - e^{-(kt)^n})$	0.082 min <sup>-0.846</sup>	1.454 mmol.g <sup>-1</sup>	0.846	0.9921

### 3.3. Regeneration of spent amine-functionalized adsorbent

In addition to the good CO<sub>2</sub> adsorption capacity on the APTES-functionalized MgO, it has also an excellent regenerability as shown in Figure 2. The CO<sub>2</sub> adsorption capability of APTES-MgO is preserved with the repetitive use. This means that the adsorbent is stable and the regeneration process of the spent adsorbent does not compromise its adsorption capacity. This is an attractive characteristic that is highly required in industrial applications. Another attractive characteristics of APTES-MgO is the mild regeneration conditions (120 °C and 1 atm). Exposing the spent APTES-MgO to N<sub>2</sub> at 120 °C and 1 atm can fully restore the original CO<sub>2</sub> adsorption capacity of this adsorbent within a very short time (< 20 min). This regeneration time can shortened with increasing the flow rate of the regeneration gas.

## 4. Conclusions

The modification of MgO with APTES greatly enhances CO<sub>2</sub> adsorption by a factor of more than 2 despite the significant drop (more than 5 times) in the adsorbent surface area

and pore volume. Kinetically, the adsorption of CO<sub>2</sub> on both adsorbents follows a pseudo-second order adsorption kinetics. The pseudo-first order model failed to reproduce the experimental data while the data fitting using the Avrami model was not as good as using the pseudo-second order. The full restoration of the adsorption capability of APTES-MgO upon the contact with N<sub>2</sub> at mild conditions in addition to the stability of the adsorbent make it a good candidate for commercial CO<sub>2</sub> capture.

Figure 2: Regeneration of APTES-MgO using nitrogen gas. The regeneration temperature and pressure are 120 °C and 1 atm, respectively.

### Abstract

Natural gas has a crucial role in minimising carbon emissions and is considered a transition fuel. Liquefied natural gas (LNG), which is derived from natural gas is one of the most promising alternative fuels, and LNG producers are actively developing their methods to reduce or offset their carbon footprints. The allocation of carbon dioxide (CO<sub>2</sub>) emissions is crucial in identifying who is responsible for reducing emissions at the economy or enterprise level. Different strategies for allocating CO<sub>2</sub> emissions have been developed and used during the last few decades. As such, this study introduces options for low carbon LNG within a CO<sub>2</sub> utilisation network in the state Qatar; where a linear programming (LP) model is developed to address the optimal CO<sub>2</sub> allocation based on environmental and economic objectives. The model considers a single CO<sub>2</sub> source (Qatar Gas), where a post combustion carbon capture technology (PCC) is utilised to capture the CO<sub>2</sub> emissions, and then allocated to 7 sinks that use CO<sub>2</sub> as input to their production (including Enhanced Oil Recovery (EOR)). Three scenarios are considered to allocate CO<sub>2</sub> to different sinks to obtain the optimal solution for each scenario. Scenario 1 had the highest total profit of 55 billion USD. The lowest CO<sub>2</sub> emissions were produced by scenario 2, which had zero emissions. Scenario 3 had a total profit of 20 billion USD and a total of 2 million CO<sub>2</sub> emissions. For all scenarios, EOR sinks had the highest CO<sub>2</sub> allocation. The total global warming potential through the lifecycle of LNG is reduced from 0.46 to 0.14 tonne CO<sub>2</sub>e/tonne of LNG produced.

**Keywords:** LNG, CO<sub>2</sub> allocation, Sustainability, Carbon Dioxide, Carbon capture and utilisation (CCU)

### 1. Introduction

Due to the growing environmental concerns, there are indicators that expanding symbiotic linkages between industries within the same vicinity may significantly contribute to the development of sustainable industrial operations. Several energy corporations have recently revealed far-reaching carbon-neutrality goals, accompanied by more or less remote time horizons. Regardless of the fact that natural gas is the cleanest-burning hydrocarbon, regulators are paying closer attention to GHG emissions linked to the natural gas supply chain, including that of liquefied natural gas (LNG) (Roman-White et al., 2021). To guarantee natural gas's place in the energy transition in a decarbonizing world with a rising proportion of renewable energy sources, natural gas emissions must be reduced, and this can be made possible through a systems approach on an industrial level. For resource allocation in industrial park, a variety of tools has been utilised previously, including optimisation, game theory, agent-based modeling, network analysis, etc. Due to the established technologies in many industries, which are mostly focused on the use of fossil fuels, the direct reduction of the emissions is currently complex in the short term. Therefore, the concept of Carbon Capture and Storage (CCS) arises as a compelling proposal for reducing emissions, where absorption has been

demonstrated as an effective approach to produce a high capture yield with various solvents, such as piperazine (PZ) or monoethanolamine (MEA) (Li and Zhang, 2018). The requirement of large storage capacity of carbon dioxide gas is a challenge that affects the adoption of CCS technologies (IPCC, 2005). Furthermore, Carbon Capture and Utilisation (CCU) aims to gain an advantage by using CO<sub>2</sub> in various industrial processes in place of conventional raw materials (Aresta, 2010). Utilising CO<sub>2</sub> is a possibility for supplying a renewable energy source for the creation of numerous valued items. The optimum method of utilising CO<sub>2</sub> is thought to be its conversion into fuel. Some of the chemicals that can be generated by using captured CO<sub>2</sub> as an input or feedstock include methane, methanol, alkanes, and syngas (Marchese et al., 2021).

Research on energy conservation in an eco-industrial park (EIP) is mostly unexplored in the field of mathematical optimisation. Boix et al. (2015) stated that many objective functions, such as EIP energy efficacy, CO<sub>2</sub> emission reductions, waste heat recovery, and network payback period, have been proposed in the literature. However, the challenge of achieving multiple conflicting objectives at once is not efficiently examined yet as well as carbon focused eco-park resource allocation with an aim of producing low carbon and zero-carbon LNG. As such, this study is an extension of previous study conducted by Sawaly et. al, (2022), with the integration of a multi-objective model and Alshaheen field as a new EOR sink. A linear programming (LP) model is developed to address the optimal CO<sub>2</sub> allocation with multi-objective to maximise the overall profit of the system while minimising CO<sub>2</sub> emissions. The model considers a single CO<sub>2</sub> source (Qatar Gas), where a post-combustion carbon capture technology (PCC) is utilised to capture the CO<sub>2</sub> emissions, and then allocated to sinks that use CO<sub>2</sub> as input in their production. Thus, this study aims at introducing additional options for low-carbon LNG within a CO<sub>2</sub> capture and utilisation (CCU) network in the state Qatar to optimise and enhance eco-parks exchanges.

## 2. Model Design and Optimisation

### 2.1 Available data and assumptions

The objective is to facilitate a resource trade scheme for CO<sub>2</sub> emissions to produce low carbon LNG in Qatar Gas. With a total of roughly 21 LNG trains, Qatar Gas (QG) is the largest LNG producer in the world, operating 14 LNG trains with a 77 MT annual production capacity (Al-Yaeshi, 2020). According to Mohammed, (2016), the corresponding CO<sub>2</sub> emissions are 35.8 MT/year (Scope 1 – Direct total GHG emissions). Therefore, a post combustion carbon capture technology (PCC) is utilised to capture 70% of the total CO<sub>2</sub> emissions emitted by QG (25 MT year), and then allocate to sinks that use CO<sub>2</sub> as input to their production (QAFCO, QAFAC, Pearl GTL, Oryx GTL, Dukhan Field Well (EOR), Alshaheen Field (EOR)).

$$\text{Enhanced Lifecycle GWP of Qatar Gas} = 30\% \times \frac{\text{tonne of CO}_2 \text{ emitted/year}}{\text{tonne of LNG produced/year}} \quad (1)$$

With an OPEX of \$40 per tonne of CO<sub>2</sub>, chemical absorption using amine solvents was expected to capture CO<sub>2</sub> with 100% efficiency. In order to prevent pressure reductions throughout the pipeline and to preserve the operational parameters of the sink, CO<sub>2</sub> must be compressed. For every 100 km along the pipeline, the unit cost for compression and subsequent transportation is roughly \$1.5/tonne CO<sub>2</sub> (Al-Yaeshi, 2020; Sawaly et. al, 2022). It is assumed that the injection cost and emissions for EOR is neglected. Table 1 lists the sinks' products, production rate, CO<sub>2</sub> capacity, and emission rate. The suggested methodology uses a Linear Programming (LP) optimisation framework to address CO<sub>2</sub> allocation and find solutions for reducing CO<sub>2</sub> emissions at a realistic cost while

also maximising the profits of value-added products. The proposed methodology is used to implement the model's outcomes using the Excel solver and MATLAB. Carbon capture and compression, along with transportation are the only expenditures taken into account in this study that have an influence on profit, whilst the only emissions included are process related emissions. Three scenarios are implemented in this study: (1) A scenario for allocating CO<sub>2</sub> from the source to the sinks with a single objective of maximising the profit of the overall network (2) A scenario for allocating CO<sub>2</sub> from the source to the sinks with a single objective to minimise the CO<sub>2</sub> emission of the overall network, and; (3) A scenario for allocating CO<sub>2</sub> from the source to the sinks with a multi-objective for profit maximisation and emission minimisation of the overall network. The commodity prices of the products are collected over the period 2014-2018 (Intratec Solutions, 2019).

Table 1: Characteristics of the sinks (Sawaly et al., 2022; Ghiat et al., 2021; IEA, 2018; Mohammed, 2016).

Sink	Process/ product	Emission Rate	Production Rate	CO <sub>2</sub> Capacity	Distance from source
Unit	-	Tonne CO <sub>2</sub> out/tonne CO <sub>2</sub> feed	Tonne of product/tonne of CO <sub>2</sub>	Million tonne/year	Kilometre
QAFAC H <sub>2</sub>	Methanol from H <sub>2</sub>	0.02	5.9	1.83	100
QAFAC NG	Methanol from NG	2.09	3	0.60	100
QAFCO	Urea	0.23	1.35	1.01	100
Pearl GTL	ATR-GTL-Wax	2.33	0.884	2.19	5

Dukhan Field	EOR	0	0.2	15.6	111
AlShaheen Field	EOR	0	0.32	13.9	80

## 2.2 Model Formulation

$$\text{Maximise } \sum_{i=1}^7 \sum_{j=1}^5 x_{ij} [P_{ij} PR_{ij} Q - C_{operating,ij}] \quad (2)$$

$$\text{Minimise } \sum_{i=1}^7 \sum_{j=1}^5 x_{ij} Q ER_i \quad (3)$$

Subject to

$$\sum_{i=1}^7 \sum_{j=1}^5 x_{ij} Q PR_i \leq C_{Pij} \quad (4)$$

$$\sum_{i=1}^7 x_{ij} = 1 \quad (5)$$

$$\text{Where; } C_{operating,ij} = \sum_{i=1}^7 \sum_{j=1}^5 (C_{transport} + C_{pcc} + C_{OPEX}) \quad (6)$$

$$C_{transport} = Q x_{ij} \times \left( \frac{D_i}{100} \right) \times 1.5 \quad (7)$$

$C_{operating,ij}$  = Cost for pcc, transport, OPEX of sink i for year j

$C_{p,ij}$  = Capacity of sink i for year j

$Q$  = Carbon Captured from source (tonne/year)

$x_{ij}$  = Fractional amount allocated to sink i for year j

$PR_{ij}$  = Production Rate of sink i for year j as a function of carbon feed

$ER_{ij}$  = Emission Rate of sink i for year j as a function of carbon feed

$P_{ij}$  = Product price of industry/sink i for year j

$D_i$  = Distance from the source to sink i

## 3 Results and Discussion

The proposed methodology is used to implement the model's outcomes using the Excel solver for scenario 1 and scenario 2, and MATLAB for scenario 3. **Scenario 1** aims to

determine the optimal solution for allocating 25x10<sup>6</sup> tonne/year of CO<sub>2</sub> to all 7 sinks with an objective to maximise the profit of the overall system. According to the findings, the market prices of the products and production rate are the key drivers of the techno-economic optimisation. The total annual profits for all sinks ranged from 8.1 to 14.6 billion USD and the total profit of the overall system throughout the specified time period is 55 billion USD. The annual amount of CO<sub>2</sub> emitted by the sinks is 10.1 million tonnes CO<sub>2</sub>/year and the total emissions of the overall system throughout the specified time period is 50.7 million tonnes CO<sub>2</sub>. Figure 1 represents the allocation across the sinks, with QAFACO, QAFAC H<sub>2</sub>, QAFAC NG, Pearl GTL, and Oryx GTL being fully satisfied due to their higher commodity prices and smaller CO<sub>2</sub> capacity in comparison to Dukhan field well and Alshaheen field, which use CO<sub>2</sub> for enhanced oil recovery. Alshaheen field has a larger share of CO<sub>2</sub> allocation than Dukhan field, which is due to Alshaheen field's higher production rate and consequently generates more profit. The total CO<sub>2</sub> utilisation of the system is 25x10<sup>6</sup> tonne/year, which implies that the captured amount of CO<sub>2</sub> from Qatar Gas (25MT/year) is fully utilised by the sinks. The allocation ratio throughout the years is relatively in the same range for all years between 2014 and 2018.

This is due to the price linkage between products, which causes them to shift together. In **Scenario 2**, the goal is to find the best way to allocate 25x10<sup>6</sup> tonnes of CO<sub>2</sub> per year among the seven sinks with the least amount of emissions possible for the overall network. The allocation's primary factor, as indicated by the results, was each sink's emission rate. During enhanced oil recovery, the majority of the CO<sub>2</sub> that is injected stays there trapped in the geological formation, causing little to no emissions of CO<sub>2</sub>. Therefore, the allocation will shift toward the sink with the lowest emissions rate in the case of emission reduction. The captured CO<sub>2</sub> was allocated equally to Dukhan Field and Alshaheen field (figure 2) since their process generates zero emissions. The total annual profits for all sinks ranged from 1.43 to 5.09 billion USD and the total profit of the overall system throughout the specified time period is 14.6 billion USD.

**Scenario 3** was generated using MATLAB for finding a set of solutions that define the best trade-off between the competing objectives. The model generated 70 different Pareto optimal solutions (figure 4), however, most of the solutions favored EOR sinks (both, Dukhan Field and AlShaheen Field), which is because they generate zero emissions, and got higher CO<sub>2</sub> capacity allowing for more profit as well regardless of the fact that they both have the lowest production rate. Furthermore, following the EOR sinks, QAFAC H<sub>2</sub> obtained the highest allocation percentage due to its high production rate and minimal CO<sub>2</sub> emissions. Out of the 70 solutions that were developed, the one with the highest profit had a GWP of 4.5 MT CO<sub>2</sub>e and a profit of 22.6 billion USD. The solution that achieved the lowest GWP had a profit of 15 billion USD and zero GWP (zero emissions). The mean solution had a profit of 20 billion USD and a GWP of 2 MT CO<sub>2</sub>-eq. Figure 3 illustrates the CO<sub>2</sub> allocation for the mean solution.

Figure 1: CO<sub>2</sub> Allocation of Scenario 1.

Figure 2: CO<sub>2</sub> Allocation of Scenario 2.

Figure 4: Pareto Front.

Figure 3: CO<sub>2</sub> Allocation of Scenario 3.

Figure 5 compares the total CO<sub>2</sub> emissions and total profit of scenario 1 and 2 with the mean solution of scenario 3. Scenario 2 witnessed a huge decrease in the profit and CO<sub>2</sub> emission compared to scenario 1; where CO<sub>2</sub> emissions were reduced by 100% and the profit was decreased by around 73%. Scenario 3 on the other hand aims to satisfy both objectives simultaneously. Therefore, CO<sub>2</sub> emissions are reduced significantly from 50.7 million tonnes CO<sub>2</sub> (scenario 1) to 2 million tonnes CO<sub>2</sub> (scenario 3), while the profit fell sharply from 55 billion USD to 20 billion USD for scenarios 1 and 3 respectively. When comparing scenario 2 and 3, the total profit increased slightly from 14.6 billion USD (scenario 2) to 20 billion USD (scenario 3). The total GWP through the lifecycle of LNG in Qatar Gas was 0.46 tonne CO<sub>2</sub>e/tonne of LNG produced. This ratio has been enhanced through this model and reduced to 0.14 (70% cut of emissions) through CO<sub>2</sub> capture and allocation by substitution approach.

Figure 5: Comparison between scenario 1,2 and 3.

#### 4 Conclusion

The findings of this study aim to provide the most efficient strategies for producing low carbon LNG within a CO<sub>2</sub> utilisation network in the state Qatar by converting carbon dioxide emissions into value added products. The model considers a single CO<sub>2</sub> source (Qatar Gas) and 7 sinks. Furthermore, the optimal CO<sub>2</sub> allocation based on environmental and economic objectives is addressed using a linear programming (LP) model where 3 scenarios were generated. Scenario 1 aimed to maximise the overall profit of the system and had a value of 55 billion USD; whereas scenario 2 aimed to minimise the CO<sub>2</sub> emissions which reached to zero emissions. Scenario 3 generated a profit of 20 billion USD and 2 million CO<sub>2</sub> emissions overall. According to the results of using allocation by substitution, only 0.14 tonne CO<sub>2</sub>e/tonne LNG is emitted whereas 0.32 tonne CO<sub>2</sub>e/tonne LNG is captured and utilised by the sinks. The lack of actual selling market price and plant data for each of the products studied between 2014 and 2018 are some of the

limitations of this study. Also, the production rate is calculated based on assumptions derived from literature that may or may not represent real operating data for the relevant time period. Future work would include: 1) implementation of carbon tax to the model, which can have an effect on both the environmental and economic objective; 2) capture a larger amount of CO<sub>2</sub> from Qatar Gas (85% and 100%).

## Abstract

The hydrodeoxygenation (HDO) of 5-hydroxymethylfurfural (HMF) is an essential step in lignocellulosic biomass conversion. In this work, we developed process flowsheet simulation models using the hydrodeoxygenation experimental conditions, yields, and separation requirements. Economic and environmental evaluations are then performed and incorporated with Bayesian optimization to search for reaction conditions that minimize production costs and greenhouse gas emissions. The Bayesian optimization demonstrates that the HDO reaction condition with the lowest production cost has a relatively high reaction temperature, no water content, high H<sub>2</sub> pressure, medium HMF loading, and short reaction time. However, the HDO condition with the lowest greenhouse gas emission has a lower temperature but a longer reaction time.

**Keywords:** Bayesian optimization, 5-Hydroxymethylfurfural, Techno-economic analysis, Life cycle assessment.

## 1. Introduction

5-Hydroxymethylfurfural has been established as a promising platform chemical from lignocellulosic biorefinery after hexose dehydration [Bozell and Petersen, 2010]. HMF typically further undergoes hydrodeoxygenation to produce the 2,5-dimethylfuran (DMF) intermediate for the downstream production of other renewable chemicals [Luo and Ierapetritou, 2020]. Over the Ru/C catalyst, HMF is first hydrogenated to 2,5-bishydroxymethylfuran (BHMF), whose alcohol group undergoes hydrogenolysis to produce DMF with the hydrogen produced from the dehydrogenation of a secondary alcohol as the solvent. The furans also undergo etherification, which slowly convert to DMF [Jae *et al.*, 2014]. Water inevitably exists in the feed and process streams as a component of biomass or a byproduct of dehydration and HDO reactions [Esteban *et al.*, 2020]. For instance, in the upstream HMF production (fructose dehydration), many water-organic biphasic systems are developed to prevent rehydration or condensation side reactions [Wang *et al.*, 2020]. As water is partially soluble in the organic phase, the HMF product stream could contain a significant amount of water. The presence of water is observed to impact the ether-alcohol-furan equilibrium and affects the reaction rate. However, removing water from intermediate streams may be energy-intensive and

expensive due to the high heat of vaporization. Therefore, it is important to study the trade-off of the water effects based on process simulation.

Bayesian optimization is an effective active-learning method that combines building the surrogate model and proposing the next experiment/simulation points [Wang and Dowling, 2022]. It thus provides an efficient solution for various practical optimization tasks involving time-consuming computation or experiments, which expedites the discovery of optimal reaction conditions and new materials [Iwama and Kaneko, 2021]. For instance, Diwale *et al.* applied Bayesian optimization under noise to reduce the time spent on computationally expensive non-equilibrium molecular dynamics simulations for the search of additives in polyethylene nucleation. Bayesian optimization also finds its application in the model predictive control parameter tuning [Lu *et al.*, 2021].

In this work, we first built HMF conversion and DMF yield surrogate models as a function of reaction temperature, time, H<sub>2</sub> pressure, HMF loading, and water content using the adaptive design of HDO experiments based on Bayesian optimization. Next, Aspen Plus process flowsheets are simulated using the reaction yields/conversion and appropriate separation process design, which provided information for the techno-economic analysis (TEA) and life cycle assessment (LCA). Next, Bayesian optimization is applied again to search optimal reaction conditions that perform the HDO reaction with the lowest DMF minimum selling price (MSP) and global warming potential (GWP). The results also revealed the effects of water content and reaction conditions on the overall HDO process economics and environmental impacts.

## 2. HMF Hydrodeoxygenation Flowsheet Design and Analysis

First, the NEXTorch (Next EXperiment toolkit in PyTorch) python package was utilized to build accurate HMF conversion and DMF yield surrogate models from the preliminary bench-top HDO reaction experiments *via* Gaussian processes, which ensures the exploration of the design space while exploiting the current best conditions [Wang *et al.*, 2021]. In this case, a multi-variable (reaction temperature, time, H<sub>2</sub> pressure, HMF loading, and water content) ordinary least squares (OLS) regression demonstrated satisfactory fitting performance for DMF yield and HMF conversion. This OLS model was used in section 3 for the process design in each step of the Bayesian optimization.

Process flowsheets are then simulated in Aspen Plus V11 for 29 initial HDO reaction conditions and their corresponding yields/conversions. These conditions affect not only the reaction outcome but also the separation process. The universal quasi-chemical activity coefficient (UNIQUAC) model was chosen for the liquid-vapor and liquid-liquid phase behavior [Abrams and Prausnitz, 1975]. Four different flowsheet configurations are developed for various pentanol/water azeotrope and feedstock compositions of the HDO processes. Figure 1 illustrates the process flowsheet when no water exists in the reaction inlet. Hydrogen gas and HMF solution in pentanol were pressurized and heated to the reaction condition before sending to R-1. After the HDO reaction, flash drum F-1 cooled down the system to 65 °C and recycled hydrogen gas. Then, humins were removed by filtration. It was assumed that most of the liquid phase was retained with a 1% loss in the waste humins stream. The liquid stream was sent to two distillation columns in series (C-1 and C-2) to recycle pentanol and obtain a DMF/water stream. Two decanters cooled down both the bottom (D-1) and distillate streams (D-2) to 40 °C, so that excess water was removed by phase separations. The process capacity was chosen as 10,000 kg HMF/h, which was in line with the scale considered in a recent paper that produced HMF

as an intermediate [Chang *et al.*, 2020]. It is noteworthy that separating the targeted DMF product from water/pentanol azeotrope is not always easy in the other flowsheets, as they have very close boiling points.

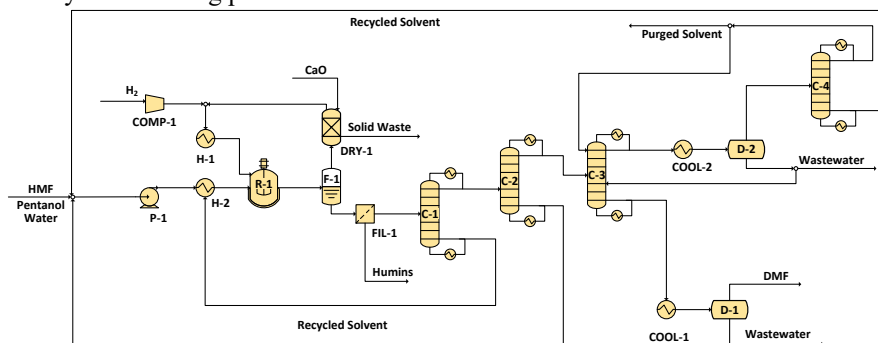

Figure 1: Hydrodeoxygenation process flowsheet without water in the feed

### 3. Bayesian Optimization

Bayesian optimization on the reaction conditions (i.e., water content, HMF loading, temperature, pressure, and reaction time) is conducted through iterative optimal search via NEXTorCh and flowsheet simulation/evaluation. The NEXTorCh package utilizes the Gaussian process surrogate model with the Matern covariance function kernel. In each Bayesian optimization iteration, new reaction condition samples are suggested based on the Monte Carlo  $q$ -expected improvement (qEI) acquisition function of the Gaussian process. The expected improvement acquisition function has the ability to effectively leverage exploration and exploitation aspects of searching [De Ath *et al.*, 2021]. The Monte Carlo sampling approach shown in Eq.(1) further reduces the computational complexity by approximating the integral over posterior distribution [Snoek *et al.*, 2012].

$$qEI(X) = \frac{1}{N} \sum_{i=1}^N \max_{j=1, \dots, q} \{\max(\xi_{ij} - f^*, \mathbf{0})\}, \quad \xi_{ij} \sim \mathbb{P}(f(X) | D) \quad (1)$$

where  $X = (x_1, \dots, x_q)$ , representing the reaction conditions (e.g., temperature, pressure, reaction time, water, and HMF loading),  $q$  is the number of points considered jointly,  $f^*$  is the best value observed so far, and  $\mathbb{P}(f(X) | D)$  is the posterior distribution of the function  $f$  (e.g., MSP or GWP) at  $X$  given the observed data  $D = (X, f)$ . Individual flowsheets are developed based on these trial points, whose economic and environmental performance is evaluated and added to observed data for the next iteration.

## 4. Results and Discussions

### 4.1. Bayesian Optimization of Minimum Selling Prices (MSP)

Techno-economic analysis (TEA) was performed to calculate each case's MSP, the selling price of the product when the net present value is zero at the end of the recovery period, was determined through discounted cash flow analysis for each condition [Athaley *et al.*, 2019]. A 15% internal rate of return (ROR) on investment and a 35% corporate tax was assumed. The straight-line method for depreciation with a 10% salvage value after 20 years was applied [Luo *et al.*, 2022]. The raw material, solvent, and catalyst prices are based on Athaley *et al.* (2019). For instance, the HMF price is taken as \$0.88/kg, and the pentanol cost is assumed to be \$1.5/kg. As illustrated in Figure 2, the best DMF MSP gradually decreases as the iterations of Bayesian optimization continue, reducing from \$5,420/t to \$4,022/t. In all cases, the HMF feedstock is the leading cost

contributor. Hence, the MSP of DMF decreases significantly when the DMF yield increases and less humins byproduct is generated. This is typically the case with little or no water loading, which has high DMF selectivity. However, when the water content increased from 0% to 4% in the feedstock, the MSP only increased by \$ 312/t.

Figure 2: Discovery plot of DMF's MSP

On the one hand, high solvent usage leads to much larger equipment sizes and more solvent loss during filtration. On the other hand, reaction conversion and selectivity generally drop as a result of lower solvent usage. Hence, medium HMF concentration at 3 wt. % was favored by Bayesian optimization as a trade-off between these two effects.

#### 4.2. Bayesian Optimization of GWP

Next, a “cradle-to-gate” LCA was performed to evaluate the environmental impacts by including the upstream activities of raw material extraction (e.g., HMF), utility generation, and the production stages. The functional unit was chosen as 1 kg of DMF produced, and the GWP was selected as the environmental impact of interest as it bears great importance in renewable technology development and policy making. The Ecoinvent v3.7 database was used to provide the background emission data, and the Tool for the Reduction and Assessment of Chemical and other environmental Impacts (TRACI) method was used for the impact assessment [Bare, 2011]. The trajectory of GWP under each explored reaction condition is demonstrated in Figure 3. During these Bayesian optimization runs, the lowest GWP was found to be 22.5 kg CO<sub>2</sub> eq/kg DMF, while the best GWP from the initial 29 experiments was 26.5 kg CO<sub>2</sub> eq/kg DMF.

Figure 3: Discovery plot of DMF's GWP

Similar to the improvement trend in the MSP case, the GWP of each process generally matches the increase of HMF conversion and DMF selectivity. Medium HMF loading, high hydrogen gas pressure, and zero water content are still favored. However, as with

other biomass-based chemical production processes, the utility cost only takes up a small fraction of the total MSP while it plays a vital role in the GWP. Based on the conversion and selectivity model, higher temperatures correspond with better yields at fixed water content, HMF loading, and reaction time. Nevertheless, a higher reaction temperature also means more hot utilities to heat up the feedstock and solvent before the reaction. Thus, the optimal temperature for the lowest GWP case (199 °C) is lower than that of the lowest MSP case (210 °C). Other contributors to utility usage include the steam required for distillation and electricity used in the compressor.

Although longer reaction time causes larger reactor sizes and higher capital investment, it has little impact on environmental performance. Thus, the lowest GWP case has increased the reaction time from 3 h to 4.3 h at a lower temperature to improve the HMF conversion without worrying about more expensive equipment. It should be noted that non-zero water content in the feedstock inlet causes a drastic increase in the GWP. The process with 4% inlet water content now has a GWP of 31.1 kg CO<sub>2</sub> eq/kg DMF, which is 38.4% higher than the lowest GWP without any water loading. This is the result of high utility usage during the product separation, as the azeotrope compositions significantly affect the distillation operating conditions. A summary of optimal reaction conditions for the MSP and GWP Bayesian optimization is listed in Table 1.

Table 1: Optimal reaction conditions suggested by MSP and GWP Bayesian optimization

Reaction Conditions	minimum MSP	minimum MSP (with H <sub>2</sub> O)	minimum GWP	maximum DMF yield*
Temperature (°C)	210	208	199	195
H <sub>2</sub> pressure (bar)	10	10	10	10
Water loading (wt. %)	0	4	0	0
HMF loading (wt. %)	3	3	3	1
Time (h)	3	3	4.3	4.6

\* “max DMF yield” is based on the best condition in the initial design of experiment

As illustrated in Table 1, the reaction conditions with the lowest cost and emission are close to the maximum DMF yield condition observed in bench-top experiments. Nevertheless, Bayesian optimization incorporates process design insights to select higher HMF loadings and shorter reaction times that would be otherwise not explored.

## 5. Conclusions

The current work incorporated process simulation, TEA, and LCA into the Bayesian optimization to determine economically and environmentally viable HDO reaction conditions in the early stage. The Bayesian optimization results illustrate that the reaction conditions that minimize the production cost have low water contents, medium HMF loadings, high H<sub>2</sub> pressure, and relatively high reaction temperatures because of low HMF feedstock usage and low solvent loss. The HDO reaction with the minimal GWP chooses a lower reaction temperature but longer reaction time to reduce the emissions associated with utility usage. Moreover, the existence of water has more significant impacts on the process’s GWP than on its production cost. The integrated TEA, LCA, and Bayesian optimization provide candidate HDO conditions and process parameters to explore. However, detailed analysis and validation should be carried out after future scale-up experiments and process improvement. Furthermore, as feedstock and solvent usage are the main contributors to the cost and emissions, more efficient upstream HMF production and effective filtration technologies have great potential to further improve the HMF HDO process.

## Abstract

Due to the rapid growth of population, urbanization and economic development, global municipal waste generation is expected to increase by nearly 70% to 3.4 billion tonnes by 2050. The mismanagement of these wastes results in the deterioration of soil, air, and water quality, causing serious health problems. As such, investigating waste valorization routes becomes more essential to alleviate the concerns associated with the burden of wastes. In this study, 10 different types of biomass used to produce biochar through pyrolysis were investigated; namely camel manure (CM), date pits (DP), sewage sludge (SS), coffee waste (CW), cattle manure (CM), poultry litter (PL), cabbage waste (CB), cucumber waste (CU), tomato waste (TM), and carrot waste (CR). Techno-economic and environmental analyses were performed from “cradle to grave”, covering the key biochar production stages from acquisition of biomass, transportation, plant's construction, pre-processing, pyrolysis, and lastly the end-use of biochar as soil enhancer. The cost and emissions savings using biochar as an alternative to commercial fertilizers were evaluated for the different biomass scenarios. Finally, an optimization model was developed to select the optimal biomass blending ratio for two scenarios to maximize the savings, which was then solved using MATLAB. The findings of this study indicated that the optimal biomass blend for maximizing cost, energy and emissions savings shall consist of the following proportions: 50% TM, 14-15% CW and PL, 5 – 10% CM and CU, 2.5% CT, 1.8-1.9% CB and DP, 1.2% CR and 0 – 0.6% SS. Future studies may involve more types of biomasses, additional optimization objectives, and may target multiple biochar's end-use applications.

**Keywords:** Pyrolysis; Biochar; Soil enhancement; Biomass.

## 1. Introduction

Global municipal solid waste generation is expected to increase from 6.94 million metric tonnes in 2021 to 3.4 billion metric tonnes in 2050 due to the rapid population growth and urbanization (NEA, 2016; Tiseo, 2021). This has accelerated the need to establish new waste-to-energy technologies including pyrolysis. Pyrolysis is a thermochemical process that works on converting biomass, which is a carbon based renewable organic material generated from animals and plants into value added products in the absence of oxygen to produce; biogas, bio-oil and biochar (BC) (Elkhalifa et al., 2019). BC is an incredibly rich source of carbon that can be employed in various disciplines to address the most significant environmental challenges as follows; (1) can be employed as a renewable energy source, (2) can be employed as a soil enhancer reducing the chemical fertilizers requirements, and (3) can be utilized as an innovative adsorbent for water and wastewater decontamination (Haider et al., 2022).

This study focused on biochar's end-use as a soil enhancer as it increases the crop yield, enhances the water retention of soil due to its porous structure, and sequesters carbon in

the soil by absorbing it from the atmosphere to mitigate climate change (Mukherjee & Lal, 2013). Moreover, this study investigates the optimal biomass blends based on 10 different types of biomass feedstocks including; camel manure (CM), date pits (DP), sewage sludge (SS), coffee waste (CW), cattle manure (CT), poultry litter (PL), cabbage waste (CB), cucumber waste (CU), tomato waste (TM), and carrot waste (CR). The aim of this investigation is to target three objectives; maximize cost, energy and carbon emissions savings.

## 2. Methodology

The methodology of this study follows two main steps, which are the data collection from literature, and formulating the equations that measure the savings that can be used for optimizing the biomass blends using the genetic algorithm tool in MATLAB. The process flow diagram is shown in figure 1.

**Figure 1:** Process flow diagram

### 2.1 Data Collection

The production of biochar from the different biomass feedstocks has been simulated using Aspen. This model has been used to evaluate the cost, carbon and energy footprint when producing biochar from each single biomass. The operating parameters of the process have included an operating temperature of 300°C, 5L/min.tonne nitrogen flowrate, 90% drying efficiency and 30 minutes' reaction time. The elemental analysis for the biomass feedstocks was collected from literature as presented in Table 1, whereas this model requires the analysis to be on a dry ash and sulfur-free basis. The price of date pits was quoted locally at 100\$/t. While the prices of the other biomass feedstocks were obtained from literature and was found to be 15\$/t sewage sludge, 88\$/t coffee waste, 25\$/t for all types of animal manure and 10\$/t for vegetable waste (Alherbawi et al., 2021; Kamil et al., 2019; Marufuzzaman et al., 2015; Yun et al., 2018).

**Table 1:** Elemental analysis of biomass feedstock.

Biomass	%C	%H	%O	%N	%S	Ash (%)	Moisture (%)	Ref.
CM	36.7	5.6	34.7	2.6	0.4	19.9	4.3	(Al-Ansari et al., 2020)
DP	46.5	6.5	44.7	0.9	0	1.4	0.3	
SS	46.9	6.8	23.2	7.4	0.5	2.6	82.2	(Poudel et al., 2015)
CW	79.3	5.0	12.5	2.1	1.1	11.1	4.2	(Uwaoma et al., 2021)
CT	41.1	5.9	49.9	2.7	0.4	15.4	10.1	(Yuan et al., 2017)
PL	42.9	5.6	33.4	5.5	0.7	12	18.1	(Tańczuk et al., 2019)
CB	44.5	4.9	35.0	2.3	0.5	11.9	8.6	(Zhang et al., 2022)
CU	56.7	6.5	32.9	3.9	0	1.9	8.1	
TM	49.7	7.4	39.3	3.7	0	4.4	10.0	(Elkhalifa et al., 2022)
CR	41.5	5.4	51.7	1.4	0	5.2	6.6	

A comprehensive comparison has been made between the application of NPK fertilizer and biochar as a soil amendment to evaluate the cost, energy and emissions for each. The model has only estimated the cost, energy and carbon footprint of BC production from each single biomass, whilst the rest of the data relative to BC and NPK application to soil and NPK fertilizer production was obtained from literature. It was found that 0.05 kg/m<sup>2</sup> of NPK fertilizer is required to grow tomato, which was selected as the reference crop for this comparison (Ziane et al., 2021). The production of NPK fertilizer costs 0.8\$/kg, requires energy of 12.45 MJ/kg and emits 0.20 kgCO<sub>2-eq</sub>/kg (Majumder et al., 2019; Samoraj et al., 2022; Wu et al., 2021). Energy and carbon emissions for BC application were found to be equal to 0.434 MJ/m<sup>2</sup> and 0.024 kgCO<sub>2-eq</sub>/m<sup>2</sup>, which are lower than the values of NPK fertilizer application which are 0.615 MJ/m<sup>2</sup> and 0.069 kgCO<sub>2-eq</sub>/m<sup>2</sup> (Brentrup & Palliere, 2008; Jiang et al., 2021).

### 2.2 Problem Formulation

The data collected was inserted in equations 1-3 to find the cost, energy and carbon emissions when utilizing NPK fertilizer and BC, where *X* refers to the percentage of NPK fertilizer being used, *k* refers to the conversion factor between NPK fertilizer and BC, *P* and *A* represent production and application.

$$Cost = (X \cdot NPK_{required} \cdot cost_{NPK-P}) + (k \cdot (1 - X) \cdot NPK_{required} \cdot cost_{BC-P}) \quad (1)$$

$$Energy = X \cdot (NPK_{required} \cdot energy_{NPK-P} + energy_{NPK-A}) + k \cdot (1 - X) \cdot (NPK_{required} \cdot energy_{BC-P} + energy_{BC-A}) \quad (2)$$

$$GWP = X \cdot (NPK_{required} \cdot GWP_{NPK-P} + GWP_{NPK-A}) + k \cdot (1 - X) \cdot (NPK_{required} \cdot GWP_{BC-P} + GWP_{BC-A}) \quad (3)$$

The values were later used to find the savings using equations 4-6:

$$Cost_{savings} = Cost_{NPK} - Cost_{BC} \quad (4)$$

$$Energy_{savings} = Energy_{NPK} - Energy_{BC} \quad (5)$$

$$GWP_{savings} = GWP_{NPK} - GWP_{BC} \quad (6)$$

Based on the savings' results from the previous section, a multi-objective mathematical optimization is performed using genetic algorithm tool within MATLAB. The objectives targeted by this optimization are; maximizing cost, energy and carbon emissions savings, where the mathematical formulation of the multi-objective optimization problem is represented by equations 7-9, and the constraint adopted is shown in equation 10.

$$\text{Maximize cost savings: } \sum_{i=1}^{10} B_i C_i \quad (7)$$

$$\text{Maximize energy savings: } \sum_{i=1}^{10} B_i E_i \quad (8)$$

$$\text{Maximize emission savings: } \sum_{i=1}^{10} B_i G_i \quad (9)$$

$$\text{Constraint: } \sum_{i=1}^{10} B_i = 1 \quad (10)$$

The multi-objective optimization was conducted based on two scenarios as shown in Table 2 to provide broader insight for decision-makers.

**Table 2:** Objectives to be obtained in each scenario.

Scenario	Objectives obtained
1	Maximize cost and emissions savings

### 3. Results and Discussion

70 solutions were obtained fulfilling the objectives for each scenario by performing a trade-off between the desired objectives using the genetic algorithm tool in MATLAB. The results of the scenarios are as follows:

#### 3.1 Scenario 1

This scenario aimed to achieve the maximum cost and emissions savings. The findings as illustrated in figure 2 show that all solutions lean more towards achieving higher emissions savings and focused less on the cost savings. Moreover, the solutions show that the most optimal biomass blends consisted of very high proportions of poultry litter, and lower proportions of the other biomass feedstocks except the camel manure that had zero contribution in achieving the objectives. Some optimal blends consisted of around 80% PL, 1.7-4% of CU, TM, SS, CW and CT, 0.2-1% DP, CB and CR, and 0% CM.

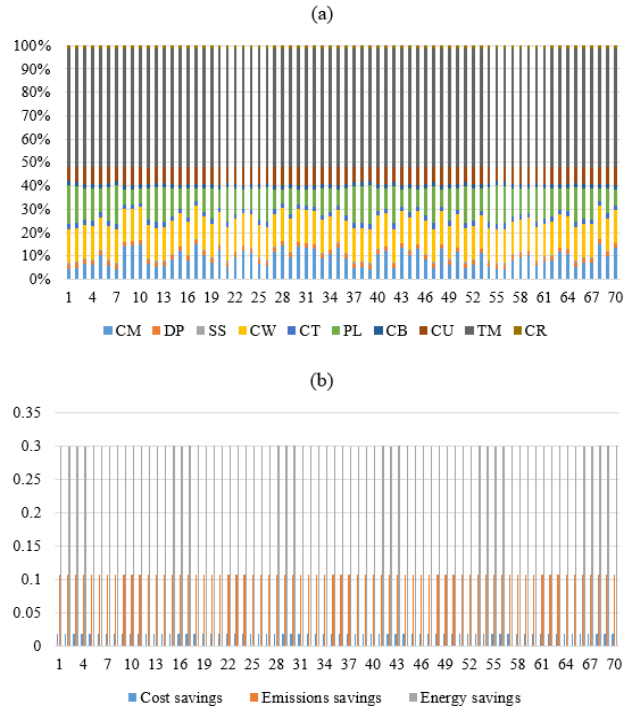

**Figure 2:** Scenario 1 – maximum cost and emission savings: (a) optimal biomass blends, and (b) optimal savings.

#### 3.2 Scenario 2

This scenario was concerned with achieving three objectives; maximize energy, cost and emissions savings and to find the optimal biomass blends that fulfill these objectives. The results as illustrated in figure 3 show that all solutions have contributed mostly to achieving maximum energy savings, then maximizing emissions and cost, respectively.

For optimizing the biomass blends, most of the results show that the optimal blend consisted of around 50% TM, 14-15% CW and PL, 5 – 10% CM and CU, 2.5% CT, 1.8-1.9% CB and DP, 1.2% CR and 0 – 0.6% SS.

**Figure 3:** Scenario 2 – maximum cost, energy and emission savings: (a) optimal biomass blends, and (b) optimal savings.

#### 4. Conclusion

Pyrolysis is a thermochemical process that converts biomass into value-added products, mainly biochar. This carbon-rich product has widely contributed into a diversity of applications including soil enhancement applications.

This study has provided insight into the sustainable solutions for researchers and decision-makers on selecting the most optimal biomass blends for biochar production from an economic and environment perspective. Two scenarios have been studied where each aimed to achieve specific objectives. Scenario 1 focused on maximizing cost and emissions only, where most solutions showed that the most optimal biomass blends consisted of very high proportions of poultry litter, lower proportions of the other biomass feedstocks, and no contribution of camel manure. On the other hand, the results of scenario 2 that aimed to achieve all three objectives, have shown that the most optimal biomass blends have consisted of very high proportions of tomato waste, less proportions of the others, and around 0% of sewage sludge. Future studies may involve more types of biomasses, additional optimization objectives, and may target multiple biochar's end-use applications.

# Methodology for estimating a country's production of biomethane from agricultural residues: a multiscale and holistic approach

Manuel Taifouris, Mariano Martin

*<sup>a</sup>Salamanca, Department of Chemical Engineering, University of Salamanca, Plza. Caidos 1-5, 37008 Salamanca, Spain*

## Abstract

Dependence on fossil fuels and recent issues on the supply chain from major natural gas providers have highlighted the importance of energy security in the countries of the European Union. This work presents a multi-scale analysis to evaluate the implementation of the circular economy to reduce the region's dependence on fossil natural gas. For this purpose, a techno-economic analysis of technologies (gasification and anaerobic digestion), size, and location of the waste treatment facilities is performed, followed by a facility location problem. This analysis is applied to a case study in Spain, concluding that an investment of 9458M€ and an operating cost of 5000M€ per year are necessary to cover 35% of the natural gas demanded. Up to 19 provinces are totally independent with this investment, favoring the creation of decentralized networks of natural gas, which is a strong incentive to invest in waste management because of the social and economic importance of natural gas as an energy source.

**Keywords:** Agricultural residues, Sustainable process design, Energy, Circular economy

## 1. Introduction

Despite the implementation of decarbonization policies in European countries, the current dependence on fossil fuels together with the centralization of their production in a reduced number of countries put the energy security of most European countries at risk (Mišik, 2022). In addition, the increase in the world's population has led to the intensification of crop, meat, and milk production processes, creating areas of high waste generation. These areas can suffer from nutrient pollution, which can lead to the eutrophication of water bodies and soil deterioration. In addition, municipal solid waste (MSW) and sewage sludge also represent an issue when cities are densely populated and waste is treated inefficiently so in most cases, ending up in landfills or incinerated (European Commission, 2021). The implantation of a circular economy for waste can solve both problems, by using waste management technologies, such as anaerobic digestion and gasification. Studies that analyze the biomethane production potential of a country are especially useful for determining where biomethane production plants should be placed, as well as determining which regions can be energy-independent (Wang et al., 2018). However, these studies directly relate the biomethane production potential to the number of animals, crops, or people, through the empirical yields. This approach decouples the estimation of biomethane (composition and amount) from the processing technology, as well as from the type and composition of waste. On the one hand, the waste composition can be highly variable, even for the same species of animal (Council, 2000). On the other hand, the composition of the waste affects both the design of the treatment equipment and the amount and composition of the biomethane produced, and therefore, the economic and environmental evaluation of its valorization. A multi-scale approach allows for addressing the different scales of the waste management system (Floudas et al., 2016),

from waste characterization and process design to treatment capacity and facility location. By analyzing all scales simultaneously, a better estimate of the biomethane production potential of a location can be determined, as well as the economic and environmental cost of the development and implementation of the process. This allows optimizing the selection of the location, the treatment process, and the type of waste. It also facilitates energy integration between the different stages of the process. This work presents a multiscale study, which uses an optimization framework, to design waste treatment plants (size and type of waste treated), select the best location, and estimate the investment and operating costs. The total amount of biomethane and its cost are also calculated. This framework is applied to the case study of Spain, where the management budget is the main optimization variable. The optimization framework aims at maximizing biomethane production and minimizing production costs.

## **2. Framework development**

This section presents the optimization framework, which addresses waste production characterization (amount and composition), the modeling of processing technologies, the scale-up/down of the facilities, and the selection of the location.

### 2.1-Estimation of the production and composition of waste

Two types of waste are considered in this work, dry waste (lignocellulosic residue) and wet waste (manure, MSW, and sludge). Lignocellulosic residues of a region are estimated from the annual production of crops and the amount of residue grown by the type of crop. Manure is calculated from the amount of waste generated based on the age and the number of animals. The production of MSW and sludge are obtained through the annual production per capita (388 kg of MSW and 105 kg of sludge) and the population. The composition of the residues is obtained from the literature. Nevertheless, it is possible to perform studies for specific residues to increase the accuracy of the estimates.

### 2.2-Process analysis and design

A techno-economic analysis is proposed to analyze and compare gasification and anaerobic digestion as possible technologies to produce biomethane from agro-industrial wastes. In addition, a scale-up study is performed for each waste and for 50 different treatment capacities. Non-linear programming (NLP) is used to optimize each design and reduce the cost of methane production.

An indirect gasification process, which consists of a combination of a gasifier and a furnace, is used for the treatment of dry waste. Both gasification and biomethane purification are modeled following first principles, such as mass and energy balances, empirical yields and correlations, and thermodynamic equilibria. The heat necessary for the gasification process is supplied by the combustion of the char formed in that same gasification when the steady-state regime is reached. Olivine is used as heat transfer media (HTM) to transmit the thermal energy generated in the combustion process to the gasifier. Therefore, the system is energetically self-sustainable. The total combustion of all compounds in the furnace is considered to perform the mass and energy balances. The composition of the syngas is estimated from the gasification temperature (Phillips et al., 2007). Regarding the syngas purification stage, empirical yields are used to estimate the separation efficiency of char, olivine, and ash in the cyclones (99%) and electrostatic precipitators (99%), as well as in the adsorbed amount of H<sub>2</sub>S in the ZnO beds (100%). The hydrocarbon reforming process, the water gas shift reactor, and the methanation

reactor are modeled by using equilibrium constants (Sánchez et al., 2019). Finally, the PSA system is used to reduce the amount of CO<sub>2</sub> down to 2% and remove NH<sub>3</sub> and H<sub>2</sub>O. This system is modeled by empirical yields (León & Martín, 2016). An anaerobic digestion system is designed for the treatment of wet waste. The composition and amount of biogas are estimated from the carbohydrate, lipid, and protein composition of the waste, stoichiometric ratios, and biodegradability (Taifouris & Martín, 2018). The distribution of the gases between the liquid and gas phases is modeled from thermodynamic equilibria. The biogas purification phase consists of an iron bed to remove H<sub>2</sub>S (100%) and a PSA system to reduce the content of CO<sub>2</sub> down to 2% and remove NH<sub>3</sub> and H<sub>2</sub>O. Both systems are modeled from adsorption yields.

The gasification and anaerobic digestion systems are scaled up/down from a minimum to a maximum size of treatment capacity. The minimum corresponds to the minimum amount of waste generated per region, considering all available regions simultaneously, while the maximum can be established by the literature (anaerobic digestion) or by the maximum availability of waste per region (gasification). Up to 50 designs with different capacities for each waste and for each technology are considered. For each design, a techno-economic evaluation is carried out to determine the operating expenses (OPEX) and the capital expenses (CAPEX) following the procedures described in the literature (Sinnott, 2005) and the results of the modeling of the processes.

### 2.3-Facility location problem

A facility location problem is formulated including surrogate models for the facilities (yields, CAPEX, OPEX as a function of their size). A mixed integer linear programming (MILP) problem is solved to select the best location and size of the waste treatment facilities. The objective function aims at maximizing methane production based on the allocated budget. With the information on the amount of natural gas demand, it is possible to determine the fraction of self-sufficiency of each spatial unit.

## **3.Result**

### **3.1-Case of study**

The optimization framework is applied to the case study in Spain. The country is divided into agricultural districts (345 possible locations). Spain is selected by its high agricultural production (Gobierno de España, 2022), high dependency on foreign suppliers of natural gas (Enagas, 2022), and low production of biofuels. The optimization framework consists of two types of models, NLP and MILP. Both are solved in a computer with an Intel Core i7-7700, 32 Gb of Ram, using GAMS.

### **3.2-Properties of the different types of factories**

The designs presented in section 2 are modeled and evaluated economically. The main results are shown in Table 1.

Table 1.- Main results of the techno-economic analysis of the residues (q: capacity of factory(t/ye), DW: dried waste)

Residue	Yield (kgBiomethane/kgDW)	Production Cost (€/kgDW)	Min.Capacity (t/ye)	Max.Capacity(t/ye)
SLUDGE	0.003	$P_{cost}=1.814 \cdot 10^9 \cdot q^{-0.97}$	700624	49754
MANURE	0.012	$P_{cost}=1.603 \cdot 10^8 \cdot q^{-0.885}$	63072	367920
MSW	0.070	$P_{cost}=7.203 \cdot 10^7 \cdot q^{-0.97}$	19657	52560
LIGNO	0.285	$P_{cost}=6.060 \cdot 10^5 \cdot q^{-0.626}$	10000	820000

As it can be seen in Table 1, the relationship between the cost of biomethane production and the treatment capacity of the plant follows a power law, due to the strong economies of scale present in both OPEX and CAPEX. Besides, gasification has the best yield to produce biomethane from lignocellulosic waste while anaerobic digestion of sludge is the worst option.

### **3.3-Total potential of biomethane production in Spain**

The application of gasification and anaerobic digestion to the total amount of waste available per year in Spain shows that the maximum percentage of natural gas that can be covered is 43%. To achieve this, a CAPEX of 21391M€ and an OPEX of 25852M€/ye are required. This allows up to 21 provinces of the 52 available in Spain, to be self-sufficient. It is observed that the areas with the highest biomethane production are those with the highest amount of lignocellulosic residues. This is because gasification has a higher yield than the anaerobic digestion of any of the wet waste. In addition, a significant mismatch is observed between the areas that consume natural gas (industrial and densely populated areas) and the areas that can produce biomethane (rural areas).

### **3.4-Determination of the optimal budget for the reduction of Spain's dependence on fossil natural gas**

The facility location problem is used to establish the optimal selection of location, size, and type of facilities for different budgets, drawing the Pareto (see Figure 1). This curve shows that there are two sections divided by the point of 5000 M€ per year. In the first segment, each 100M€ increase in the budget represents a 2% increment in the self-supply rate. However, in the second section, the self-supply rate remains constant even if the budget is increased. Therefore, the point of 5000M€/ye is selected as the best budget to invest in waste treatment in Spain. This OPEX corresponds to a CAPEX of 9505M€. Besides, the biomethane cost is similar to the current market price of natural gas (10.19 vs 6.24 USD/MMBTU). With this budget, it is possible to cover up to 35% of the country's total natural gas demand. Therefore, through an optimal selection of the budget dedicated to waste treatment, it is possible to reduce the CAPEX and OPEX of the plants by 55.56% and 80.65%, respectively, with respect to the previous section, while the self-sufficiency ratio only decreases by 18.60%. Besides, 19 provinces are totally independent of natural gas from foreign suppliers. As discussed in Section 3.3, these provinces correspond mainly to rural areas where natural gas consumption is low and potential biomethane production is high. However, the areas with the greatest potential for biomethane production are those with a large concentration of lignocellulosic residues (see Figure 2). The results of the techno-economic analysis of the treatment processes show that economies of scale are strongly favored, prioritizing the selection of large treatment plants over small ones.

Figure 1.-Relation between OPEX and the self-sufficiency rate

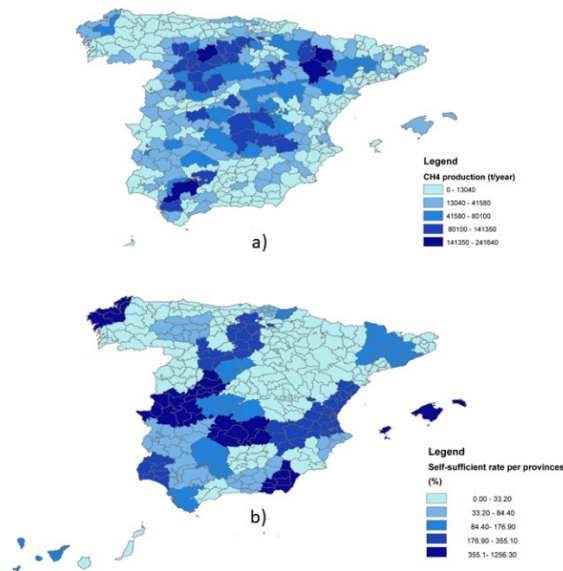

Figure 2.- (a) Production of Biomethane (ton/ye) with an OPEX of 5000 MM/ye and (b) self-sufficient rate of each province

#### 4. Conclusion

The dependence on fossil natural gas and the growing problem of waste generation have pushed European countries to analyze the circular economy of waste as a possible solution to both problems. This work presents a multiscale and holistic analysis to evaluate the biomethane production potential from different types of waste. An optimization framework is formulated to determine the best process, size, and location for the facilities, as well as the system cost. This framework is applied to the case study in Spain, where with an OPEX of 5000M€, it is possible to cover 35% of natural gas consumption and up to 19 provinces can be independent of fossil natural gas. This opens the way to create

decentralized structures to reduce the environmental and economic impacts of transporting natural gas from main pipelines to these rural regions. Therefore, this potential energy independence is a strong incentive to invest in infrastructure for waste treatment in these regions. Most of the biomethane comes from the treatment of dry waste through gasification since it has a performance of 4 times greater than anaerobic digestion. Therefore, the treatment of lignocellulosic waste is prioritized over the others. The optimization framework developed in this work can be applied to other countries, changing the crop, population, and animal databases. Some parameters, such as the composition of the residues, can be modified to improve the estimates, without modifying the models of the optimization framework.

# Energy management for controlled environment agriculture based on physics informed neural networks and adaptive linearization based data-driven robust model predictive control with AI

Guoqing Hu<sup>a</sup>, Fengqi You<sup>a</sup>

<sup>a</sup>*Cornell University, Ithaca, New York, 14853, USA*

## Abstract

Reducing stress on energy demand is crucial for promoting controlled environment agriculture, the most energy-intensive sector. Refining the modeling approach and control strategies can help reduce energy demand from crop cultivation facilities. This study presents a novel physics-informed neural network that considers both greenhouse energy demand and crop models to minimize weather forecast errors in controlled environment facilities. The adaptive linearization feedback scheme is used to handle nonlinear relationships between environment, crops, and control elements such as heating, ventilation, CO<sub>2</sub> enrichment, and more. The proposed control inputs are determined by the data-driven robust model predictive control, which uses machine learning to address weather forecast uncertainties. The proposed control framework has been demonstrated to effectively reduce energy consumption while maintaining suitable growing conditions for crops, even in challenging conditions.

**Keywords:** controlled environment agriculture, model predictive control, neural network.

## 1. Introduction

Controlled environment agriculture provides a promising solution for the food demand arising from ascending global population (Costantino et al., 2021). Energy-intensive agricultural systems can contribute to the energy crisis and high levels of greenhouse gas emissions during the cultivation process (FAO, 2018). Therefore, effective control is needed to enhance energy usage efficiency and maintain a favorable cultivation environment for crop productivity and environmental sustainability. The conventional control strategies may not be able to adequately be used for energy management since they didn't comprehensively consider the nature of highly coupled nonlinear climate and crops dynamics and intensive environmental disturbances (Chen et al., 2022). The lack of consideration for these could result in excessive/limited energy applied and failure to maintain a favorable cultivation environment. Alternatively, Model predictive control (MPC) has been acknowledged as a suitable control strategy to solve the problem of regulating the climate and growth processes and guarantee the fulfillment of the constraints specification. There are two fundamental notions in tuning an MPC application: (1) high-fidelity model and (2) robustness of control in application (Garriga and Soroush, 2010). An accurate model could prevent the violation of the constraints caused by modeling error during the application and further control efforts to adjust the states.

We propose a novel control framework for regulating energy consumption and boosting crop yield. To construct the comprehensive high-fidelity model for control strategies, we leverage the physics-informed neural network (PINN) in estimating the nonlinear model,

which considers heating/cooling, humidification/dehumidification, ventilation, CO<sub>2</sub> enrichment, lighting, irrigation, and fertilization. In this work, instead of using a single state-space model (SSM) to generalize the dynamics of the indoor production facility, adaptive linearization feedback is adopted to calculate each SSM based on the data predicted from PINN at each control interval. Afterward, each control interval's robust control strategy is determined from the RMPC framework based on the SSM and historical forecast uncertainties. Historical weather forecast data and historical weather measurement data are gathered to form the forecast uncertainties. The data-driven uncertainty set is constructed by machine learning methods, including principal component analysis (PCA) (Wold et al., 1987) coupled with kernel density estimation (KDE) (Zhang et al., 2006). Based on these methods, we further develop a data-driven polyhedron uncertainty set, in which quantile functions are used to describe confidence intervals. Using this modeling and control approach, the nonlinear correlations between environmental disturbances and control effort can be linearized with acceptable accuracy, and control energy can be developed more effectively based on a more accurate model.

## 2. Physics informed neural network and control framework formulation

The physics-informed layer contains all the differential equations to numerically approximate the values of the temperature states described in the section above. However, the nonlinear dynamics of the greenhouse contain stiff ordinary differential equations, which are numerically unstable in the traditional Euler method integration process (Gear et al., 1985). Therefore, to relieve this issue during the integration process, the Radau method (Guglielmi and Hairer, 2001) which is under fully implicit Runge-Kutta class and is essential for the numerical integration over the stiff problems (Hairer and Wanner, 1999), is included in the integration process. Then the values calculated from the physics-informed layer will be fed into the linear weighted-bias layer for fitting to the experimental values. We recognize that the PINN can retain a higher accuracy when the sample data is limited (only 30 samples were used for training). Meanwhile, PINN with stiff ordinary differential equation integration methods can achieve better simulation results than with the Euler methods and save 194% of the simulation time needed. Disjunctive uncertainty sets are built for learning the trend of the uncertainty data. The uncertainty set  $\mathbb{W}$  can be formulated under the introduction of forward and backward deviation variable  $z^+$  and  $z^-$  (Ning and You, 2018; 2019):

$$\mathbb{W} = \left\{ \mathbf{w} \in R^H \left| \begin{array}{l} \mathbf{w} = \hat{\boldsymbol{\mu}} + Q\xi, \quad \xi = \underline{\xi}z^- + \bar{\xi}z^+ \\ \mathbf{0} \leq z^+, z^- \leq \mathbf{1}, \quad z^+ + z^- \leq \mathbf{1}, \quad \mathbf{1}^T(z^+ + z^-) \leq \Gamma \\ \underline{\xi} = [\hat{F}_1^{-1}(\alpha), \dots, \hat{F}_1^{-1}(\alpha)]^T \\ \bar{\xi} = [\hat{F}_1^{-1}(1-\alpha), \dots, \hat{F}_1^{-1}(1-\alpha)]^T \end{array} \right. \right\} \quad (2)$$

With the data-driven uncertainty set, the MPC problem with ADF can be formulated as :

$$\begin{aligned} & \min \sum_{i \in B_u} c_i u_i + \lambda^T L \lambda \\ & \text{s.t. } F_u[Mw + h] \leq f_u, \quad \forall w \in \mathbb{W}^k \\ & \quad F_x[Ax_0 + B_u h + B_v v + (B_w + B_u M)w] \leq f_x + \lambda, \quad \forall w \in \mathbb{W}^k \end{aligned} \quad (3)$$

where  $F_x$ ,  $F_u$ ,  $f_x$ ,  $f_u$  represent the state variable constraints matrix, control input constraints matrix, constraints for state variables, and constraints for the input.  $L$  is the weighted cost matrix that penalizes the violation to the constraints.  $\lambda$  is the slack variable that allows some extent of violation to the hard constraints. The data-driven disjunctive uncertainty

sets are adopted in this work and incorporated into the RMPC framework, because one of the major challenges for control lies in the inherent uncertainty of weather forecasting, due to the stochastic nature of atmospheric processes and the imperfection of the weather model. However, a box uncertainty set can potentially lead to over-conservative solutions to the RMPC problems. Hence, the introduction of data-driven uncertainty sets can alleviate the over-conservatism issue confronted by the most commonly used single uncertainty set-based RMPC frameworks.

### **3. Performance profile of control framework**

Six control strategies are applied to the semi-closed greenhouse year-round control. We can observe that CEMPC could have the violation to the constraints with the disturbance of forecast uncertainties. On the other hand, the RMPC and DRMPC without the PINN framework could still have large violations of the constraints due to the significant model errors in the state prediction, as those model errors could have a non-negligible impact on the system control even though the control scheme left some space for the violation. This result implies the importance of having an accurate prediction model. Alternatively, with the help of PINN in accurately predicting the states, all robust MPC frameworks with the PINN leave some space to prevent constraint violation when weather forecast errors are significant. Thanks to these margins, most constraints are not violated even under extreme scenarios or model errors strike. The results are demonstrated in Table 1. The control frameworks with PINN are observed to have comprehensive advantages over the control schemes which are simply based on the single linear model. Therefore, in comparison to the forecast uncertainties, the model errors are also influential during the control decision-making process. The over-conservatism issue of RMPC could make control frameworks leverage more energy instead of relying on the ambient environment because uncertain forecast errors and purposes of avoiding the violation penalty (Zhao and You, 2022). Therefore, in order to fulfill the state constraints, the control actuators are more often open to maintain the humidity, leading to excessive energy usage. Hence, even though RMPC can achieve a higher yield in the result, the higher energy and resources expenses prevent it from being the most profitable control framework. From this perspective, our control framework can be safely acknowledged as the optimal control strategy compared to other control frameworks by having the highest yield-energy ratio. Despite that the simulation is conducted within Ithaca, in which the climate is relatively hospitable for crop growth, harsh conditions such as Tucson should also be tested. The recent increment in magnitude and frequency of extreme climate in Tucson requires prompt and efficient control strategies to mitigate the effect of climate change (Ghasemi Tousi et al., 2021). To ensure the feasibility and wide applicability of our proposed control framework, the control of the crop cultivation facility is simulated with the summer weather data of Tucson. This location is chosen because of its harsh conditions for crop cultivation. The temperature in Tucson in 2021 was measured as high as 42 °C, and the humidity was less than 50% in summer. As these growing conditions pose tremendous challenges to controlled environment agriculture to minimize the total control cost in maintaining the ideal growing conditions (Alkhalidi et al., 2019), especially for growing tomatoes and leafy green. Therefore, the simulation of growing tomatoes in Tucson was also conducted and served as a case study to demonstrate the performance of our proposed control framework. Our proposed control framework can handle the model error effectively. Similar to the case study above, the control framework with the PINN can noticeably lower the violation rate of 58.07% for temperature control and 2.82% for humidity control. Another observation is that with more severe conditions, the model errors and

forecast uncertainties become more influential in the control decision-making process. Therefore, in order to hedge against the sources of the errors, a more accurate predictive model and more robust control methods are needed. By comparing the results to those simulated with Ithaca weather conditions, we can observe that because of the high ambient temperature and sparse precipitation in Tucson, the climate within the cultivation facility tends to be hotter and drier (Hu and You, 2022). Despite of the harsh cultivation environment in Tucson (Chen et al., 2021), our controller still succeeds in maintaining the hospitable growing environment for the crops. Overall, under both scenarios, our control framework can achieve the highest yield-to-cost ratio, i.e., can achieve the same amount of the yield with the lowest cost, comparing to other control frameworks.

Table 1. The statistical summary of the control results of six controllers in the year 2020 in the indoor cultivation facility in Ithaca, New York. DRMPC is data-driven robust MPC with single linear models based on the training dataset; CEMPC is certainty equivalent MPC with single linear models based on a training dataset; RMPC is robust MPC with single linear models based on the training dataset.; DRMPC\_PINN is data-driven robust MPC with the multiple linear models calculated from PINN; CEMPC\_PINN is certainty equivalent MPC with the multiple linear models calculated from PINN; RMPC\_PINN is robust MPC with the multiple linear models calculated from PINN.

#### 4. Discussion

In this study, we proposed a novel control framework for minimizing the energy input and sustaining the yield under both forecast uncertainties and model errors. This model takes into not only the greenhouse energy demand model, which includes cover temperature, tray temperature, vegetation temperature, mat temperature, floor temperature, soil temperature, water vapor density, and CO<sub>2</sub> concentration, but also the crop model, which contains both mass of carbohydrate and relative growth rate in leaves, fruit, and stem. This model was incorporated into the physics-informed neural network and integrated with the Radau method to ensure stability throughout the simulation process. The validation results demonstrate that our proposed physics-informed neural network can have high-fidelity prediction over the simulated data which is disturbed under random model error. After the model construction, adaptive linearization feedback is adopted to relieve the computational effort from the nonlinearity within the greenhouse dynamics. Within each linear state-space model, we adopted the data-driven robust MPC to calculate the optimal control solution in each control interval. The case studies are conducted to test the controller's performance under the weather conditions in Ithaca, New York, USA, and Tucson, Arizona, USA. On average, our modeling approach can also help contribute to 85.76% of benefits boost under the same energy cost by balancing

the accuracy from the nonlinear models and computational efficiency from the linear models. On the other hand, both results demonstrate that our proposed data-driven robust MPC framework uses minimal control efforts to achieve the highest yield-to-cost ratio.

# Life Cycle Assessment on Chemical Recycling-aided Cascaded Use of Polypropylene Plastics

Xiang Zhao,<sup>a</sup> Fengqi You<sup>a,b</sup>

<sup>a</sup>*System Engineering, Cornell University, Ithaca, New York 14853, USA*

## Abstract

Plastic pollution posed by material losses and their subsequent chemical emissions is pervasive in nature and varies with age. Cascaded polypropylene plastic use enables the re-manufacturing of virgin polymers from waste and minimizes its generation and environmental exposure. Here we showed the advantages of this cascaded use over other waste end-of-life management pathways by investigating the environmental consequences of plastic losses across the entire life cycle. Plastic losses could form volatile organic chemicals via photo-degradation and pose non-negligible global warming, ecotoxicity, and air pollution effects that worsen by at least 189% in the long run. These environmental burdens could be increased by above 9.96% under high ultraviolet radiation levels and participation rates, which facilitated plastic particulate compartment transport and degradation. Plastic cascaded use aided by fast pyrolysis technologies could effectively cut environmental losses and outperform landfills and incineration in reducing 23.35% ozone formation and 19.91% air pollution by replacing the external monomer and fuel production with onsite manufacturing.

**Keywords:** plastic losses, chemical recycling, cascaded use, life cycle assessment.

## 1. Introduction

Plastics commonly used by humans always come with an environmental cost (Thomas, 2022). Limiting the reuse of plastics can release tons of waste into natural ecosystems (Chin et al., 2022), if not properly addressed through effective waste recovery technologies (Wen et al., 2021), including incineration and recycling, which aim to recover virgin material from waste (Zhao and You, 2021a). These technologies are still not dominantly used in end-of-life (EoL) waste treatment (Fan et al., 2022), and most waste will end up in landfills, posing an environmental burden due to the loss of plastic materials (Min et al., 2020). These chronic plastic losses in the form of micro- and nanoparticles are can easily ingested by organisms and produce volatile organic chemicals through photodegradation (Wu et al., 2022). Explicit assessment remains unmet research needs due to the lack of knowledge about the compartment transport of plastic particles. The cascade use of plastics enables material and waste used in tandem, including re-manufacturing virgin materials from monomers aided by chemical recycling (Zhao et al., 2022), and effectively minimizing material loss release and the derived environmental impacts. However, given the existing knowledge gaps regarding the environmental burden of plastics loss throughout their life cycle, these advantages over other waste management pathways have not been evaluated. This life cycle assessment (LCA) work investigated the advantages and disadvantages of cascade plastic use assisted by chemical recycling processes, which enable material re-production from monomers yielded from effectively cracking plastic waste. Polypropylene (PP) plastic was studied because it embodies similar chemical properties to other plastics (Bora et al., 2020) and is a major source of plastic contamination (Rosenboom et al., 2022). The environmental

burden of plastic losses was assessed based on a novel post-disposal fate model (Wang et al., 2019), and a time-dynamic assessment was considered, reflecting the short- and long-term environmental burden of plastic pollution. Then, a holistic life-cycle assessment approach was used to evaluate the environmental performance of polypropylene cascade use, involving the EoL fate at the life-cycle stage from raw material and resource extraction to plastic loss. Full-spectrum environmental impact results of cascade plastic use over 20, 100, and 500 years were evaluated to reflect pros and cons, point out the future technological innovations, and inform policy implications.

## 2. LCA Methodology

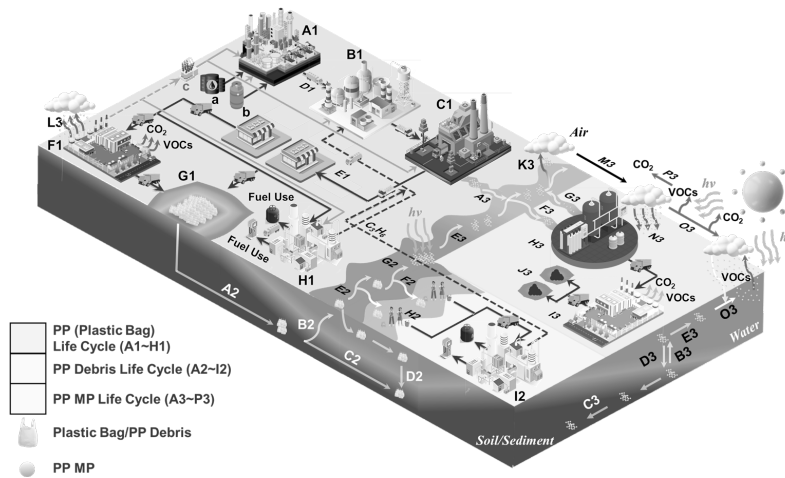

Figure 1. This LCA study's system boundary of PP plastics cascading system.

This LCA study aims to evaluate the life cycle environmental impacts of PP plastics, which are widely used in packaging materials and are also well-known major (micro)plastic (MP) pollution sources (Zhao and You, 2022). The upstream life cycle stages corresponding to the PP manufacturing, use, and EoL waste management, including incineration, landfill, and polypropylene chemical recycling, are included in the system boundary shown in Figure 1, while the downstream processes are related to plastic losses formation, degradation, aquatic waste collection and reclamation by fast pyrolysis-based chemical recycling, MP removals via drinking water treatment (DWTP) (Tian et al., 2020), and incineration. The functional unit was chosen as one-ton waste polypropylene plastic bag treated to align with the mass and energy balance across the entire life cycle (Lal and You, 2022). The life cycle inventories (LCIs) of all polypropylene pre-disposal life cycle stages are extracted from the well-archived Ecoinvent V3.8 Database based on their mass- and energy balance data. The LCIs of onsite energy and chemical production, including the mid-voltage electricity and process heat co-generation from polypropylene waste incineration and virgin chemicals produced from polypropylene chemical recycling, were modelled as their market processes avoided by their internal production, referring to the avoided burden approach (Curran, 2013). The PP waste chemical recycling chemical composition is extracted from relevant PP fast pyrolysis LCA studies (Zhao and You, 2021b). The mass flow rates of the plastic losses and their derived chemical emissions via degradation are evaluated based on the mass balance-based EoL fate model, which is developed based on the random sampling methodology. This methodology has more than 95% accuracy represented by less than

5% relative errors (Wang et al., 2003) in the multimedia transport and exposure dose model. The LCIs of plastic debris removal processes concerning coastal waste collection and drinking water treatment processes are modelled based on the Ecoinvent V3.8 Database (Niaz and You, 2022). The collected LCIs are then interpreted into environmental impact assessment results based on the global warming potential (GWP), ReCiPe 2016, EF3.0, and USEtox indicators in 20, 100, 500 years (Thomassen et al., 2019). The elucidation of the environmental assessment results should help reinforce the effective plastic EoL waste management choices towards pollution reduction by achieving the following goals: 1. Understanding the extent of environmental pollution caused by polymeric material losses and its effect factors; 2. Identification of the environmental pros and cons of current EoL waste management pathways. 3. Comparing the full-spectrum environmental performances of various EoL pathways.

### 3. Result and Discussion

We evaluate the environmental consequences of plastic losses over 20, 100, and 500 years to assess the time-dependent environmental effects across the entire life cycle and inform the disadvantages of plastic pollution. Figure 2 shows that global warming, ecotoxicity, air pollution corresponding to particulate matter (PM) formation, and ozone formation corresponding to photochemical ozone formation and its specific effects on human health and terrestrial ecosystems are four major environmental consequences of the chemical and MP releases. In the long run, the plastic particulates break up and yield smaller MPs and worsen the air pollution effects associated with PM formation by 15 times, while the ozone formation impacts that harm human health and the terrestrial ecosystem shift by 2,105%. The ecotoxicity effects also increase in the long run by at least four times.

Figure 2. The absolute environmental impacts of plastic losses in 20, 100, and 500 years.

Figure 3 indicates that temperature and UV radiation dose can determine plastic losses and their subsequent chemical releases. High UV radiation levels in summer can enhance the degradation rate of the airborne polymer particulates by two times, resulting in at least 41.48% increments in full-spectrum environmental impacts. During the winter season, these environmental impacts will decrease by over 10.90% at 0 °C. Therefore, as the temperature varies, the plastic degradation rates and their derived chemical emissions can be influenced by the season change and the subsequent long-term environmental burdens. Based on the investigated environmental burdens of the plastic losses, we then evaluate the environmental effects of the PP plastic wastes treated by diverse EoL waste

management pathway, which includes landfill, incineration, and recycling. We consider three typical plastic EoL waste management pathways: 1. U.S. EoL waste management pathway; 2. 50% incineration with 50% recycling; 3. All chemical recycling aided by fast pyrolysis processes. The U.S. pathways are denoted by 2.73% recycling, 19.96% incineration, and 78.31% treated by landfills.

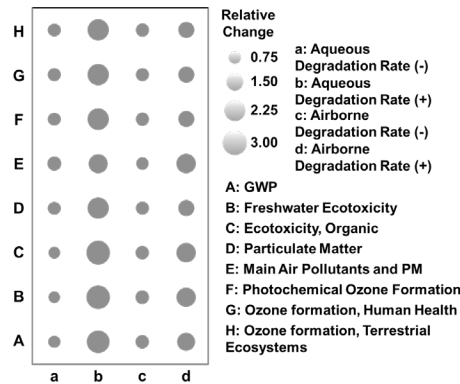

Figure 3. The effect factors of the absolute environmental impacts posed by plastic losses and the relative changes of the environmental impacts with parameter variations.

Figure 4. Environmental breakdowns of the life cycle processes of the polypropylene waste treated by U.S. EoL waste management pathway, 50% incineration with 50% recycling, and 100% chemical recycling.

Figure 4 shows that the plastic losses and their environmental impacts can be significantly reduced if other EoL waste management technology options, including incineration or recycling, replace landfilling. Moreover, plastic losses can be cut by above 99.99% if 50% of solid wastes go to incineration and another half by chemical reclamation. However, the onsite incineration processes can contribute 32.15% to the overall GHG emissions due to the intensive CO<sub>2</sub> emissions. On the other hand, fast pyrolysis processes can allocate the carbons to fuels involving gasoline, diesel, and ethylene and propylene to reduce direct GHG emissions from their onsite production. This process can also reduce the environmentally hazardous plastic losses and their derived environmental burdens, as illustrated by 92.58%, 40.87%, and 25% decrements in total ecotoxicity posed by life cycle organic chemical emissions, photochemical ozone formation, and ozone formation that harms terrestrial ecosystems, respectively. Although high organic solvent use in the aromatic extraction process within polypropylene chemically recovery processes can increase ecotoxicity from life cycle organic emissions, this EoL waste management process still outperforms other EoL options, including incineration and landfills, in terms of the full-spectrum environmental impacts. Onsite monomer and fuels and energy production aided by polypropylene chemical recycling can decrease environmental burdens from offsite manufacturing by reducing 19.91% PM formation, 26.49% photochemical ozone formation, and 23.35% ozone formation. The PP can then be used multiple times because the propylene produced from chemical recycling can be re-polymerized into PP plastics. The environmental benefits of this PP cascaded use, as illustrated by Figure 4, are shown as a decrement of 6.74% photochemical ozone formation, 5.70% ozone formation that harms human health, 5.86% ozone formation harming the terrestrial ecosystem, and 4.57% GWP. Moreover, this chemical recycling-aided PP cascaded use can save the raw material and fossil fuels by 11.25% and 25.75%, respectively. Further improving the monomer recovery rate, limiting energy use, and specialized air pollution controls on the exhaust gas can better hinder environmental consequences from plastic losses and reduce fossil resource consumption.

#### **4. Conclusion**

This work investigated the environmental burdens posed by the plastic losses from PP waste mismanagement in current practices to inform the future EoL disposal towards environmental sustainability. The environmental advantages of PP cascaded use, which is aided by chemical recycling, over other waste end-of-life management pathways can be illustrated by an above 99.99% reduction in plastic losses and their derived environmental burdens. Specifically, the volatile organic chemicals formed by plastic losses via photo-degradation can pose non-negligible global warming, ecotoxicity, and air pollution effects that worsen by at least 189% in the long run. These environmental burdens could be increased by above 9.96% under high ultraviolet radiation levels and participation rates. Based on the investigated environmental burden results, the environmental advantages of plastic cascaded use aided by fast pyrolysis technologies are specified as a reduction of 23.35% ozone formation and 19.91% air pollution compared to landfills and incineration. By replacing the external monomer and fuel production with their onsite manufacturing in PP cascade use, 25.75% of fossil fuel is saved.

## Abstract

Ethylene is the most important organic chemical in terms of global demand and production capacity. Of the sustainable alternatives to conventional ethylene production based on steam cracking of natural gas and naphtha, both direct electrochemical reduction of CO<sub>2</sub> as well as a tandem process consisting of CO<sub>2</sub> electro-reduction to CO followed by CO electro-reduction to ethylene have attracted attention. This conference paper presents a comparison between the tandem and direct CO<sub>2</sub> electro-reduction processes both from an economic and environmental point of view, including a global sensitivity analysis of key process parameters on production cost and climate change impact. The results depict a clear trade-off between the economic and environmental performance of both electrochemical routes, although the tandem process remains more favorable at the current carbon price of the EU emission trading system (ETS).

**Keywords:** ethylene, tandem process, CO<sub>2</sub> electro-reduction.

## 1. Introduction

There is an urgency to reduce carbon dioxide (CO<sub>2</sub>) emissions to limit the impact of global warming and climate change. This motivates the development of low-carbon technologies based on CO<sub>2</sub> utilization for the production of major chemicals, with a view to feeding a circular chemical economy.

With global demand and production capacity of 172 and 200 Mt per year in 2021, and a forecast that these values will keep increasing in the near future, ethylene remains the most important organic chemical (Statista, 2022). Most ethylene production is currently via steam cracking of natural gas or naphtha, which is energy intensive (up to 40 GJ heat per ton of ethylene) and emits between 1.8–2 ton of CO<sub>2</sub> per ton of ethylene. About 30% of the total energy consumed by the chemical industry is used to meet the global ethylene demand, leading to the emission of 0.26 GtCO<sub>2</sub>eq (Haribal et al., 2018).

Of the alternatives to produce ethylene in a more sustainable way, direct CO<sub>2</sub> electro-reduction (CO<sub>2</sub>ER) has attracted significant attention (Berkelaar et al., 2022). Nevertheless, the performance and sustainability of this technology at scale is still hindered by low current densities, significant CO<sub>2</sub> losses by crossover in neutral membrane electrode assemblies (MEA), and carbonate formation in alkaline flow cells (AFC). In response to these challenges, Sisler et al. (2021) proposed a tandem process, whereby CO<sub>2</sub> is first reduced to carbon monoxide (CO) in solid-oxide electrolytic cells (SOEC)

followed by CO reduction to ethylene using MEA or AFC. This paper presents a comparison of the tandem and direct CO<sub>2</sub>ER processes. The techno-economic and environmental performance of the two routes is evaluated through scaling up ethylene production based on current performance of electrochemical cells, following Sisler et al. (2021) for the tandem process and Jouny et al. (2018) for the direct process. Multiple CO<sub>2</sub> feed and electricity sources are furthermore considered and uncertainty quantification is conducted for key process parameters using global sensitivity analysis (GSA).

## 2. Methodology

### 2.1. Process modelling

The tandem process is based on two electrolysis stages: CO<sub>2</sub> is first reduced to CO in an SOEC, followed by the reduction of CO to ethylene in an AFC, thereby avoiding CO<sub>2</sub> losses through carbonate formation. Modeling of these electrolytic cells is based on simple material balances and considers the optimistic conditions for the SOEC and AFC, respectively (Sisler et al., 2021): cell voltage of 1.3 V and 1.8 V, Faradaic efficiency of 100% and 90%, current densities of 1000 mA/cm<sup>2</sup>, single-pass conversion of 60% and 53%. Pressure swing adsorption (PSA) units are used after each stage for gas separation. Modeling of the electrolytic cell for direct CO<sub>2</sub>ER to ethylene is also based on simple material balances, considering alkaline conditions and the following assumptions (Jouny et al., 2018): current density of 300 mA/cm<sup>2</sup>, cell voltage of 2 V, Faradaic efficiency of 90%, CO<sub>2</sub> conversion of 50%. As with the tandem process, a PSA unit is used for gas purification.

### 2.2. Techno-economic analysis

The analysis considers a plant producing 100 ton of ethylene per year, with the mainland UK as the geographical location. The CO<sub>2</sub> sources include: natural gas processing/coal to chemicals, ammonia/bioethanol/ethylene oxide, methane steam reforming, iron and steel, cement, power generation, and direct air capture (DAC) with respective costs of \$23.7, \$35.6, \$77.1, \$83, \$106, \$88.9 and \$325 per ton of CO<sub>2</sub> (IEA, 2022); and the electricity sources include: solar, wind, conventional nuclear, and small modular nuclear reactor (SMR), with respective costs of \$0.14, \$0.09 (IRENA, 2019), \$0.059 (NAMRC, 2022) and \$0.049 per kWh (BEIS, 2016).

For the tandem process, capital (CAPEX) and operating (OPEX) expenditures are estimated using the same methodology as Sisler et al. (2021), assuming values of \$1,067 and \$300 per kW for the SOEC and AFC, respectively. For the direct process, the methodology reported in Jouny et al. (2018) is used for the overall CAPEX costs (\$920 per m<sup>2</sup> of electrolyser), while the OPEX costs follow Peter & Timmerhaus (1991). These costs are then used to estimate the production cost of ethylene.

### 2.3. Environmental assessment

The life-cycle assessment (LCA) follows the four phases defined in the ISO 14040 standards: (i) goal and scope, (ii) inventory analysis, (iii) impact assessment, and (iv) interpretation. The aim is to compare the environmental impacts of the two ethylene

production routes, considering 1 kg of ethylene production as the functional unit. The system boundaries are defined for a cradle-to-gate analysis. The foreground inventory data are provided by the process models, for a plant located in the UK. The carbon footprint of the different CO<sub>2</sub> sources is taken from Muller et al. (2020). The impact assessment relies on the Environmental Footprint 2.0 method, as recommended by the European Commission (2018), through the software SimaPro interfaced with ecoinvent.

#### 2.4. Global sensitivity analysis

A GSA is conducted to quantify the overall uncertainty in the KPIs of interest (ethylene production cost and global warming impact) by simultaneously varying all of the uncertain factors through their entire range, then apportioning a KPI's uncertainty to each factor. The uncertain factors for each route assume triangular probability distributions, shown collectively in Table 1. The GSA is conducted using the software SobolGSA, which constructs high dimensional model representation (HDMR) surrogates by drawing 1000 Sobol samples (Sobol, 2001) from the uncertainty distribution and reevaluating the process model inventories, then estimates the first- and total-order Sobol sensitivity indices (Rabitz & Salis, 1999) for the ethylene production cost and global warming impact.

Table 1: Uncertain factors in the GSA of the CO<sub>2</sub>ER direct and tandem processes

Factor	Distribution	Lower	Mode	Upper
Electricity price (\$/kWh), wind	Triangular	0.0675	0.09	0.1125
CO <sub>2</sub> price (\$/ton), NG processing	Triangular	14.22	23.7	33.18
<b>Direct CO<sub>2</sub>ER to ethylene:</b>				
Cell voltage (V)	Triangular	2	2	2.3
Current density (mA/cm <sup>2</sup> )	Triangular	200	300	300
<b>Tandem CO<sub>2</sub>ER to ethylene:</b>				
CO <sub>2</sub> conversion in SOEC (%)	Triangular	50	60	60
Current density in SOEC (mA/cm <sup>2</sup> )	Triangular	475	1000	1000
CO conversion in AFC (%)	Triangular	43	53	53
Current density in AFC (mA/cm <sup>2</sup> )	Triangular	144	1000	1000
Cell voltage in AFC (V)	Triangular	1.8	1.8	2.32
Faradaic efficiency in AFC (%)	Triangular	38	90	90

### 3. Results and discussions

#### 3.1. Economic and environmental analyses

The ethylene production costs are compared in Figure 1 for the various electricity and CO<sub>2</sub> sources. They range between \$1.3–3.7 per kg of ethylene with the tandem process and between \$2.1–8.2 with the direct process. The lowest cost corresponds to nuclear energy from SMR followed by conventional nuclear, wind and solar given the assumed

electricity prices. The contribution of CO<sub>2</sub> price to the production cost is small in comparison to electricity, except in the case of CO<sub>2</sub> from DAC that leads to significantly higher production costs. These production costs are also to be compared with the business-as-usual (BAU) technology, naphtha cracking, at a cost of \$1.3 per kg of ethylene (ICIS, 2022). Under nominal operating conditions, only the tandem process is economically competitive with the BAU, which concurs with the findings by Sisler et al. (2021).

Figure 1: Ethylene production costs for the tandem and direct CO<sub>2</sub>ER processes considering different CO<sub>2</sub> and electricity sources, and comparison with the BAU process

The global warming impacts compared in Figure 2 for the same electricity and CO<sub>2</sub> sources show a different reality, whereby the direct and tandem routes have predicted impacts between -2.5–1.8 and 0.8–2.3 kgCO<sub>2</sub>-eq per kg of ethylene, respectively. Note that the direct route has negative emissions (from a cradle-to-gate accounting) in most electricity and CO<sub>2</sub> source scenarios, which concurs with the findings by Pappijn et al. (2020). Emission from the tandem route are consistently below 1 kgCO<sub>2</sub>-eq per kg of ethylene (for electricity sources other than solar), still making it a positive emitter compared to the direct route, but a significant improvement in comparison with the average global warming impact of naphtha cracking (BAU) at around 1.6 kgCO<sub>2</sub>-eq per kg of ethylene. Interestingly, even with emissions allowances (EUA) traded on ETS at a historically high carbon price of \$100 per ton of CO<sub>2</sub> the direct process fails to be competitive with the tandem process or naphtha cracking. By contrast, the tandem process could be competitive with naphtha cracking in the nuclear scenario, although still 50% more expensive than BAU with wind energy.

Figure 2: Global warming impact for the tandem and direct CO<sub>2</sub>ER processes considering different CO<sub>2</sub> and electricity sources, and comparison with the BAU process

### 3.2. Global sensitivity analysis

The GSA considers the scenario of wind energy and CO<sub>2</sub> captured from natural gas processing/coal to chemicals (Table 1). For the direct CO<sub>2</sub>ER route, the interquartile (IQ) range for the ethylene production cost is \$3.78–4.19 per kg of ethylene, with electricity price as the dominant factor (total-order Sobol index (TSI): 90%) followed by cell voltage (TSI: 9%); while the global warming impact is seldom affected by the uncertainty with an IQ range of -2.34–2.32 kgCO<sub>2</sub>eq per kg of ethylene. For the tandem CO<sub>2</sub>ER route, the interquartile (IQ) range for the ethylene production cost is \$2.54–3.28 per kg of ethylene, now with Faradaic efficiency in AFC (TSI: 73%) as dominant factor followed by electricity price (TSI: 20%) and cell voltage in AFC (6%); while the uncertainty in global warming impact is again small with an IQ range of 0.862–0.886 kgCO<sub>2</sub>eq per kg of ethylene. Some of these factors provide relevant targets for future technology improvements.

## 4. Conclusions

Economic and environmental analyses have been conducted for two CO<sub>2</sub> electroreduction processes producing ethylene from CO<sub>2</sub>. A comparison under different CO<sub>2</sub> and electricity sources has shown that the tandem process is economically superior to the direct route, and could even be competitive with naphtha cracking with nuclear energy. Nevertheless, the direct process presents a lower global warming impact than the tandem process, itself lower than naphtha cracking. These results depict a clear trade-off between the economic and environmental performance of both CO<sub>2</sub>ER routes, although the tandem

process remains more economically favorable even at a high carbon price of the EU's emission trading system.

## Abstract

Biodegradable and bio-based polyhydroxyalkanoates (PHAs) are ecological alternatives to conventional crude oil-based polymers. PHAs can be produced by microorganisms using waste streams from the food industry and domestic households, CO<sub>2</sub>, or other biogenic residues. To increase the current market share of PHAs, producing biopolymers with tailor-made properties by adjusting process parameters is a desirable goal.

In the biotechnology community, much is known about different cultivation conditions, e.g., bioreactor concepts or carbon sources, affecting the thermal and mechanical properties of PHAs (McAdam *et al.*, 2020). Those properties depend mainly on chain length distribution and polymer composition. Mathematical modeling can help investigate the effect of different process conditions on chain length distribution quantitatively.

This contribution outlines a multiscale model that describes the dynamics of chain length distribution and composition of the copolymer Poly(3-Hydroxybutyrate-co-3-Hydroxyvalerate) produced in a fed-batch process with *Cupriavidus necator* using fructose and propionic acid as carbon sources. Theoretical predictions are compared with experimental findings.

**Keywords:** Biopolymer, Multiscale Modelling, Polymerization, *Cupriavidus necator*, Poly(3-Hydroxybutyrate-co-3-Hydroxyvalerate)

## 1. Introduction

Compared to conventional crude oil-based polymers, biopolymers like PHAs are a promising alternative raw material for producing plastic compounds. These polymers can be produced by various bacteria and archaea using different, mostly inexpensive substrates. They are biodegradable under environmental conditions and are open to a wide range of possible applications. In comparison to conventional plastics, PHAs are still expensive. One way to reduce production costs is using organic waste from agriculture and food industries as carbon sources. In addition, polymer properties are essential. For this, monitoring the distribution and composition of PHAs is desirable to assess polymer quality and thus wanted (or unwanted) properties directly within the production process. However, for some important quantities, e.g., the chain length distribution that cannot be measured online, model-based sensors must be applied for the abovementioned goals

(Dürr *et al.*, 2021b). Furthermore, mathematical modeling is a powerful tool for investigating the dynamics of this distribution. Previous works introduced multiscale modeling approaches to simulate chain length distribution of the homopolymer Poly(3-Hydroxybutyrate) (PHB), the best-known representative of the PHA group (Penloglou *et al.*, 2012; Duvigneau *et al.*, 2022).

The current article focuses on the production process of the copolymer Poly(3-Hydroxybutyrate-co-3-Hydroxyvalerate) (PHBV). PHBV outperforms PHB because of better processability and a broader range of possible applications caused, for instance, by decreased crystallinity compared to PHB. The considered production process is a fed-batch process with *Cupriavidus necator* using fructose and propionic acid as carbon sources to produce the copolymer. Here, we present an updated metabolic model based on the model published in Duvigneau *et al.* (2021a) that leads to improved dynamic concentration profiles. By coupling this metabolic model with polymerization kinetics (Dürr *et al.*, 2021a) and calculating an average monomer concentration, we can qualitatively describe changes in PHBV composition and chain length distribution. To demonstrate this, characteristic values of chain length distribution are calculated and compared with measurements to evaluate the multiscale approach.

## 2. Experimental Methods

### 2.1. Microorganism and cultivation

*Cupriavidus necator* (H16, DSM 428) obtained from DSMZ GmbH Braunschweig was used to produce PHBV. The preculture of the bacteria before transfer in a bioreactor is described in detail in Duvigneau *et al.* (2021a). The bioreactor experiment was performed in a DASGIP parallel bioreactor system with an initial optical density of 0.4 at 600 nm. As carbon sources, 21.75 g/L fructose and 0.48 g/L propionic acid are supplemented to an M81 media. During the experiment, the dissolved oxygen (DO) level was kept at 70 % and the temperature was 30 °C. A 20 g/L propionic acid solution and 2 M sodium chloride were used to stabilize the pH at 6.8.

### 2.2. Substrate concentrations

Ammonium chloride and fructose were determined from the supernatant of the samples using an enzymatic test kit (Kit No. 5390 and No. 10139106035, R-Biopharm AG, Germany). Propionic acid concentrations were measured with an Agilent 1260 high-performance liquid chromatography (HPLC). After preparation of the supernatant, 10 µL was loaded on a reverse phase column (Inertsil 100A ODS-3, 5 µm pore size, 250 × 4.6 mm, MZ-Analysentechnik GmbH, Germany) and eluted isocratically with 1 mL/min and 0.1 M NH<sub>4</sub>H<sub>2</sub>PO<sub>4</sub> at pH 2.6 and 40 °C. The propionic acid was detected with a diode array detector (Agilent, Germany) at 210 nm.

### 2.3. Determination of PHBV and biomass concentrations

To validate our modeling approach, it is necessary to determine the distribution of the PHBV polymers. For this, 5 mL of trichloromethane was added to a fixed value of lyophilized biomass (> 4 mg). The mixture was incubated for 48 h at 37 °C and 150 rpm. After extraction, the polymer was filtered and precipitated using 5 mL ice-cold ethanol. The glass tubes were left open under the laboratory hood to ensure solvent evaporation. The extracted polymer was dissolved again in trichloromethane to achieve a concentration of 0.4 g/L. 100 µL of the solution was separated by gel permeation chromatography (GPC, Agilent + PSS, Germany) using four poly(styrol-co-divinylbenzene) columns (PSS, Germany) at 40 °C and trichloromethane as eluent. Detection of the polymer chains was done by conventional calibration with a refractive

index detector (Agilent, Germany). As reference material, 12 polystyrene standards were measured with a weight average molecular weight between 576 Da and  $1.42 \cdot 10^7$  Da. The differential distributions  $W(\log M)$  as well as the weight average molecular weight  $M_w$ , the number average molecular weight  $M_n$ , and polydispersity PDI of the samples were calculated with WinGPC UniChrom Software (PSS, Germany). The biomass concentrations were determined gravimetrically, as described in Duvigneau *et al.* (2021a). A detailed description of the procedure for determining the total 3-Hydroxybutyrate and 3-Hydroxyvalerate monomer concentrations in the PHBV polymer can be found in Duvigneau *et al.* (2021b).

### 3. Mathematical Model

The metabolic model used in the current work is based on Duvigneau *et al.* (2021a) and adapted as described below. Within the metabolic model, state equations for the dynamics of the substrates and products are given.

One key element in the advanced metabolic model approach is using online data for exhaust  $CO_2$  to follow the dynamics of substrate and product concentrations during the process. This is achieved in Duvigneau *et al.* (2021a) by introducing a factor called metabolic activity coefficient:

$$b_{CO_2} = \frac{CO_{2,out}(t)}{CO_{2,in}} \quad (1)$$

In this contribution, we use a slightly adapted version of the metabolic activity coefficient that can include the relative amount of residual biomass:

$$b_{CO_2} = \frac{CO_{2,out}(t)}{CO_{2,in} P_{res}(t)} \quad (2)$$

The relative amount of residual biomass  $P_{res}$  can be defined as follows:

$$P_{res}(t) = \frac{c_{res}(t)}{c_{res}(t) + c_{hb}(t) + c_{hv}(t)} \quad (3)$$

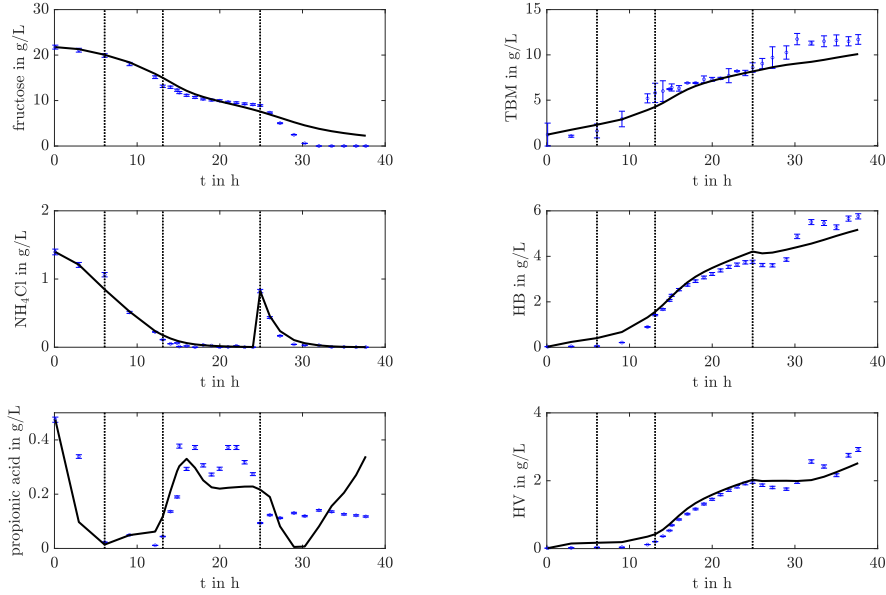

The relative amount of residual biomass  $P_{res}$  is the ratio between the concentration of residual biomass and the total biomass consisting of residual biomass and the total HB and HV monomer concentrations.

Besides the update of the metabolic activity coefficient, we decided to include the dependency not only for biomass growth but also for the uptake of fructose to produce HB (terms with  $k_4$  as rate constant). The updated state equations for fructose and HB are:

$$\frac{dc_{fru}}{dt} = -b_{CO_2} c_{res} c_{fru} [k_1 c_n inh_1 + k_4 inh_2 inh_3 + k_7] - D c_{fru} \quad (4)$$

$$\frac{dc_{hb}}{dt} = c_{res} inh_2 inh_3 [b_{CO_2} k_4 c_{fru} + k_5 c_P] - k_3 c_{res} c_n c_{hv} - D c_{hb} \quad (5)$$

The remaining equations for propionic acid, HV, ammonium chloride, and biomass can be found in our previous publication (Duvigneau *et al.*, 2021a).

**Figure 1: Dynamics of substrate (left) and product concentrations (right) for a PHBV production process.** Propionic acid is added after 10 hours by pH-depended feeding strategy. 3-Hydroxyvalerate (HV) can be included in the chain using this additional odd carbon source. The total biomass (TBM) consists of 3-Hydroxybutyrate (HB), HV, and residual biomass.

An algebraic condition can be applied as described in Duvigneau *et al.* (2022) to couple the metabolic model and polymerization kinetics:

$$\frac{1}{MW_{HA}^P} m_{HA} = \sum_{i=1}^{\infty} i ([LP]_i + [DP]_i). \quad (6)$$

This implies that the number of all HA monomers in all polymers is the same in both model parts. For the polymerization kinetics, all active [LP] and inactive chains [DP] are multiplied by the corresponding chain length  $i$  and added up to calculate the total number of monomers. To calculate the total monomer mass  $m_{HA}$ , the total masses of HB ( $m_{HB}$ ) and HV ( $m_{HV}$ ) monomers from the metabolic model were joined:

$$m_{HA} = m_{HB} + m_{HV} \quad (7)$$

The determination of the average molecular weight of a monomer unit  $MW_{HA}^P$  in equation (6) is much more complex than in the case of the homopolymer PHB. For example, copolymer chains with the same number of monomer units can have different molecular weights caused by varying HB:HV ratios from chain to chain. Conversely, this means that with known molecular weights of the polymer chains, the composition and the number of monomers in the individual chains cannot be determined. For simplification, we assume that the HV fraction in all chains is the same and corresponds to the measured total HV fraction. With these assumptions, an average molecular weight for the monomer can be calculated:

$$MW_{HA}^P = x_{HB} MW_{HB}^P + x_{HV} MW_{HV}^P. \quad (8)$$

Therein,  $x_{HB}$  and  $x_{HV}$  are the fractions of HB and HV in the polymer measured by HPLC. The molecular weight for an HB or HV unit in a polymer ( $MW_{HB}^P$ ,  $MW_{HV}^P$ ) can be found in literature. All other equations to describe the dynamics of all chain and monomer concentrations can be found in Duvigneau *et al.* (2022). Important characteristic values of the chain length distribution to estimate the potential processing properties of the

**Figure 2: Average dynamical molecular monomer weight ( $MW_{HA}^P$ ) and normalized chain length distribution  $W(\log M)$  for chosen time points. Simulated distributions are given as solid black lines and measured distributions are shown as dashed red lines.**

**Figure 3: Characteristic values of the chain length distribution.** The characteristic values are weight average molecular weight ( $M_w$ ), number average molecular weight ( $M_n$ ), and polydispersity (PDI). Simulated values are given as solid black lines, and measured values as red circles.

polymer are the weight average molecular weight ( $M_w$ ), the number average molecular weight ( $M_n$ ), and the polydispersity index (PDI). The calculation of the values is shown in Duvigneau *et al.* (2022).

#### 4. Results

The updated metabolic model based on Duvigneau *et al.* (2021a) is adapted to datasets from experiments with fructose and propionic acid as carbon sources and another experiment with fructose as single carbon source (not shown here). With that model, it is possible to depict the dynamics of substrate and product concentrations. This is shown in Figure 1 for the setup with fructose and propionic acid as carbon sources. Propionic acid is essential to produce the copolymer PHBV but has an inhibitory effect on bacterial growth. Hence, the acid is added after 10 hours with a variable feed rate coupled to pH control to ensure that inhibitory concentrations cannot be reached (Kim *et al.*, 1992). To observe not only accumulation but also the degradation process, ammonium chloride is added after 24 h by the operator. After that, the polymer concentration decreases while consumption rates of the external carbon sources fructose and propionic acid are accelerated. The metabolic model can generally capture the concentration profiles with good agreement. Only in the experiment's last phase (>24 h) mismatch between simulation and experiments can be seen, especially for the carbon sources. One possible explanation for the gap could be the unsecure propionic acid measurement by HPLC that is covered by more apoptotic fragments in the late phase of the experiment. In addition to mapping concentration curves, the chain length distribution is essential for evaluating polymer quality. The dynamics of the chain length distribution can be simulated after coupling the metabolic model to a polymerization kinetics. Using this simple and less detailed approach in terms of the polymerization process, the monomers' average molecular weight must be assumed to simulate the chain length distribution of a PHBV copolymer. Figure 2 shows the average molecular weight of the monomers, as well as

two normalized differential distributions during the PHBV accumulation at 21 h and the end of the process at 36 h. It can be seen that the simulated differential distributions have a similar order of magnitude as the experimental distributions. However, the model simulation cannot reproduce partially occurring chains in the range of  $10^5$  g/mol. The same applies to polymers with long chain lengths. This discrepancy is also reflected in the comparison of the characteristic values shown in Figure 3.

## 5. Conclusion

In this paper, a multiscale model for the PHBV production process using fructose and propionic acid was presented. Using the model, it becomes possible to examine product yields as well as the composition and quality of the copolymer. Future work should deal with adjusting the parameters for the polymerization kinetics to achieve higher accuracy for the prediction of chain length distribution. Furthermore, the preliminary results presented here for the experimental chain length distribution should be repeated and evaluated with universal calibration to examine the influence of measurement noise on the distribution mean values (Figure 3) and simultaneously determine the exact concentrations of the chain lengths. Finally, the influence of certain cultivation conditions, such as pH, temperature, or feed composition, should be experimentally validated and integrated into the multiscale model (Pederson *et al.*, 2006; McAdam *et al.*, 2020). Such knowledge is essential to achieve online control of chain length distribution during microbial PHBV production.

## Abstract

The present work proposes a general kinetic model for wet oxidation (WO) of hydrothermal liquefaction (HTL) process water (PW) that can aid towards upscaling, integration with HTL and overall optimization of the system. Aspen Plus is used to build a model by incorporating WO kinetics of 13 components selected to represent the composition of HTL-PW derived from sewage sludge. The model showed very good fit with experimental data for WO temperature of 350°C and residence times greater than 2min, with absolute error in COD and TOC removals prediction below 8%. The validated kinetic model was then used for the design of an upscaled WO process to examine the heat performance and energy requirements of the system. The results showed that WO can be operated autothermally with the only external energy input being related to oxygen compression and further cooling of the WO products.

**Keywords:** hydrothermal liquefaction; process water; wet oxidation; kinetics; Aspen plus

## 1. Introduction

Hydrothermal liquefaction (HTL) is not only one of the technologies with the greatest potential for the production of advanced biofuels but is also considered as an advanced technology for efficient waste valorization. However, being a wet thermochemical process, it involves processing of slurries with high water content (typically 80wt.% water), hence resulting in a large fraction of process water (PW) as a by-product stream. The formed PW has high COD (chemical oxygen demand), TOC (total organic carbon) and NH<sub>3</sub> content, hindering direct treatment by conventional biological technologies for wastewater treatment (WWT). Nevertheless, it contains between 20 and 40% of the organics present in the biomass feed (Si et al., 2019) offering the potential for an untapped energy source, that if utilized can potentially improve the overall efficiency of HTL technology.

Several different technologies, including anaerobic digestion, microbial electrolysis, electrochemical oxidation, hydrothermal gasification, etc. have been considered for the efficient valorization/treatment of HTL-PW (SundarRajan et al., 2021). All pose certain advantages and disadvantages related to energy efficiency, cost, catalyst stability, toxicity, inhibition, etc. Recently, we proposed wet oxidation (WO) as a pre-treatment technology to significantly reduce the organic loading of HTL-PW prior directing it in a conventional WWT plant for the final polishing (Silva Thomsen et al. 2022).

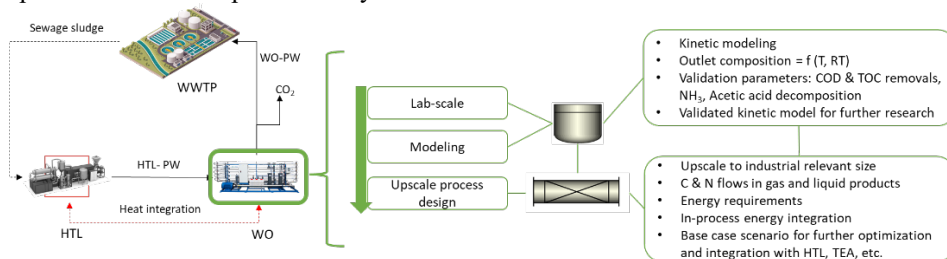

During WO a gaseous form of oxygen (oxygen, air) is used to oxidize the organics present in PW. The process takes place at elevated temperatures and pressures, maintaining PW in its liquid state and enhancing oxygen's solubility in water under these conditions. Upon

total oxidation the carbon and nitrogen present in PW are oxidized to  $\text{CO}_2$  and  $\text{NH}_3$ , respectively. However, partial instead of total oxidation usually takes place giving rise to acetic acid as an intermediate product via a free radical mechanism (Debellefontaine and Foussard, 2000). Both partial and total oxidation however result in significant reduction of the COD, TOC and toxicity contents of the PW enabling the seamless return to the WWT plant for final treatment (**Figure 1**). At the same time, the exothermicity of the oxidation reactions releases heat at an estimated flux of 435 kJ/mol  $\text{O}_2$  reacted (Debellefontaine and Foussard, 2000).

The heat release during WO opens opportunities for heat integration either ‘in-situ’ the WO process by utilizing excess heat for minimizing the overall energy needed to operate the process, or for process-to-process heat integration between HTL and WO. Until now WO has not been subject of flowsheeting and process simulations, both necessary steps for further examining the integration and upscale possibilities.

Hence, the aim of this work is twofold; first to develop a kinetic model in Aspen Plus that can give satisfactory prediction of the WO process of HTL-PW derived from sewage sludge and second, to upscale the model to industrial relevant size and examine the thermal behavior and heat integration options. **Figure 1** depicts the general concept of application of an integrated HTL-WO system in wastewater treatment plants and the specific focus of the present study.

**Figure 1.** General concept of application of wet oxidation (WO) for hydrothermal liquefaction (HTL) process water (PW) treatment and specific focus of present study (in green).

## 2. Methodology

A rigorous kinetic model is built in Aspen Plus (v12) to give realistic prediction for WO of HTL-PW. The PW considered in this study comes from HTL of sewage sludge. Typical organics present in PW from sewage sludge include alcohols, carboxylic acids, aldehydes, ketones, aromatics, N-components and N-containing aromatics (Silva Thomsen et al. 2022). Published kinetic data for WO of individual compounds present in HTL-PW were implemented in individual models in Aspen Plus and validated according to the original experimental kinetic data. Subsequently the individual kinetic reactions were combined to build a multi-reaction kinetic model by incorporating the relevant reaction mechanism. In total 13 compounds (namely: acetic acid, acetaldehyde, acetamide, acetone, butyric acid, cyclopentanone, ethanol, formic acid, formaldehyde, methanol, phenol, propanoic acid and pyridine) were selected to represent the PW stream. Typical products of WO included  $\text{CO}_2$ ,  $\text{H}_2\text{O}$ ,  $\text{NH}_3$ ,  $\text{C}_2\text{H}_4\text{O}_2$ ,  $\text{CO}$  and  $\text{H}_2$ . Own experimental data from batch-scale WO of sewage sludge HTL-PW at different temperatures and residence times (Silva Thomsen et al. 2022) were used for the validation of the multi-reaction kinetic model. The composition of the inlet PW stream was adjusted to match the Chemical Oxygen Demand (COD), ammonia and total N (TN) contents of the PW in the study used for validation. **Table 1** shows the characterization of PW by Silva Thomsen et al. 2022 vs

the one used in the present study according to the adjusted model compounds composition. For the simulation in Aspen Plus, RBATCH was used for the representation of the batch reactor used in the experiments, while the Predictive Soave–Redlich–Kwong (PSRK), which is adequate for water and hydrocarbon mixtures in the presence of light gases, was selected as the property method. An excess amount of O<sub>2</sub>, equivalent to 1.5 times the theoretical O<sub>2</sub> needed for the complete oxidation of the organics present in PW, was provided for the oxidation.

**Table 1.** Characteristics of PW from HTL of sewage sludge as determined experimentally and as represented in the model

	Experimental (Silva Thomsen et al. 2022)	Model
COD (mg/L)	28,300	28,598
NH <sub>3</sub> (mg/L)	208	208
TN (excluding NH <sub>3</sub> ) (mg/L)	477	485
TOC (mg/L)	11,900	9,205

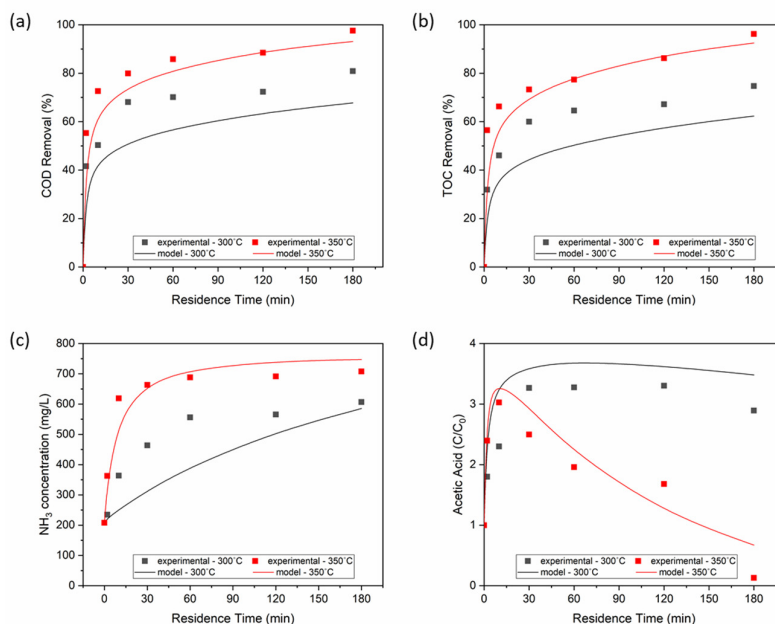

After validation, the model is scaled up to represent mass flows of PW resulting from HTL processing of sewage sludge slurry of 20 wt.% dry matter (DM) content at 1 t/h. The process flowsheet is shown in **Figure 3** where an RPlug reactor and a heat exchanger are implemented to model the scaled-up WO process. The property methods, reaction kinetics, composition of model-feed and reaction conditions remain mostly the same compared to the batch-model. Mass and energy balances have been calculated at 350°C and 15 min residence time (RT). These process conditions were selected since the WO process will likely take place at similar temperature and residence time as the HTL process and represent the base case scenario that can subsequently be further optimized.

### 3. Results & Discussion

#### 3.1. Kinetic multi-reaction model validation

The kinetic multi-reaction model, represented by RBatch reactor, was run under the exact conditions the experimental data were produced to check its validity. **Figure 2** presents predicted (solid lines) versus experimental (data points) COD and TOC removals, as well as final NH<sub>3</sub> concentration and acetic acid decomposition in post-WO PW at two different temperatures (300°C and 350°C) and residence times (0-180min). As it is clear from Figure 2 the model gave satisfactory predictions at 300°C and very good predictions at 350°C for all indicators and RT examined. The absolute error for both COD and TOC removal ranged between 6%-17% at WO temperature of 300°C and between 1%-15% at WO temperature of 350°C and different residence times. For WO temperature of 350°C maximum absolute errors for both COD and TOC removals were observed at 2min RT (9% and 15%, respectively) while the errors were significantly lower (less than 8%) for longer than 2min RT. In general, both COD and TOC removal rates predicted by the Aspen model are lower than the experimental ones for most of the RTs examined, however the general trends are consistent with the experimental data. A similar behavior is observed for NH<sub>3</sub> concentration and acetic acid decomposition in post-WO PW (figure 2-c and 2-d, respectively) with the absolute errors decreasing with increased WO temperature. Overall, the highest agreement with experimental data is reached for WO temperature of 350°C and residence times longer than 2min for all indicators examined. The two prevailing reasons for the deviation between experimental and modeling results (especially at lower temperature) are the assumed composition of the modeled PW and the implemented kinetic parameters of some of the considered compounds. A significant fraction of the components present in PW remains unidentified by conventional analysis

methods employed such as GC-MS. However, even if the complete composition was known, a model feedstock consisting of 13 compounds was assumed for the present study that might not represent the actual PW composition completely. Even though the concentration of the 13 compounds in the model feedstock was adjusted to match the experimental COD, NH<sub>3</sub> and TN contents of PW, the respective TOC content of the model feedstock was just 78% of the one experimentally measured (**Table 1**). Furthermore, the implemented kinetics for the selected 13 compounds were derived during WO of pure components. These can slightly defer when the compounds are present in a multi-component mixture as in the case of the present study. Nonetheless, despite these discrepancies, the developed model showed satisfactory (at 300°C) to very good (at 350°C) predictions for the key performance indicators (KPIs) examined. It was therefore used for the design of an up-scaled WO process that can be used as the base case scenario for further optimization of the overall system.

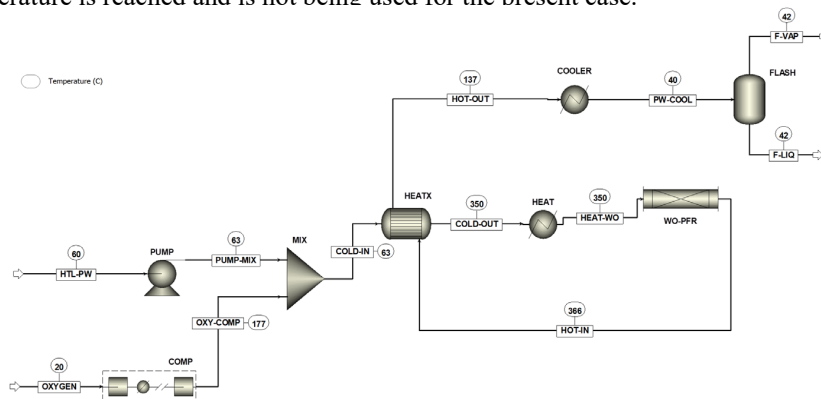

**Figure 2.** Predicted (solid lines) vs experimental (data points) post-WO PW (a) COD removal, (b) TOC removal, (c) NH<sub>3</sub> concentration and (d) acetic acid decomposition at 300°C (black lines and symbols) and 350°C (red lines and symbols) and  $2\text{min} < RT < 180\text{min}$ .

### 3.2. Process design of the scaled-up WO reactor

**Figure 3** presents the flowsheet of the scaled-up WO system. 800 kg/h of HTL-PW (assuming an upstream HTL plant with capacity of 1t/h of sewage slurry at 20wt.% dry matter content) at 60°C is pressurized at 220 bar and mixed with a compressed oxygen stream (at 220 bar) before entering the cold side of the heat exchanger (HEATX). Oxygen is fed at approximately 1.5 times the stoichiometric oxygen needed for the complete oxidation of the organics present in the modeled HTL-PW stream and is compressed in a 5-stage compressor at 220bar. The combined inlet stream (COLD-IN) enters the cold side of the heat exchanger at 63°C and is being heated to reaction temperature (350°C) by exchanging heat with the post-WO stream (HOT-IN). The overall heat transfer coefficient

(U) is assumed as  $500 \text{ W/m}^2 \cdot ^\circ\text{C}$ . Subsequently the heated stream (COLD-OUT) enters an adiabatic PFR reactor (WO-PFR) where the previously validated kinetics have been implemented. The PFR reactor consists of 15 tubes with 10m Length and 0.07m Diameter which ensures residence time of approximately 15min. The hot outlet stream from WO (HOT-IN) is cooled in two stages; first by exchanging heat with the inlet cold stream in HEATX to  $137^\circ\text{C}$  and then by a simple cooler to  $40^\circ\text{C}$ , before separating the stream into vapor (F-VAP) and liquid (F-LIQ) products in a flash drum (FLASH). The HEAT block between the heat exchanger and the WO reactor is used to ensure that the desired reaction temperature is reached and is not being used for the present case.

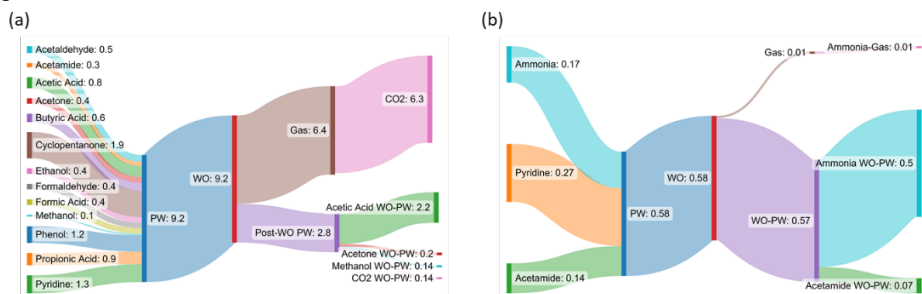

**Figure 3.** Process flowsheet of scaled-up WO process, with stream temperatures indicated on the flowsheet, in Aspen Plus (v12).

The results from the upscaled system indicate that WO can be operated autothermally with the only external energy input being related to oxygen compression and further cooling of the WO products. Autothermal operation is achieved due to the exothermicity of the oxidation reactions, increasing the temperature of the WO outlet stream to  $366^\circ\text{C}$  in the present case. Heat capacity of liquid water increases substantially at elevated temperatures, especially above  $340^\circ\text{C}$ . As an indication  $c_p$  of liquid water increases from  $135.9 \text{ J/mol}\cdot\text{K}$  at  $350^\circ\text{C}$  to  $210.7 \text{ J/mol}\cdot\text{K}$  at  $365^\circ\text{C}$  (Lemmon et al., 2022). Additional external utilities are estimated as  $5.6 \text{ kW/m}^3$  of HTL-PW for oxygen compression (electricity),  $-4.6 \text{ kW/m}^3$  of HTL-PW for compressor cooling and  $-109.9 \text{ kW/m}^3$  of HTL-PW for final cooling of WO products, for the present case with the assumed organic loading of HTL-PW. The results suggest a unique potential for heat integration with HTL process which needs to be further examined. The developed model sets strong fundamentals for the subsequent investigation of the heat integration options.

Carbon and nitrogen flows in HTL-PW assumed in this study and in WO products (gas and WO-PW) are depicted in **Figure 4** (4-a and 4-b, respectively) in the form of a Sankey diagram. The majority of carbon ( $\sim 70\%$ ) present in HTL-PW is oxidized to gaseous products upon WO (figure 4-a). The gaseous stream is composed almost entirely of  $\text{CO}_2$  ( $\sim 98.5\%$ ) offering a relative pure- $\text{CO}_2$  stream that can be potentially further utilized to produce synthetic fuels in a power-to-X approach. The liquid stream from WO still contains approximately 30% of the inlet carbon with most of the carbon ( $\sim 24\%$  of initial TOC) found in the form of acetic acid. Acetic acid is an exceptionally refractory intermediate and is also formed during oxidation reactions of several other organic components (Shende and Levec, 1999). As also shown previously (Figure 2-d) higher temperatures and residence times are required for its decomposition. COD and TOC removals for upscaled WO at  $350^\circ\text{C}$  and 15min were 73.5% and 70.8%, respectively, in

line with both modeling and experimental results obtained from batch scale WO shown in **Figure 2**. Unlike carbon, that is mostly distributed in the gas phase as CO<sub>2</sub>, nitrogen, present in the N-containing components assumed in HTL-PW (pyridine, acetamide), end up as ammonia in WO-PW.

**Figure 4.** (a) Carbon and (b) Nitrogen flows ( $\text{kg}/\text{m}^3$  PW) before and after WO at 350°C and 15min RT as predicted by the developed model.

#### 4. Conclusions

A kinetic multi-reaction model was developed in Aspen Plus to predict the wet oxidation of organics present in process water from hydrothermal liquefaction of sewage sludge. The model showed satisfactory to very good predictions with batch-scale experimental data on COD and TOC removals, NH<sub>3</sub> and acetic acid concentrations in post-WO PW. Especially at higher oxidation temperatures (350°C) and longer than 2 min RT, the absolute error was less than 8% in all key performance indicators examined. Process up-scale revealed that WO can be operated autothermally, leveraging on the excess heat generated by the oxidation reactions. At the same time, the results revealed further potential for heat-integration with HTL technology. The developed kinetic model sets the base case scenario to assist in a subsequent process up-scale optimization design, in terms of tuning WO process conditions to achieve both the desired organic loading reduction and the desired heat release for the different integration options and HTL-PW composition.

## Abstract

Hydrogen and methanol are among the most vital fuels and chemicals nowadays. Hydrogen is considered as clean fuel because it produces zero carbon emissions. Comparably, methanol is regarded as a low-carbon alternative fuel. The resources of the two fuels are mainly crude oil, coal, and natural gas. Alternative sources of the two fuels are highly needed to meet the increasing energy demand. On the other hand, plastic waste is also a pollutant and drastically affects the environment. Thermochemical recycling and processing of plastic waste could lead to hydrogen and methanol production. Two comparative models have been developed in Aspen Plus to produce hydrogen and methanol from the waste plastics. In base model (case 1), the waste plastic is first gasified using steam as a gasification agent and the produced syngas containing H<sub>2</sub>, CO, and CO<sub>2</sub> is introduced to the water gas shift unit to maximize hydrogen production. Finally, the CO<sub>2</sub> was captured to recover the pure hydrogen. In the alternative model (case 2), the integration between plastic gasification and steam methane reforming (SMR) is proposed to increase the syngas yield while minimizing the overall process energy requirements. The two cases have been technically and economically evaluated to determine the best case. The results showed that the process efficiency of case 2 is higher than base case by 3%. The case 2 also showed a potential to reduce the fuel production cost by 51.8% as compared to case 1. The CO<sub>2</sub> specific emissions in case 2 are reduced by 34% as compared to case 1. Overall, it has been seen that integrating the SMR process with plastic gasification for the dual hydrogen and methanol production is less energy intensive and represents better project feasibility.

**Keywords:** Gasification; SMR; Waste Plastic; Methanol production; GHG Emissions.

## Introduction

The global production of the plastics over the past 70 years is more than 6.3 billion tons (Okunola A et al., 2019). The huge amount of plastic waste has been contributing to huge environmental problems and distributing the earth ecosystem. The thermochemical conversion of waste plastics is 12%, whereas, 9 % is usually recycled (Okunola A et al., 2019). Therefore, proper recycling of the plastics should be considered to minimize its massive environmental impacts and to utilize them in beneficial applications. The thermochemical recycling of plastic waste is a good option because it eliminates the need for plastic classification and simultaneously produce syngas that could be used to produce several fuels and chemicals with high purity. Plastics in general have a high heating value with high hydrogen and carbon content, thus, syngas with high heating value can be produced by thermochemical conversion. This route offers alternatives to produce clean

fuels from carbon-based raw materials. Hydrogen and methanol are some of the essential fuels that could be produced from waste plastics with a minimum carbon emission. Therefore, the recycling of the plastics should be focused in this approach synthesizing hydrogen and methanol from plastic waste via thermochemical route. AlNouss et al. (2020) performed a techno economic analysis on the conversion of carbonaceous fuels to hydrogen testing several feedstocks and several gasification agents. It was concluded that steam as a gasification agent performed better than others in terms of maximizing the hydrogen production with considerable cost. Another related study conducted by Al-Qadri & Ahmed (2022) on the conversion of waste plastics (polyethylene and polypropylene) to hydrogen via steam gasification. They performed the whole technical and economic analysis investigating an alternative model that integrates the steam methane reforming with plastic gasification to maximize the hydrogen production, enhance the syngas quality, and reduce the cost. They found a net increase in the process efficiency by 4% and a reduction in the levelized hydrogen cost by 29%. Ahmed (2021) also performed a technoeconomic analysis on the dual production of hydrogen and methanol from coal, integrating the steam methane reforming with coal gasification. The study was succeeded in enhancing the fuel production by 22% and reduce the fuel cost by 13% when compared to the conventional methodology. Since there is an interest to produce hydrogen and methanol from alternative resource (plastic waste) to meet the energy demand, the integrated design between plastic gasification and steam methane reforming is an option. Therefore, the objective of this work is to develop two case studies that produce hydrogen and methanol from waste plastics (polyethylene blended with polypropylene) and then performing the technoeconomic analysis for different process alternatives.

### Modelling and Simulation

Aspen Plus (V12) was used to build the simulation models for the dual production of hydrogen and methanol. The thermodynamic package used in the study is Peng Robinson because it is applicable to high temperature and pressure, and several studies had used it in the gasification field. The composition of polyethylene and polypropylene were defined on the basis of their approximate and ultimate analysis. Table 1 represents the assumptions and the modules used for developing the simulation model. The plastic gasification results were validated with the literature (Saebea et al., 2020). Additionally, the methanol synthesis from syngas was also confirmed in terms of methanol yield (Mccaul, 2019). The steam methane results were also validated based on hydrogen to carbon monoxide ratio (Ghoneim et al., 2016).

Table 1: Design Assumptions for case 1 and case 2

Equipment	Aspen Model	Assumption
Flowrate of plastics	RYield	Plastics = 100 kg/h Steam/Plastic = 1.25
Gasifier	RGibbs	Entrained flow gasifier 1500 °C and P = 25 bars
Pre-reformer	RStoic	Methane/Plastics (mass basis) = 1.5
Reformer	RGibbs	1200 °C and 25 bar, steam: methane (mass basis) = 1.6; with nickel-based catalyst
H <sub>2</sub> S Removal	RadFrac	Rectisol process; 0 °C, and 25 bar H <sub>2</sub> S remaining = 1 ppm using 20 stages.
Methanol Synthesis	Plug flow reactor	25 bars and 270 °C Using Graaf. et al kinetics

Water Gas Shift	REquil	Two reactors, Molar steam: CO = 2 using $\gamma$ - $Al_2O_3$ - $\alpha$ - $Ga_2O_3$ catalysts
CO <sub>2</sub> Removal	RadFrac	Rectisol process; 0 °C, and 1 bar CO <sub>2</sub> Removal = 99% using 10 stages.

### 3. Process Description

Two case studies have been developed in this study for dual production of H<sub>2</sub> and methanol. Figure 1 represents the base case (case 1) which consists of several units containing steam plastic gasification, H<sub>2</sub>S removal, methanol synthesis unit, water gas shift (WGS), CO<sub>2</sub> removal unit, and solvent regeneration. The syngas produced from gasification unit is treated in the acid gas removal unit to remove the H<sub>2</sub>S followed by its conversion into methanol synthesis unit, whereas, the remaining gases were fed to the WGS to maximize the hydrogen content followed by the CO<sub>2</sub> removal.

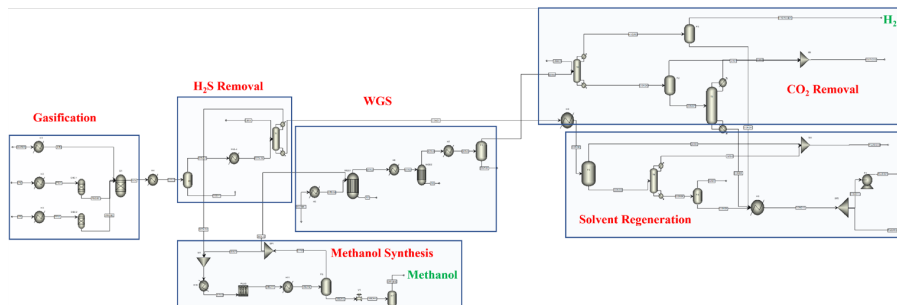

Figure 1: Aspen Plus Model for the Production of H<sub>2</sub> and Methanol from Waste Plastics

The case 2 shown in Figure 2 also represents the dual production of H<sub>2</sub> and methanol. It is similar to case 1, however, this case integrates the steam methane reforming (SMR) technology with plastic gasification, where, the produced syngas from gasification and reforming unit is mixed to enhance the overall syngas production. Then H<sub>2</sub>S is removed from the syngas feed to make it suitable for the methanol synthesis unit and the unconverted syngas is recycled back to WGS unit to get the maximum conversion of unconverted CO to H<sub>2</sub>.

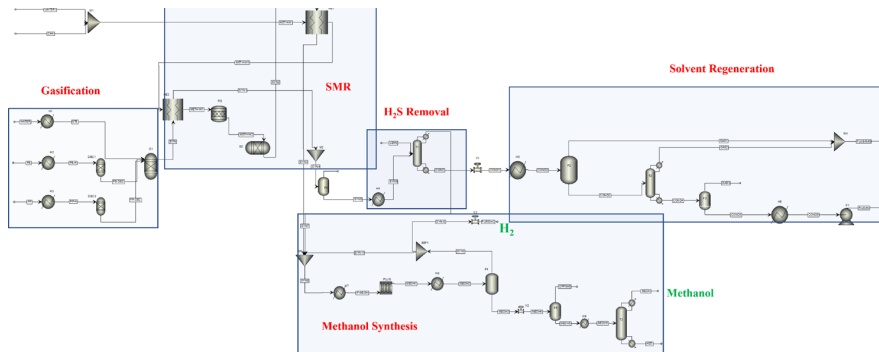

Figure 2: Aspen Plus Model of Waste Plastic Gasification and Methane Reforming models for the Production of H<sub>2</sub> and Methanol

## 4. Results and Discussion

### 4.1. Hydrogen and Methanol Production

The results for the two cases were analyzed in terms of syngas compositions, hydrogen production, methanol production, CO<sub>2</sub> emissions, and overall process efficiency. The case 2 produces syngas with higher hydrogen content of 9% and higher heating value by 11% compared to case 1. The hydrogen production rate on mass per unit feedstock basis (hydrogen yield) has been calculated as 0.06 and 0.10 for case 1 and case 2, respectively. On the other hand, the methanol production rate on mass per unit feedstock basis for case 1 and case 2 has been calculated as 2.12 and 2.18, respectively. From the results, it has been seen that the second case is more efficient than case 1 in term of producing H<sub>2</sub> and CH<sub>3</sub>OH.

### 4.2 Process performance analysis

The following equation (Eq 1) is used to calculate the overall process efficiency.

$$\text{Process Efficiency} = \frac{\text{H}_2 \text{ thermal energy [MWth]} + \text{CH}_3\text{OH thermal energy [MWth]}}{\text{Feed stock thermal energy [MWth]} + \text{Energy consumed [MWth]}} \times 100\% \quad (1)$$

Case 2 utilizes an additional feedstock namely, methane, intaking more feedstock thermal energy of 1995.92 MW. In addition, the second case required 1070.13 MW more utilities for the process needs. While comparing the total energy content, it has been seen that the thermal energy content in terms of produced hydrogen and methanol was higher in the case 2 than case 1 by 2392.96 MW. Developing the heat exchanger network and calculating all the energy requirements using Equation 1, the overall process efficiencies for Case 1 and case 2 is estimated as 73% and 76%, respectively, as represented in the Figure 3. The results also showed that the yield of H<sub>2</sub> and methanol in case 2 is higher than case 1. Additionally, the second case reduces the specific carbon dioxide emissions by 34%. Therefore, case 2 found to be more effective and feasible for dual hydrogen and methanol production from waste plastics. Furthermore, the economic analysis is performed to analyse the overall process feasibility.

Figure 3: The fuel production and process efficiency for the two cases

## 5. Project Feasibility

The project feasibility is determined via economic analysis which basically included the capital expenditures and operating expenditures for the two cases. The economic analysis was performed based on several assumptions specified by the previous paper (Al-Qadri et al., 2022). The capital expenditure (CAPEX) mainly encompasses the equipment cost,

installation and piping costs, instrumentations, and civil work costs. On the other hand, the operational expenditure (OPEX) consists of utilities, catalyst replacement maintenance, labor costs, and administration costs. The power law (order of magnitude) analysis has been used to estimate the CAPEX, where, the CEPCI of 620 has been used for the year 2022 in the equation (Eq 2).

$$\text{Cost}_{\text{New}} = \text{Cost}_{\text{Old}} \times \left( \frac{\text{Capacity}_{\text{New}}}{\text{Capacity}_{\text{Old}}} \right)^x \times \frac{\text{CEPCI}_{\text{New}}}{\text{CEPCI}_{\text{Old}}} \tag{2}$$

The total investment cost of case 2 is higher than case 1 by 40%. Nevertheless, the total investment cost (TIC) per ton of fuel produced is lower in case 2 than case 1 by 46% which shows the feasibility of the second case in terms of higher fuel yield. The fuel levelized cost over 30 years was reduced in the case 2 by 52% when compared to the base case. The net present value for case1 and case 2 were calculated to be 2.734 M€ and 26.201 M€ respectively. Additionally, the present value ratio for the two cases were 1.614 M€ and 5.301 M€. Table 2 represents the main parameters for the technoeconomic analysis. The economic analysis has been presented in terms of cash flow diagram in Figure 4.

Table 2: Technoeconomic Analysis

Parameter	Units	Case 1	Case 2
Produced hydrogen per feedstock	mass basis	0.06	0.10
Produced methanol per feedstock	mass basis	2.12	2.18
Process Efficiency	%	73	76
Total Investment Cost	€ (10 <sup>3</sup> )	4070	5690
TIC per ton of H <sub>2</sub> and MeOH	M€/ton	18530	9970
Total OPEX/Year	€ (10 <sup>3</sup> ) / Year	839.1	1032.2
Total OPEX/ton H <sub>2</sub> and MeOH	€ (10 <sup>3</sup> ) / ton	16.4	4.9
Revenue	M€/Year	1.7	5.2
Hydrogen and MeOH Cost	€/kg	0.534	0.257

Case 2 is more attractive compared to the case 1 in terms of cash flow and return on investment. This significant enhancement in the return on investment is attributed to the higher revenue generation capacity of case 2 since it represented higher annual income of 3.526 M€ compared to base case. Case 2 can pass the breakeven point in the fifth year, whereas, case 1 requires 12 years to return the initial investment. Therefore, case 2 has been found to be more economically feasible for dual production of hydrogen and methanol.

Figure 4: The cash flow diagram for base case and alternative case

## Conclusions

The dual production of hydrogen and methanol from waste plastics has been represented in two different cases. The first case represents on plastic gasification design for the production of hydrogen and methanol. On the other hand, case 2 integrates the steam methane reforming with plastic gasification to enhance the syngas heating value with higher hydrogen content. The results revealed that, case 2 produces 65% and 3% more hydrogen and methanol, respectively, compared to the case 1. The overall process efficiency of the case 2 showed an increment of 3% and reduction of CO<sub>2</sub> specific emissions by 34% compared to case 1. Moreover, Case 2 offers an annual revenue of 5.2 M€ compared to case 1, which is only 1.7 M€. The fuel (hydrogen and methanol) production cost has been found to be lower in the case 2 by 51% as compared to case 1. Keeping in view all the preliminary analysis, case 2 has been found to be more technoeconomically attractive compared to the case 1.

## Abstract

Here, we have designed an integrated hydrogen transport process including hydrogenation and dehydrogenation processes using a toluene-methylcyclohexane (MCH) system. The toluene-MCH system is one of the promising liquid organic hydrogen carrier (LOHC) candidates because it is relatively less toxic and an economical option. For efficient energy utilization, we have carried out heat integration using pinch analysis. To determine the minimum hydrogen transport cost, techno-economic analysis was performed using discounted cash flow analysis. It was estimated that the minimum hydrogen (H<sub>2</sub>) transport cost is \$2,083/kg when 400,000 tons of hydrogen is transported per annum. The sustainability of the proposed process was determined through life-cycle assessment quantifying the direct and indirect carbon emissions. This study can give insight into technological development for the realization of the hydrogen economy.

**Keywords:** Eco-friendly, Hydrogen storage-transportation, Clean energy, Separation process, comprehensive analysis

## 1. Introduction

Recent climate crisis has prompted researchers to take an interest in the transition from a petrochemical-based energy society to a renewables-based energy society. However, regional inconsistency and intermittent energy generation make the commercialization of renewable energy complicated. To resolve this drawback, hydrogen is attracting attention as a carbon-free energy carrier. Although the high gravimetric energy density of hydrogen (120 MJ/kg) is suitable for an energy carrier, its low volumetric energy density (10.9 kJ/L) is a major contributor to increase transport costs (Markiewicz et al., 2019).

There are two major methods for efficient hydrogen storage: physical storage and chemical storage. For physical storage, compression and liquefaction are mainly used. Although they have the advantage of relatively simple processes, their strict storage conditions (400~700 bar and -253°C, respectively) entail safety accident risk and require lots of energy causing indirect carbon emissions. Chemical storage means storing hydrogen in other chemicals by forming chemical bonds. Chemical storage requires sophisticated separation processes to recover high-purity hydrogen, but it consumes relatively low energy (Singh et al., 2021; Teichmann et al., 2011).

Liquid organic hydrogen carriers (LOHCs) are promising candidates for chemical storage systems due to their high hydrogen storage capacity. Furthermore, LOHCs can store hydrogen in the liquid state at ambient conditions with relatively low energy loss and has similar properties with petroleum derivatives, which makes it available to use existing petrochemical infrastructures. LOHCs are well known in industrial set-ups and so they are easy to produce in large quantities.

Among LOHCs, the toluene-methylcyclohexane (MCH) system was selected for the designed process due to its relatively high hydrogen storage capacity (6.2 wt.%) (Niermann et al., 2019). It also has a relatively affordable price and reversible hydrogenation reaction which makes toluene recycle after dehydrogenation to reduce the hydrogen transport cost (Preuster et al., 2018). However, toluene and MCH have high volatilities that make it hard to separate hydrogen from unwanted organics.

In this study, we have designed the integrated hydrogen transport process composed of two sections (hydrogenation and dehydrogenation sections) based on the experiment data from the literature. Especially, the sophisticated separation process including the extraction column and pressure swing adsorption (PSA) column was designed considering the volatile property of toluene and MCH. We have also made heat networks to use waste energy efficiently reducing indirect carbon emissions. Then, techno-economic analysis (TEA) and life-cycle assessment (LCA) were performed to evaluate economic feasibility and sustainability.

## 2. Technology Overview

Toluene in the proposed design is converted to MCH by a hydrogenation reaction and converted back to toluene by a dehydrogenation reaction. For the hydrogenation reaction, we have used a commercially available Ni-SiO<sub>2</sub> catalyst at 120°C with excess hydrogen condition. Although the experimental data from the literature was originally based on ambient pressure, we designed it to react at higher pressure (370 psi) (Atsumi et al., 2020). Generally, hydrogenation reaction at higher pressure results in higher conversion, but we assumed that it has the same yield at ambient pressure due to no experimental data at higher pressure. Instead, the high-pressure reaction can reduce the cost required for pressurization when separating unreacted hydrogen. Unlike the hydrogenation reaction, the dehydrogenation reaction has a higher conversion at lower pressure. MCH dehydrogenates under 1atm at 310°C (Okada et al., 2006). More details including stoichiometric equations and yields are specified in Table 1.

Table 1. Summary of reaction condition.

Reaction	Reaction	Yield
Hydrogenation	$\text{Toluene} + 3 \text{H}_2 \rightarrow \text{MCH}$	0.99
	$\text{Toluene} + \text{H}_2 \rightarrow \text{CH}_4 + \text{Benzene}$	0.01
Dehydrogenation	$\text{MCH} \rightarrow \text{Toluene} + 3 \text{H}_2$	0.9491
	$\text{MCH} \rightarrow \text{CH}_4 + \text{Benzene} + 2 \text{H}_2$	0.0002
	$\text{MCH} + \text{H}_2 \rightarrow \text{Others}$	0.0008

### 3. Method

#### 3.1. Process synthesis

The process is developed to target the white birch handling of 2,000 dry tons per day which is the commercial scale of biorefinery. The process is simulated using the Aspen Plus process simulator V11 and the Soave-Redlich-Kwong (SRK) equation as the thermodynamic method. The heat networks are created based on the pinch analysis method using the Aspen Energy Analyzer V11.

#### 3.2. Techno-economic analysis

The cost of equipment is calculated using the Aspen Process Economic Analyzer V11, and the equipment and material costs are scaled to unify the base year of 2018 using the Chemical Engineering Plant Cost Index. Using the scaled costs, the minimum transport cost is estimated as an indicator of economic feasibility by discounted cash flow method when the internal rate of return is assumed to be 10%. The economic parameters are derived from the National Renewable Energy Lab report, and major economic parameters are summarized in Table 2 (Davis et al., 2018).

Table 2. Major assumed economic parameters.

Economic parameter	Value	Economic parameter	Value
Plant financing by equity	40.0%	Plant life	30.0 years
Income tax rate	21.0%	General plant depreciation	7.0 years
Interest rate for dept financing	8.0%	Steam/electricity plant depreciation	20.0 years
Term for dept financing	10.0 years	On-stream percentage	90.0%

#### 3.3. Life cycle assessment

LCA is performed by following the international guideline presented by the International Organization for Standardization, which is constituted of four steps: 1) goal and scope definition, 2) inventory analysis, 3) impact analysis, and 4) interpretation. The system boundary is defined from the production of input materials and energies (cradle) to the production of hydrogen from the dehydrogenation section (gate), and the functional unit is defined as 1 kg of transported hydrogen. The environmental impacts were estimated using SimaPro V9.1 with the EcoInvent 3.6 database with ReCiPe 1.13V of mid-point from the hierarchical perspective. The environmental impacts were calculated based on the functional unit and allocated based on the mass production rate of the products.

## 4. Process design

### 4.1. Process synthesis

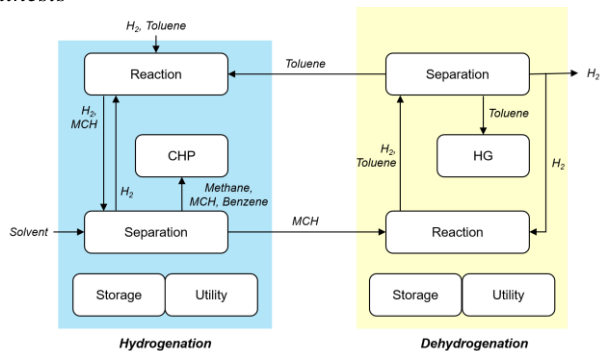

Fig 1. Block flow diagram of the proposed process.

In this study, we designed the integrated process using the Aspen Plus process simulator assuming that 400,000 tons of hydrogen are transported per annum. The integrated process consists of two sections such as hydrogenation and dehydrogenation sections which are 10,000 km apart. including five subsystems respectively. The hydrogenation section is constituted of 1) Reaction, 2) Separation, 3) Combined heat and power (CHP), 4) Storage, and 5) Utility. The dehydrogenation section has the same subsystems except for CHP. Instead of CHP, the dehydrogenation section has a heat generation (HG) subsystem because electricity is not produced in the dehydrogenation section.

#### 4.1.1. Hydrogenation section

Toluene supplemented to compensate for the toluene loss and transported from the dehydrogenation section is hydrogenated to MCH in the reaction subsystem. Since the hydrogenation reaction occurs in the excess hydrogen condition, hydrogen and MCH need to be separated to reduce hydrogen loss. Hydrogen can be separated by depressurization and cooling using the boiling point difference between hydrogen and MCH. Benzene produced as a byproduct from the hydrogenation reaction is easily accumulated in the proposed process. However, eliminating benzene is challenging because its physical property is similar to MCH. Therefore, the extraction column was introduced using N-formylmorpholine (NFM) as a solvent (Chen et al., 2007). The benzene-removed MCH is transported to the dehydrogenation section, and the used NFM is recycled to the extraction column after separating from the benzene using a distillation column.

The separated byproducts are utilized as energy source in the CHP subsystem. After using the heat required for the hydrogenation section, the remaining heat is used to produce the electricity which can be sold as a byproduct or used to produce hydrogen through water electrolysis (Sen et al., 2012). To reduce CO<sub>2</sub> emissions, carbon capture units are also installed in the CHP subsystem (Lee et al., 2021)

#### 4.1.2. Dehydrogenation section

The transported MCH is dehydrogenated in the reaction subsystem with some hydrogen. Since hydrogen (5-20 mol% of MCH) can improve the life period of the catalyst and the yield, the purified hydrogen from the separation subsystem is recycled to the dehydrogenation reactor. Further, the produced hydrogen is purified in the separation

subsystem by pressurization and PSA. Firstly, volatile toluene is liquefied at high pressure and low temperature to recover toluene, then the remaining organics are removed by PSA.

Byproducts are utilized as a heat source like the hydrogenation section to supply the heat required for the dehydrogenation section. However, since the dehydrogenation reaction is endothermic, it is difficult to meet the heat required by byproducts alone. Therefore, some of the produced hydrogen is also burned in the HG subsystem. The HG subsystem also has carbon capture units like the hydrogenation section.

#### 4.2. Heat integration

To lower the operating costs and to efficiently use energy, we have carried out heat integration using pinch analysis. As we assumed that the hydrogenation and dehydrogenation sections are far away, heat integration is conducted separately for each section, and the results are summed up and shown in Figure 2.

Fig. 2. The result of heat integration and major heat networks

The total heating requirement for the proposed process was 715 MW before heat integration. Most of the heating requirement (44%) was used for separation in the hydrogenation section. However, the heating requirement became zero after heat integration. The hydrogenation section has sufficient heat sources such as the heat from CHP and the hydrogenation reaction which is exothermic. The heat required for the dehydrogenation section is satisfied by burning produced hydrogen.

For the cooling requirement, most of the energy (52%) was required for the power cycle of the CHP subsystem. To liquify the steam used to generate electricity, a huge amount of cooling water was required. Furthermore, the large flow rate of the power cycle made it difficult to form heat networks completely. As a result, only 33% of the cooling requirement was decreased.

## 5. Result and Discussion

### 5.1. Techno-economic analysis

Fig. 3. The result of capital cost breakdown.

As shown in Fig. 3, the hydrogenation section requires a larger capital cost than the dehydrogenation section mainly because of the CHP subsystem. The generator in the power cycle is the most cost-intensive equipment due to the large flow rate. For the dehydrogenation section, the separation subsystem is the most cost-intensive subsystem. Multi-compressor was used to recover toluene, but the high flow rate of a mixture stream required a large-size compressor accounting for a major fraction of the capital cost in the separation subsystem.

Fig. 4. Operating cost breakdown

As shown in Fig. 4, most of the operating costs come from toluene supplementation and catalyst replacement. Although toluene was recycled in the proposed process, some of the toluene was lost in the separation process of each section. Most of the catalyst replacement cost (89%) comes from the dehydrogenation catalyst because of the high price of platinum. The cost of electricity also accounted for a large portion. While electricity can be self-sufficient in the hydrogenation section because it generates electricity on its own in the CHP subsystem, all electricity required for the dehydrogenation section have to be purchased externally.

### 5.2. Minimum transport cost

We have calculated the minimum hydrogen transport cost which is the value when the total cost of the process and revenues including byproduct (electricity and captured CO<sub>2</sub>) incomes are identical. Fig. 5 shows the total cost and revenue, and the portion of each inventory.

Fig. 5. Minimum transport cost of the process

The total cost of the proposed process is \$2,511/ton-H<sub>2</sub>, and the byproduct incomes are \$428/ton-H<sub>2</sub>. Therefore, the minimum hydrogen transport is found to be \$2083/ton-H<sub>2</sub>.

### 5.3. Life cycle assessment

Fig. 6. The result of life-cycle assessment.

The life-cycle assessment was performed to determine the environmental impact of each section. Fig. 6 shows each section's contribution to climate change based on CO<sub>2</sub> emission. The hydrogenation section produced the most carbon emissions mainly because of the solar energy needed for hydrogen production. Though solar energy is sustainable, noticeable amounts of carbon emissions occur when constructing solar power plants. However, since produced electricity and captured from the CHP subsystem are environmentally beneficial, most of the carbon emissions in the hydrogenation section can be offset. The major cause of carbon emission is electricity used in the separation subsystem. The multi-compressor for pressurization consumes 98% of total electricity consumption.

Therefore, carbon emission would be further reduced if pressurized in a less energy-intensive manner.

## 6. Conclusion

In this study, we have proposed an integrated process for long-distance hydrogen transport using a toluene-MCH system and designed heat networks reducing 100% of heating requirement and 33% of cooling requirement. Based on the designed process and heat networks, TEA and LCA were conducted to study economic feasibility and sustainability of the proposed process. It was found that the hydrogenation section incurs higher capital costs than the dehydrogenation section mainly due to the power cycle of the CHP subsystem. It also found that toluene supplementation and catalyst replacement are the major cost contributors. From a sustainable point of view, although more carbon emissions occur in the hydrogenation section compared to the dehydrogenation section, most of the carbon emissions are offset because of the environment friendliness of the produced electricity and captured CO<sub>2</sub> from the CHP subsystem. The carbon emissions of the dehydrogenation section can be decreased by reducing electricity consumption.

## Abstract

In this work the integration of metabolic (structured) models, which describe the entire metabolic network of microorganisms, into a superstructure optimisation framework is presented. These models are of particular interest because they can predict the outcome of a fermentation with different substrates, and without the need of experimental data. In this contribution, a workflow for 2 types of structured models is described: i) genome-scale metabolic models (GEMs) and ii) community models where product yields can be influenced by environmental factors (e.g., pH). To showcase this methodology a simple case study is presented of a superstructure optimisation problem. With this case study it is demonstrated that the described workflow can aid the design of novel biorefineries, by screening potential cultures using metabolic models without the need of experimental data.

**Keywords:** Structured models, biorefinery design, superstructure optimisation, surrogate models, Genome-scale metabolic models

## 1. Introduction

A current hurdle towards the implementation of biorefineries are the various process alternatives which lead to a multitude of possible refinery designs. To aid the design of biorefinery networks, superstructure optimisation tools, like O2V have been created (Gargalo et al., 2022). A superstructure represents all the possible links between process units (and their possible substitutes) formed by flowchart and logic rules, where alternative topologies of processing networks can be visualized. Optimisation techniques can be applied to this superstructure to generate an optimal processing network according to a desired objective (e.g., maximizing profit) (Bertran et al., 2017).

In a superstructure the unit processes are represented by mathematical models, describing the flow and/or transformation of mass. For biorefineries, key unit processes are bioreactors, responsible for the chemical transformation of feedstocks. Metabolic models, simulating intra- and extra-cellular spaces, are commonly used for simulating biotransformations. These models can predict the microbial products from different substrates and can be linked to several inputs, or outputs of other reactors, thereby increasing the amount of new possible network topologies. Additionally, the creation of these models is not dependant on data from time consuming fermentation experiments.

A common type of metabolic model are genome-scale metabolic models (GEMs). A GEM comprehensively reconstructs the organism's entire metabolic network using its genome (Lieven et al., 2020). Another type of metabolic model are community models, such as the bioenergetic model of Regueira et al. (2020). These models are of interest because of their ability to describe open and co-culture fermentations with different

substrates and at different operational conditions (e.g., different pH values). Additionally open culture fermentations are interesting to include because they have economic and operational advantages, such as avoiding sterilisation and being able to handle complex substrates (Kleerebezem et al., 2015).

Unfortunately, structured bioreactor models are often too complex to feasibly incorporate into a superstructure and thus are often not considered. In other words, the integration of GEMs or community models in a superstructure problem is not strait forward. For this reason, the aim of this contribution is to create a workflow to incorporate these models in a superstructure optimization problem. To showcase this workflow a simple superstructure optimization problem is presented to produce propionate and acetate where GEMs and community models are incorporated as surrogate models.

## 2. Methodology

The workflow for the integration of two types of models into a superstructure optimisation problem, by creating surrogate models, will be discussed. The first type of surrogate model is derived from GEMs, where the yield of a product is only dependant on the selected substrate. The second are derived from community models where the yield is dependent on external influences (e.g., pH) other than the type of substrate.

### 2.1. Workflow

A flowchart to incorporate the 2 types of structured models into a superstructure optimization problem is shown in Figure 1. The goal of this flowchart is to find a mathematical expression (i.e., a reaction equation) that can be used in a superstructure optimisation problem, starting from a community model or a GEM. These reaction equations represent the chemical transformation of mass, hence linking the inputs to the outputs (i.e., a yield) of the bioreactors.

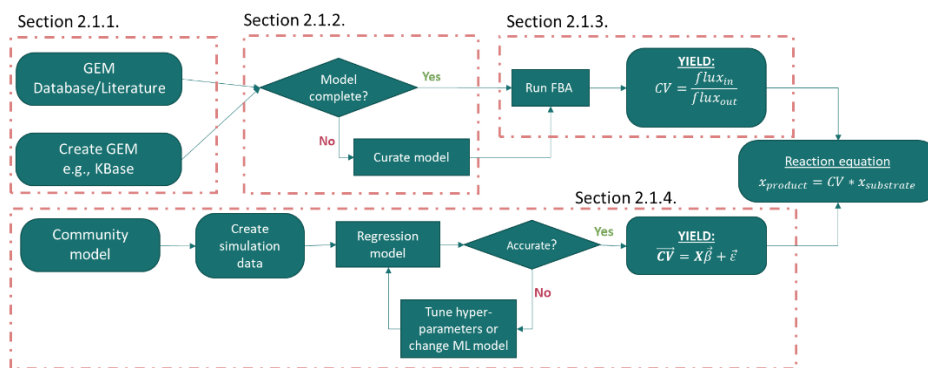

Figure 1. Flowsheet to make reaction equations (i.e., surrogate models) from structured models for superstructure optimisation problems

#### 2.1.1. Making/finding GEMs

To generate a GEM of a particular microorganism(s), software tools and genetic data available on platforms such as KBase and MetaNetX can be used, which enable the creation of metabolic network reconstructions (Arkin et al. 2018). Alternatively, already existing GEMs can be downloaded from databases such as BiGG Models, BioModels, or published work in literature.

### *2.1.2. Validating GEMs*

Many GEMs often lack the required quality to be used reliably and need to undergo a quality assurance and further manual curation. Here the software tool MEMOTE which is an open-source software, representing a unified approach to ensure the formally correct definition of GEMs, was used to check the quality (Lieven et al., 2020). The criteria used to assure the quality of the GEMs are the following: 1) the percentage of metabolic reactions where the chemical elements are correctly balanced; 2) the percentage of metabolic reactions that have a correct charge balance; 3) the percentage of dead-end metabolites (i.e. internal metabolites which do not participate in the internal metabolism); and 4) a leak test, which tests if biomass is created without any substrate. If any of the criteria are not met, the model must be manually curated. For this curation the reader is referred to the work of Thiele & Palsson (2010).

The percentage of correct mass and charge balanced reactions should obviously be as high as possible. In this work a threshold of 95% of correctly mass and charge balanced reactions is chosen as a selection threshold for GEMs. This threshold was taken to minimise the time needed to curate models, as manually correcting the reactions is a very time-consuming procedure. The percentage of dead-end metabolites should be kept as low as possible but are not *per se* indicators of low-quality models. However, a large proportion of dead-end metabolites (e.g., >50%) may indicate problems in reconstruction that need solving.

All non-balanced reactions and the dead-end metabolites need to be checked, and manually corrected if they take part in essential reactions (i.e., essential for the formation of a product). Finally, models producing biomass without substrates indicate an incorrect model formulation and need to be checked thoroughly.

### *2.1.3. Incorporating GEMs into the superstructure problem*

For GEMs, yields are found by solving a flux balance analysis (FBA). An FBA returns the flux of all the metabolites flowing through the metabolic network at steady state (Orth et al., 2010). Using the flux data from the model solution, yields are determined as the ratio of the produced extracellular metabolites and the substrate.

### *2.1.4. Incorporating community models into the superstructure problem*

For community models where the yield is dependent on environmental influences, machine learning (ML) techniques can be used to find simplified algebraic relationships between the yield and the operational variables (e.g., varying pH) (Vollmer et al., 2022).

To create the data needed to calibrate such models, simulations need to be run under varying operational conditions, hence covering the input space. With this data, polynomial equations describing the yield are fitted using lasso regression. This regression technique is used because it effectively avoids overfitting and has a simple algebraic formulation which can easily be handled by superstructure optimization algorithms (such as BARON). To validate the equations, parity plots are made to compare the observed and predicted values of the yields. The normalised mean standard error (NMSE) is also used as a validation metric to make sure the surrogate models reproduce the original model sufficiently. If an insufficient quality of the surrogate model is attained, calibration parameters should be tuned (e.g., the hyperparameter  $\alpha$  determining the degree of regularisation) or the number of polynomials can be changed. If the obtained model still does not sufficiently reproduce the original model, a different ML technique should be used (Vollmer et al., 2022).

## 2.2. Superstructure model

The objective, the flow of mass and logic rules (i.e., the selection of a path in the process network) of the superstructure are represented as mathematical equations (Eq. 1 to Eq. 6):

$$\begin{array}{lcl} \max f(x, y) & (1) & \left| \quad g(x, y) \geq 0 \quad (2) \quad \right| \quad h(x, y) = 0 \quad (3) \\ x \in X & (4) & \left| \quad x^{LO} \leq x \leq x^{UP} \quad (5) \quad \right| \quad y \in \{0; 1\}^n \quad (6) \end{array}$$

where  $f$  is the objective function (e.g., maximising profit),  $x$  is the vector of continuous variables representing operating variables (e.g., the flow of mass) defined by their lower and upper bounds  $x^{LO}$  and  $x^{UP}$  in a continuous feasible region  $X$ ,  $y$  is the vector of binary variables representing the selection of a unit-process,  $g$  and  $h$  are the vectors of inequality and equality constraints, representing the process models and process specifications of a unit process. The equations for the process models are represented by generic process intervals. Every interval in the superstructure is modelled with the same set of generic equations, representing a sequence of processing tasks, namely mixing, reaction, waste removal and product separation, as well as utility consumption (Bertran et al. 2017). The reaction equations are mass conversions between inputs and outputs to a reaction step and are represented by the surrogate models of the structured models.

## 2.3. Case study

The goal of this simplified case study is to find out which type of microbial culture(s), producing propionate and acetate, can generate the largest profit from 2 alternative feedstocks being fructose or glucose. Here 5 different *Propionibacterium* species (*P. acidipropionici*, *P. acnes*, *P. avidum*, *P. freudenreichii*, and *P. propionicum*) and an open fermentation are considered (Figure 2). The surrogate models for the pure cultures are obtained from GEMs from the works of McCubbin et al. (2020), while the open fermentation surrogate model was derived from the bioenergetic model of Regueira et al. (2020). All the cultures use either glucose or fructose as substrate, except for the bioenergetic model that can only consider glucose. In this example, the profit is defined as the revenue generated through sales of the products (i.e., acetate and propionate), minus the operating cost being the cost of raw material (i.e., glucose and fructose). The wholesale prices of the raw materials were found on SELINA WAMUCII (<https://www.selinawamucii.com>) while the wholesale prices for the products were found on ECHEMI (<https://www.echemi.com>). Furthermore, logic constraints were defined to ensure the selection of only one substrate and one type of culture. To further simplify the case study, no utility consumption, waste removal or mixing was considered, and product separation is assumed to be perfect after all reactors.

The formulation of the superstructure was created using PYOMO (version 6.4.2), in the Python environment (version 3.10.1). The formulation of this problem results in a multiple integer non-linear program (MINLP) and was solved using outer-approximation and generalized Benders decomposition (DICOPT) which is accessible through GAMS (GAMS Development Corporation, 2021).

## 3. Results and Discussion

### 3.1. Validating the GEMs

The first step after finding the GEMs from literature, is to assess their quality. The models have been previously curated by McCubbin et al. (2020) and appear to have a good quality where at least 95 % of all reaction are mass and charge balanced. The few metabolic reactions which were not mass or charged balanced were found to not affect essential

reactions producing the products. Furthermore, the percentage of dead-end metabolites are all low (< 5%) and no biomass was created from any of the models without substrate.

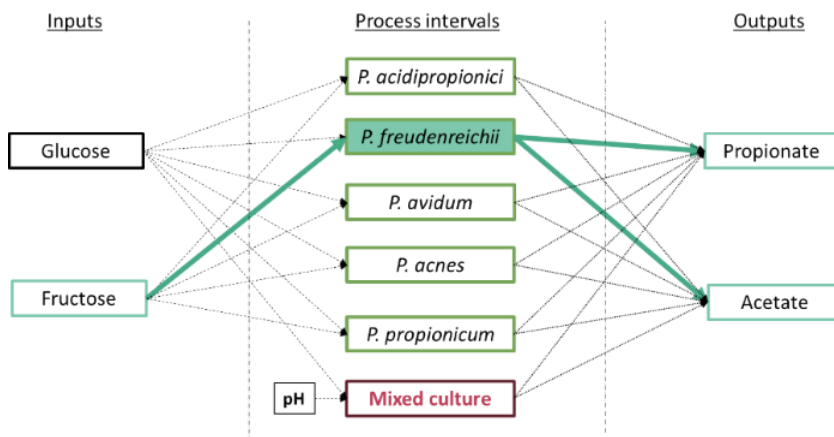

Figure 2. Superstructure representation of the case study. □: process intervals derived from GEMs; □: process intervals derived from community models; → and ■: optimal processing route.

### 3.2. Creating the surrogate reaction models

With the quality of the GEMs assured, the yields can be found (Table 1) by taking ratio of the substrate and product fluxes obtained by solving the FBA for each GEM.

Table 1. Yields (g-carbon<sub>product</sub>/g-carbon<sub>substrate</sub>) of the different substrates (G: Glucose, F: Fructose) and products (P: Propionate, A: Acetate) resulting from the flux balance analysis

Species/yield	P/G	A/G	P/F	A/F
<i>P. acidipropionici</i>	0.32	0.11	0.32	0.11
<i>P. acnes</i>	0.46	0.07	0.48	0.03
<i>P. avidum</i>	0.36	0.05	0.33	0.11
<i>P. freudenreichii</i>	0.34	0.13	0.42	0.16
<i>P. propionicum</i>	0.29	0.15	0.27	0.17

To find the reaction equations for the open fermentation, the bioenergetic model was run to create datapoints of the fermentation outcome at different pH, which were sampled uniformly between 4 and 8.5. Using lasso regression, 5<sup>th</sup> order polynomial equations were obtained to express the yields, with pH being the sole variable of the equations. The NMSE values of the fitted equations were low (0.04 g-carbon<sub>acetate</sub>/g-carbon<sub>glucose</sub> for the yield of acetate and 0.05 g-carbon<sub>propionate</sub>/g-carbon<sub>glucose</sub> for propionate) and the parity plots of the predicted and observed yields closely resemble each other. With these observations it can be concluded that the used regression technique sufficiently reproduces the bioenergetic model and can thus be used in the superstructure model.

### 3.3. Solution of the superstructure

The solution of the superstructure (Figure 2) resulted in fructose being the preferred feedstock with *P. freudenreichii* being the optimal culture to produce acetate and propionate. In this process network 100 kg-C of fructose is transformed into 42.45 kg-C of propionate and 15.56 kg-C of acetate resulting in a profit of 32.39 €.

#### 4. Conclusion

A workflow to incorporate structured models into superstructure optimization problems was developed and successfully showcased using a simplified/conceptual case study. With this workflow more intricate superstructure problems can be defined (starting from different available feedstocks) which can result in the design of novel biorefineries. More specifically this workflow allows for a screening of different microbial cultures in biorefinery designs. This includes open fermentations which are key to handling complex substrates in a biorefinery design.

## Abstract

Millions of tonnes of silicon are produced each year as part of a global supply chain supporting the manufacture of steel, automobiles, electronics and silicones. However, the supply chain does have its challenges – particularly the high energy intensity of silicon purification methods, and the lack of global supply chain diversity. Consequently, this study investigates the benefit of producing high purity silicon metals (>98 wt% Si) from agricultural biomass wastes from an environmental perspective using Life Cycle Assessment methodology. Taking rice husk as a case study, findings show a reduction in carbon emissions is achievable for co-recovery of silicon with bio-energy. The robustness of these findings is also addressed through uncertainty modelling, which provides further confidence in the major findings. Future agricultural sources of biomass-derived silicon have also been projected for staple crops including corn, sugarcane and wheat.

**Keywords:** silicon, rice husk, life cycle assessment, global warming potential, uncertainty.

## 1. Introduction

8.5 M-tonnes of silicon is produced annually to meet demand for iron alloys in the steel industry, aluminum alloys in the automotive industry, semiconducting materials for electronics products, and a range of wider industrial products such as silicones, silicon carbide and silanes (USGS, 2021). Consequently, a large silicon supply chain (SSC) exists to meet global demand by recovering silicon from mineral deposits of silica (SiO<sub>2</sub>). However, the SSC has its challenges. First, mineral excavation introduces a range of environmental impacts. Second, commercial methods for silicon refinement are energy intensive (Maurits, 2014), making sectoral decarbonization challenging. Third, the SSC lacks diversity as ~70 wt% of global production comes from China alone (USGS, 2021). For these reasons, gaps exist for the development of the economic and environmental sustainability of the SSC. One way this could be achieved is by using biomass-derived silica (bSiO<sub>2</sub>) as a substitute for mineral-derived silica (mSiO<sub>2</sub>). This appeals as it: 1) avoids mineral excavation, 2) provides a pathway for decarbonizing the energy used in silicon purification (via bio-energy co-recovery), and 3) promotes SSC diversity.

Yet, the benefit of using bSiO<sub>2</sub> to produce bio-derived silicon (bSi) is still unknown. Consequently, this work provides the first evaluation of that benefit from the perspective of carbon emissions reductions. Reflecting the SSC, three purity grades of silicon are considered – metallurgical grade (MG-Si), solar grade (SG-Si) and electronic grade (EG-Si). Rice husk-derived bSiO<sub>2</sub> (RH-bSiO<sub>2</sub>) is used as a case study due to its production volume (100s of Mtonnes per year), the availability of relevant impact models

(Errington et al., 2022 and 2023), and because it may be considered an agricultural waste product.

## 2. Overview of the Silicon Supply Chain

Global demand for silicon comes from the functionality that it provides to wider products. Consequently, the SSC involves intermediate products concerning mainly industrial actors. Thus, silicon materials are often categorised based on their purity by weight (wt%). This includes: ferrosilicon (>50 wt%), MG-Si (>98 wt%), SG-Si (>99.9999 wt%), and EG-Si (>99.9999999 wt%) (USGS, 2022; Chigonodo, 2018) - see Figure 1.

Of the 8.5 Mtonnes produced, approximately 70% (5.95 Mtonne) is used in the production of ferrosilicons, with the remainder (2.55 Mtonne) being used for silicon metals (USGS, 2022). Recent statistics suggest as much as 21% of silicon metal use (0.54 Mtonne) may be attributed to the combined production of polycrystalline silicon (p-Si), EG-Si and SG-Si – with the remainder (2.01 Mtonne) finding use as MG-Si in aluminium alloys, silicones and other products (USGS, 2019).

Figure 1: A summary of the major categories of silicon as considered within this work.

## 3. Agricultural Biomass as a Source of Silicon

Many investigations have reported over the past 40 years on the recovery of silicon dioxide from agricultural biomass. This has included a strong focus on rice husk (RH) – a natural waste from Rice Grain Agriculture (RGA) – due to its high silica content. Accordingly, the present authors have recently reported a model for assessing the environmental impact of RH-bSiO<sub>2</sub> in a process including RH combustion for co-recovery and use of RH bio-energy (Errington et al., 2022 and 2023). Having found a potential environmental benefit for such a method, and given the high purity (>90%) of RH-bSiO<sub>2</sub> typically produced, it seems a logical extension that bSi may be produced by using RH-bSiO<sub>2</sub> as a feedstock by extending the method as is summarised in Figure 2.

Figure 2: The process for recovery of silicon using rice husk biomass as a resource.

## 4. Method

This work aims to evaluate the benefit of producing MG-Si, EG-Si and SG-Si from bSiO<sub>2</sub>. The “benefit” has been defined based on greenhouse gas emissions reductions associated with producing each grade of Si from bSiO<sub>2</sub> instead of mSiO<sub>2</sub>. This has been done using a Life Cycle Assessment (LCA) methodology to: 1) assess the environmental impact of individual mSi and bSi silicon metal products, 2) calculate the benefit of bSi by

comparison of mSi and bSi material impact predictions, and 3) quantify the uncertainty associated with each benefit prediction. Further information on methods is given below.

#### 4.1. Impact Assessment: Life Cycle Inventories and Impact Characterisation Factors

A summary of the scope and relationship of Life Cycle Inventories (LCIs) for silica and silicon products considered is shown in Figure 3. LCIs for each silicon grade produced by existing industrial methods were taken from the Ecoinvent database (v3.6, Allocation at Point-of-Substitution basis). Inventories for RH-bSiO<sub>2</sub> were adapted from models provided by Errington et al. (2023) - in which RH combustion is followed by the recovery of RH-bSiO<sub>2</sub> via the “wet method”. All LCIs were modelled on a global level.

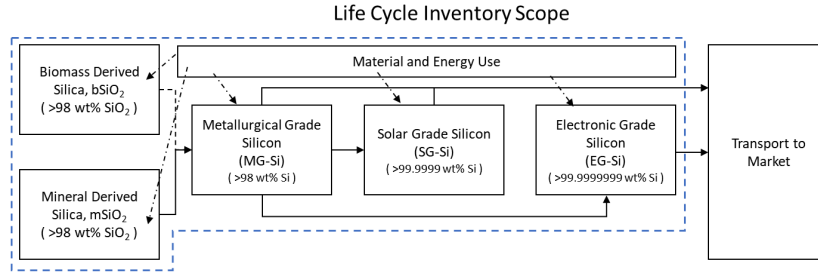

Figure 3: Life cycle scope associated with LCA assessments carried out for the comparison of mineral and biomass derived silicon in this work. Values for energy and material demands are taken from relevant inventories for each metal grade within the Ecoinvent Life Cycle Inventory Database.

The environmental impact,  $EI$  (impact per kg<sub>Si</sub>), of each product was calculated as the sum of impacts from all activities over the entire product life cycle as described by Errington *et al* (2022). Assessment was based on the Global Warming Potential (GWP) of the ReCiPe (H) method (Huijbregts *et al.*, 2017) using calculation cut-off of 0.1%.

##### 4.1.1. Calculation of the Benefit of bio-derived silicon (bSi)

The benefit of bSi production,  $B^{bSi}$  (GWP/kg) was calculated by region based on the assumption that bio-energy co-recovered during bSiO<sub>2</sub> production,  $\hat{Q}^b$  (MJ/kg<sub>Si</sub>), was used to substitute for local electricity in a region with an associated environmental impact,  $EI^e$  (GWP/MJ) – see Equations 1 and 2. Benefits were also converted to a decarbonization extent,  $D^{bSi}$  (%), using Equation 3.

$$B^{bSi} = EI^{bSi} - \hat{Q}^b EI^e \quad (1)$$

$$\hat{Q}^b = (\eta^{BC} / \eta^{SR}) \times [(\hat{Q}^{LHV} (1 - x^{H_2O}) - \lambda x^{H_2O}) / x^{SiO_2} (1 - x^{H_2O})] \quad (2)$$

$$D^{Si} = B^{bSi} / EI^{bSi} \quad (3)$$

Where  $\eta^{RHC}$  is the electrical efficiency of bioenergy recovered during combustion (%),  $\eta^{SR}$  is the efficiency associated with recovering usable bSi from a dry biomass feedstock (%),  $\hat{Q}^{LHV}$  is the lower heating value of the biomass used (MJ/kg<sub>feedstock</sub>),  $x^{H_2O}$  is the moisture content of the biomass feedstock prior to combustion (wt%, wet basis), and  $x^{SiO_2}$  is the silica content of the biomass used (wt%, dry basis). LCIs for the impact of medium-voltage regional electricity were based on the ecoinvent LCI database (Wernet *et al.*, 2016). Regions Europe, USA, Japan and China were considered as case studies for  $EI^e$  due to the extent of contribution that they currently supply to the SSC.

#### 4.1.2. Quantification of Uncertainty in Impact Predictions

The sensitivity of impact evaluations to uncertainty in LCIs (arising from data quality) was quantified by the pedigree matrix approach - in which, the quality of inventory data was rated against five criteria: reliability, completeness, and temporal, geographic and technological representativeness. Ratings were quantified as log-normal probability distributions based on the method of Frischknecht et al. (2004). Monte-Carlo simulations were used to estimate prediction uncertainty (sample size = 10,000).

## 5. Results and Discussion

### 5.1. Impact Predictions and Implications for Industry Decarbonisation by Region

Predicted environmental impacts of different purity grades of bSi and mSi are shown alongside associated decarbonization extents for Europe, USA, Japan and China in Figure 4. Associated estimates for the regional availability of rice husk and regional demands for silicon metal are shown in Table 1.

Figure 4: Impact predictions for producing 1 kg of mSi and bSi (left) and the decarbonization expected from a transition to production of bSi (right). Error bars represent a 99% prediction interval.

Table 1: Feasible annual supply of bSi and associated decarbonisation extent

Statistic	Europe	Japan	USA	China	World
RH Production <sup>a</sup> (Mtonne)	0.81	1.94	2.06	42.72	151.35
Available RH-bSiO <sub>2</sub> <sup>b</sup> (Mtonne)	0.10	0.23	0.25	5.09	18.02
Benefit of bMG-Si (kg <sub>CO<sub>2</sub></sub> /kg <sub>Si</sub> )	-1.2	-8.1	-14.4	-5.2	-1.2
Benefit of bEG-Si (kg <sub>CO<sub>2</sub></sub> /kg <sub>Si</sub> )	-10.0	-17.7	-24.9	-14.4	-10.0
Benefit of bSG-Si (kg <sub>CO<sub>2</sub></sub> /kg <sub>Si</sub> )	-1.3	-8.6	-15.4	-5.5	-1.3
Silicon Metal Production <sup>c</sup> (Mtonne)	0.37	N.G.	0.09	1.69	2.40
Possible bMG-Si Supply <sup>d</sup> (Mtonne)	0.04	0.09	0.09	1.88	6.67
Possible bSG-Si Supply <sup>d</sup> (Mtonne)	0.03	0.08	0.09	1.77	6.26
Possible bEG-Si Supply <sup>d</sup> (Mtonne)	0.03	0.08	0.08	1.67	5.91

<sup>a</sup> based on paddy production reported by the United Nations Food and Agriculture Organization (UNFAO, 2022) assuming 20 wt% of paddy is RH, <sup>b</sup> based on a mass ratio of 8.4 kg<sub>RH</sub>/kg<sub>SiO<sub>2</sub></sub> reported by Errington et al. (2023), <sup>c</sup> based on values from U.S. Geological Survey (USGS, 2022), <sup>d</sup> based on silica-to-silicon ratios present for each silicon purity grade in the ecoInvent LCI database (Wernet et al. 2016), N.G.: not given

Results in Figure 4 indicate that significant amounts of decarbonization may be expected to occur in all regions where bSi is produced as an alternative to mSi. However, the extent of decarbonization as well as uncertainty in the extent of decarbonization appear to be sensitive to both region and the silicon grade being produced. These correlations are understandable for two main reasons.

Firstly, correlations between the extent of decarbonization and the region considered are driven by differences in the GWP of electrical energy available in each region. This is due to differences in energy generation fuel blends – as shown by Errington *et al.* (2023).

Secondly, correlations between the magnitude of extent of decarbonization and the silicon grade considered (as well as associated uncertainty in the extent of decarbonization) are attributable to differences in the energy demand associated with each silicon grade considered. Particularly, the demand for energy rises significantly more quickly than the demand for bSiO<sub>2</sub> when increasing the purity of a silicon metal. Consequently, the fraction of bio-energy available to offset regional energy use is significantly diminished for EG-Si and SG-Si when compared to MG-Si – causing the magnitude and certainty in decarbonization to also reduce.

Finally, results in Table 1 imply a reduction in carbon emissions of 25 Mtonne<sub>CO<sub>2</sub>-eq</sub> for silicon metal production in the USA and China (both of which show a reasonable extent of certainty in decarbonization in Figure 4). This is equivalent to approximately 0.05% of global greenhouse gases emitted in 2019 (World Resources Institute, 2022). However, the assumption of complete utilization of global RH waste is an unrealistic scenario. Thus, alternate sources of agricultural bSiO<sub>2</sub> are detailed below.

### 5.2. Alternatives to RH for the recovery of bSiO<sub>2</sub> and bSi from biomass at scale

A summary of estimates for the availability of bSiO<sub>2</sub> associated with five possible alternatives to RH for bSiO<sub>2</sub> and bSi is shown in Table 2. These are: rice straw, wheat straw, corn stalk, corn cob and sugar cane straw. Results in Table 2 indicate 88 Mtonne of bSiO<sub>2</sub> may be practically recoverable from a combination of the agricultural wastes of rice, wheat, corn and sugar globally. This equates to more than 10 times the annual demand for silicon metal in the SSC (assuming 3 kg<sub>SiO<sub>2</sub></sub>/kg<sub>Si</sub> based on the LCI of EG-Si), which may act as a more reasonable scenario for recovery of bSiO<sub>2</sub> from waste biomasses.

Table 2: Amounts of bSiO<sub>2</sub> available annually in major agricultural biomass wastes.

Statistics	Rice Husk	Rice Straw	Wheat Straw	Corn Stalk	Corn Cob	Sugar Cane Straw
Global Production <sup>a</sup> (MT/yr)	757	757	761	1162	1162	1870
Product-to-Biomass Ratio <sup>b</sup> (wt%)	20	20	50	50	38	20
Silica Content <sup>b</sup> (wt% dry basis)	20	10	6	3	2	2.4
High Heat Value <sup>c</sup> (MJ/kg)	14	19	19	18	18	14
Moisture Content <sup>b</sup> (wt%)	12	12	7.5	16	16	12
Theoretical bSiO <sub>2</sub> <sup>d</sup> (Mtonne)	27	13	21	15	7	4
Biomass Use (kg <sub>RH</sub> /kg <sub>SiO<sub>2</sub></sub> , wet basis)	8	23	37	81	121	170
Bioenergy Recovery <sup>d</sup> (MJkg <sub>SiO<sub>2</sub></sub> )	22	86	144	269	403	298

<sup>a</sup> based on 2020 crop production reported by the United National Food and Agriculture Organisation (UNFAO, 2022), <sup>b</sup> assumed values, <sup>c</sup> assumed values, <sup>d</sup> based on a 69% mass recovery efficiency as reported by Errington *et al.* (2023) for RH and assuming a conservative recovery efficiency of 49% (i.e.  $\eta^{SR} = 0.49$ ) for other crops.

### 5.3. Financial Incentives for using bSiO<sub>2</sub> as an alternative to mSiO<sub>2</sub>

Assuming a cost of 100 and 250 \$ tonne<sup>-1</sup> for RH and mSiO<sub>2</sub> respectively, the effective cost of RH-bSiO<sub>2</sub> (800 \$ tonne<sup>-1</sup>, scaled based on “Biomass Use” in Table 2) is larger than that of mSiO<sub>2</sub>. However, the value of co-recovered RH-bSiO<sub>2</sub> bioenergy (22 MJ kg<sub>bSiO<sub>2</sub></sub><sup>-1</sup>, Table 2), equates to 5148 \$ tonne<sub>RH-bSiO<sub>2</sub></sub><sup>-1</sup> - assuming a 0.065 \$ MJ<sup>-1</sup> grid energy cost, EU Commission (2023). Thus, estimates suggest that the cost of RH-bSiO<sub>2</sub> is compensated for in a grid energy substitution scenario. Future work should better account for bioenergy co-recovery costs and different energy substitution scenarios.

## 6. Conclusion

In conclusion, this work aimed to assess the benefit of using biomass-derived silica as an alternative feedstock in production of silicon metals. This has been achieved using rice husk as a biomass case study and led to three main findings. Firstly, results show that a benefit is expected for all silicon grades considered. However, the extent of decarbonization is sensitive to the grade of silicon produced and the region in which it is produced. This is due to differences in the energy required for each grade of silicon, fuel sources used to produce regional energy, and the fraction of energy replaced with co-recovered bioenergy. Secondly, results show a transition to biomass-derived silicon could reduce global emissions by ~25 Mtonne per year (i.e. ~0.05% of global annual carbon emissions), which is driven by the yearly volume of metallurgical grade silicon (2 Mtonne). Finally, preliminary estimates show that as much as 10 times the current demand for silicon metals may be accounted for from agricultural products of rice, wheat, corn and sugarcane. Findings of this study generate new insights into the resource recovery potential from agriculture biomass and sustainable development of the SSC.

## Abstract

In this study, a technoeconomic and Life Cycle Assessment (LCA) methodology was developed to identify the best compromises between costs and environmental performance of an integrated mRNA vaccine production plant. The plant-wide simulator was obtained and adopted from the literature which helped generate the technoeconomic data along with the life cycle inventories. The LCA was developed using SimaPro software based on the Ecoinvent database and ReCiPe 2016 method. A prediction tool based on artificial intelligence was used to estimate the environmental footprint of several raw materials. A base case scenario helped identify the environmental hotspots which laid the ground for a new set of scenarios to explore ways to lower the overall environmental footprint. Consequently, several recycles were implemented which helped reduce the endpoint categories by up to 10% while reducing the operating expenditures by 13%. The results gave key insights into the optimization of mRNA vaccine production and waste minimization.

**Keywords:** Plant-Wide Simulator, mRNA vaccine, Life Cycle Assessment (LCA), Technoeconomic Assessment, Recycles.

## 1. Introduction

Over the last few years mRNA technologies have gained a resurgent interest, due to recent technical advances and growing industrial investment putting mRNA vaccines in the position to substitute protein based conventional vaccines. Compared to the conventional vaccines, such as live attenuated and killed virus vaccines, subunit, and DNA-based vaccines, mRNA vaccines are safe, more efficient, and can be produce at large scales (Pardi et al., 2018). The upstream processing of mRNA vaccines is relatively straight forward and exhibits less sources of variability compared to cell-based vaccines. Furthermore, mRNA vaccines production process requires smaller bioreactors (from 30 L to 50 L) compared to cell-based vaccines where typically 2000 L bioreactors are required. With a relatively smaller production scale reduced facility footprints, the capital costs of the mRNA plant may be much lower. In addition, mRNA plants are flexible and versatile and can be rapidly deployed to produce new vaccines to responded for new variants, because different RNA sequences that used into different vaccines can be produced in the same process (Pardi et al., 2018). However, the production of mRNA requires complex recipes and a large set of raw materials, excipients and solvents which may exhibit significant environmental impacts.

The new mRNA vaccines played a prominent role during the covid-19 pandemic. The global mRNA production capacity is skyrocketing and is expected to exceed 8 billion doses per year (Kis et al., 2021). Consequently, it is a crucial time to evaluate the available performance compromises, which include the economic, quality and environmental

criteria, to make well informed decision at this early stage of a new era of mRNA vaccines. Flowsheet and plant wide models are critical in all design stages to help identify the most economic and environmentally friendly options optimize process operation and develop plant wide control strategies (Benyahia et al, 2012; Benyahia 2018; Ramin et al., 2018).

This work is focused on the technoeconomic and Life Cycle Assessment (LCA) of an integrated end-to-end mRNA production plant. The plant-wide simulator was obtained and adopted from the literature (Kis et al., 2021). It is worth emphasizing that process data are still very scarce and so are the environmental data associated with the chemicals, and raw materials. Here, the environmental footprint of the chemicals not available in the data bases were estimated using artificial intelligence-based methods (Wernet et al., 2009). Firstly, a base case LCA was conducted to identify the environmental hot spots which informed on the best opportunities for the implementation of recycles and resulted in 2 new design alternatives. Additional LCA were conducted for the new scenarios along with inherent economics to help evaluate and compare the performance of different design alternatives.

## 2. Material and Methods

### 2.1. Process description

The process was modelled and simulated by using SuperPro Designer V10. The initial SuperPro simulation version was obtained from the literature (Kis et al., 2021) then adopted to the current needs. The mRNA vaccine production process starts with a biochemical reaction called *in vitro* transcription where the mRNA is synthesized, with a series of additions of raw materials including different nucleotides, DNA templates and enzymes to the bioreactor as shown in the upstream processing in Figure 1. This is followed by a series of separation processes to purify the solution and sperate solid and liquids. Firstly, a tangential flow filtration (TFF) along with diafiltration unit is applied to remove RNA fragments, with the ultrafiltration membrane size of 500 kDa and KCl buffer to wash the filter to increase the efficiency. This stage is followed by a chromatography unit which separates the content based on size, total charge, surface hydrophobic groups. After the chromatography unit, another TFF unit is used with different buffer sodium citrate followed by sterile filter to prepare the formulation step. Finally, the mRNA is encapsulated within lipid nanoparticles (LNPs) to deliver the final injectable suspension.

### 2.2. Life cycle assessment

LCA is a holistic approach that can be used to capture the environmental footprint of a process, a product or a service across its life cycle. It provides a comprehensive tool to evaluate the environmental burdens based a large set of impact indicators referred to as midpoint and endpoint categories which are far beyond the capabilities of the green engineering metrics. Here, a gate-to-gate approach is used to evaluate different design and recycle options. The LCA requires the inventory data which can be obtained from the simulators under different scenarios. The implementation of the LCA requires 4 key steps namely:

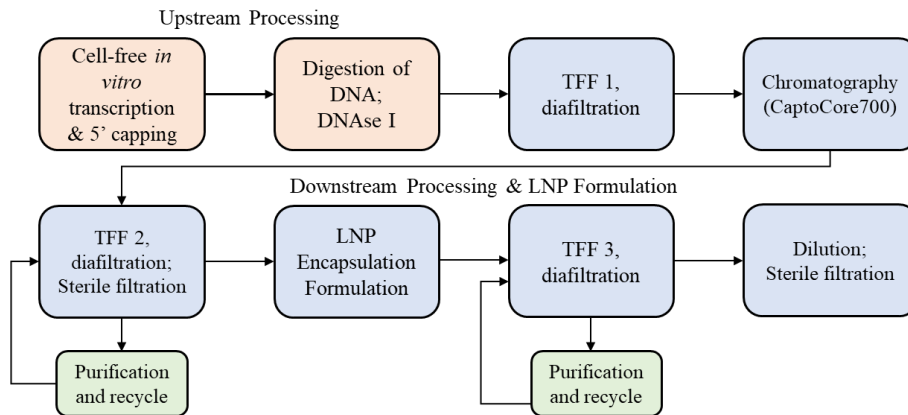

Figure 1. Simplified mRNA plant wide flow diagram (Kis et al., 2021) with recycles.

- *Goal and scope*

Here, the first objective is to perform a LCA for the base case mRNA vaccine production process using a functional unit of 1 kg of mRNA product. The second objective is to evaluate alternative designs by implementing different recycles.

- *Life cycle inventory*

LCI data were obtained from the plant wide simulation of the process flow diagram above using SuperPro Designer.

- *Impact assessment*

In this study, the impact assessment is based on the method ReCiPe 2016 in SimaPro with Ecoinvent 3, environmental footprint database and European and Danish Input/Output data base. ReCiPe 2016 method has three endpoint categories (human, ecosystems, and resources) and seventeen midpoint categories. These different categories will help compare the different design options.

- *Interpretation of results*

Finally, the results obtained from the previous steps are interpreted and the environmental hotspots are identified.

To capture the environmental footprint of the different processing steps, the plant was divided into six main stages: Upstream processing, first filtration TFF1, Chromatography, second filtration TFF2, Encapsulation, and final filtration TFF3. It should be emphasized that several chemicals used in the process are not available in the Ecoinvent database or any other environmental databases. To address this limitation, a prediction tool, based on machine learning Finechem was used to predict the global warming potential (GWP), cumulative energy demand (CED) and Eco-Indicator 99 score (EI99) based on the chemical structure of the molecules (Wernet et al., 2009). These data were then fed to Simapro to obtain the overall impact results.

The proposed LCA was implemented for the following scenarios:

*Scenario 1: Base case* - the initial design presented in Figure 1 without recycles.

*Scenario 2: TFF2 Recycle.* In this design option, the waste from the second filtration is purified using an ultrafiltration and a distillation unit to retrieve pure solvent.

*Scenario 3: TFF2 and TFF3 Recycles.* Here, the wastes from both hotspots are purified and recycled.

To evaluate the economic performance of each of the scenarios, the operating and capital expenditures/costs (OpEX and CaPex) were estimated by using the built-in tool within SuperPro Designer. The economic data were obtained based on the current plant/equipment capacity and material and energy usage for each scenario.

### 3. Results and Discussions

#### 3.1. LCA results

Figure 2 shows the normalized impacts categories for each of the 6 processing stages in the base case scenario. The second tangential flow filtration stage (TFF 2) exhibits the largest contribution in all impact categories. This can be explained by the large amount of solvent used and wastes generated at this stage along with large quantities of sodium citrate which is used as a buffer to adjust the pH of the product solution. The second largest contribution is associated with the diafiltration (TFF3) followed by the encapsulation. These results clearly confirm the environmental hotspots and justify the alternative scenarios based on different recycle options.

#### 3.2. Assessment of scenarios with recycles

As described above, TFF2 is the most important environmental hotspot among all stages. To purify then recycle the waste stream TFF2, a filtration and a distillation unit are proposed and integrated to the flowsheet simulator in SuperPro designer. The reason to choose these units is that in this stream the objective is to recycle pure sodium citrate, so the first ultrafiltration is used to desalt the solution and remove waste RNA transcripts by adding water as solvent to wash the waste. This step is followed by a distillation unit used to separate water and sodium citrate. TFF3 is the second hot spot based on the base case LCA results. In this case, a new recycle scenario is proposed to remove lipids left from encapsulation process and desalt the waste solution to retrieve the buffer from the waste.

With the new recycle scenarios associated with TFF2 and TFF3 process, the LCA were conducted. The corresponding midpoint and endpoint indicators along with the cost

Figure 2. Normalized midpoint categories for the base case scenario.

performance are summarised in Figure 3. Compared to the base case, both recycle scenarios exhibit dramatic reduction in all midpoint categories particularly, the global warming, stratospheric ozone depletion, and land use (Figure 3a). When comparing both recycle seniors, their performances are close with a visible advantage for the senior with combined recycles particularly on the freshwater eutrophication impact category.

The economic performance indicators along with endpoint indicators are shown in figure 3b. Again, the environmental advantages of both recycle scenarios are clear. Although both recycle scenarios require increased capital expenditures associated with the waste purification and recycle equipment, their operating expenditures are reduced by nearly 8% and 13% respectively for the simple and combined recycles respectively. This is a very important outcome which clearly highlights the advantages of the recycle far beyond the environmental consideration and confirms the practicality and feasibility of the recycles in pharma and biopharma which are both notorious for their costly chemicals and additives.

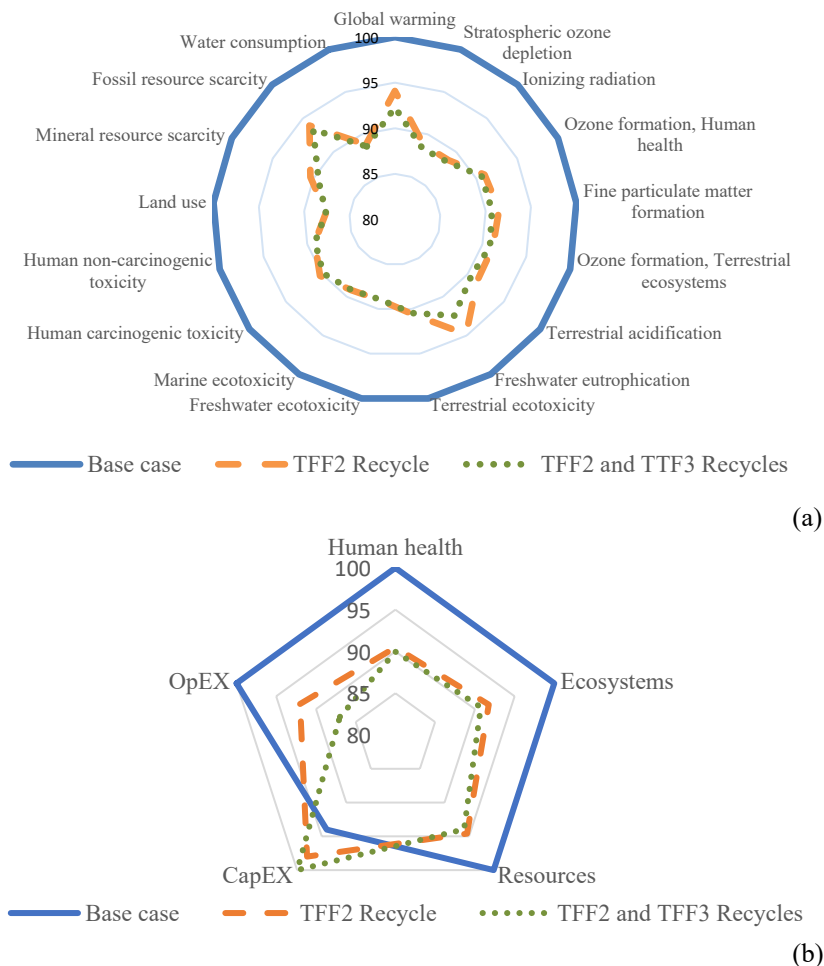

Figure 3. Summary of the environmental and economic key performance indicators for all scenarios. (a) Midpoint indicators. (b) End-point indicators and economic criteria.

#### 4. Conclusions

A technoeconomic analysis and Life Cycle Assessment of a COVID-19 mRNA vaccine production plant was developed. The integrated end-to-end mRNA simulator was developed in SuperPro designer. A first LCA was conducted using the base case scenario to identify the hotspots, based on which new designs with recycles were proposed and simulated. Consequently, new inventory and economic data were obtained for the proposed new designs which helped build new LCA and economic evaluations. As expected, the recycles reduced dramatically the environmental footprint of the process which translates into a decrease in the endpoint indicators, namely human health, ecosystem and resources, from 6% to 10%. Most importantly the results show that the implementation of recycles can also reduce the operating expenditures by up to 13% making the whole process more viable and more environmentally friendly. These results highlight the benefits of the recycles in pharma and biopharma which allows recycling precious or very expensive pharma grade chemicals and reduce inherent wastes. These benefits can be even more important when the production scale or the number of batches is large which is true for the current mRNA vaccine production plants.

### Abstract

Population growth has advanced by leaps and bounds, which has caused the agricultural sector to see the need to meet this demand. Conveniently, the practices of the agro-industrial sectors have directly affected natural resources. Within the discharges from agro-industries, they are mainly conditioned by pollutants with organic and inorganic compounds, being the objects of study of the present investigation organic waste because they are a potential source that compromises human health. In such a way that, the purpose of the present investigation consisted of collecting residues from strawberry and mango agro-industries in Zamora-Jacona, Michoacán, Mexico, such residues were synthesized as biodiesel and were characterized by Fourier transform infrared spectroscopy (FT-IR) and UV-VIS, so it was possible to identify absorption bands, corresponding to the functional groups, which are similar to those of hydrocarbons. Thus, it is concluded that the conversion of agro-industrial remnants can be used in the field of biofuels.

**Keywords:** biodiesel, agroindustry, remnants.

### 1. Introduction

Mexico is one of the main producing countries of both strawberries (*Fragaria spp*) and mango (*Mangifera indica spp*), with the central region of the country being the area with the highest production, this is due to the fact that they were produced in 2016, 468.25 and 1.89 million tons respectively of these fruits, and it is estimated that by 2030 production will increase between 26 and 42% (SAGARPA 2016).

Berries, strawberries or forest fruits, refer to the various fruits of different botanical groups, which are characterized by their short shelf life. They tend to be small, tart-sweet, juicy, and brightly colored, making them very attractive to eat. The production of berries at the national level is concentrated in four states, highlighting the state of Michoacán as the most important producer, followed by Baja California, Jalisco and Guanajuato. The country exported close to 1,000 million dollars of fresh berries to the world in the 2015, which projects this group of fruits as one of those with the greatest growth potential in the agricultural sector (González et al 2019).

In the case of the present investigation, the site of interest focuses on 2 municipalities in the state of Michoacán, which are Zamora and Jacona, since they are the main producers of berry and mango crops nationwide. In such a way that the objective was to elaborate the synthesis of biofuels from the organic waste material generated by agro-industries of Zamora and Jacona of the State of Michoacán de Ocampo.

## 2. Case study

### 2.1 *Geographical characteristics of Zamora-Jacona*

Zamora R., & Salazar in 2019, describe in their manuscript that the municipality of Zamora is among the 6 most important in the state of Michoacán, because it produces 4.6% of the total gross production. It has a population of 170,748 inhabitants (4.3 percent of the total population), of which 26,997 are employed persons, with 6,778 economic units. The city represents one of the three conurbations of the state; Zamora-Jacona-Tangancicuaro. One of the great advantages that Zamora has in strawberry production is its proximity to several of the main trade distribution points nationwide, such as the markets of the Federal District. In addition to its proximity to several of the freezing and packing companies that are involved with the strawberry agro-industrial activities, located mainly in the cities of Irapuato and Celaya, they are also dedicated to freezing and storing strawberries, located in several trading and industrializing companies' leaders in the export of strawberries.

### 2.2 *Contaminating sources of strawberry and mango crops*

At present there is an indiscriminate demand for the consumption of different fruits, among them red fruits stand out, unfortunately high amounts of waste materials produced by these fruits are produced annually.

Fraire-Cordero M., et al (2003), carried out an investigation whose purpose was based on identifying pathogenic fungi in strawberry fruit and their relationship with varieties and the cultivation system, five postharvest samplings were made: three in the region of Zamora, Michoacán, México, in December 2001, and in February and May 2002, in the *Camarosa* and *Aromas* varieties, cultivated with the traditional system, and with plastic cover. In their research they describe the identification of nine pathogenic fungi which were identified from national and imported fruit: *Aspergillus*, *Botrytis*, *Colletotrichum*, *Geotrichum*, *Mucor*, *Penicillium*, *Pestalotiopsis*, *Phytophthora*, and *Rhizopus stolonifer*; and more than eight saprophytic fungi.

Estrada-Loera et al (2018), carried out various samples in mango crops, subsequently carried out microbiological tests, thus in this study they allowed to identify the presence of *Klebsiella spp*, and non-enterohemorrhagic *E. coli*.

Due to the aforementioned, waste from agro-industries is produced, which have different places where they are stored and if they do not have an appropriate treatment, they are a potential source of microorganism reservoirs and these, in turn, can compromise human health. In this way, the purpose of the investigation lies in identifying freezers in the Zamora-Jacona region and sampling the generated waste so that it can be converted into a biofuel.

## 3. Methodology

For the development of the present investigation, it was divided into 4 stages, which consist of: 1) identification of agro-industries, 2) sampling of strawberry and mango agro-industrial residues, 3) extraction of essential oils and obtaining biodiesel, and 4) characterization of oils and biodiesel

*Stage 1.* Identification of agro-industries. Agro-industries that process and distribute strawberry and mango were identified in the municipalities of Zamora-Jacona, Michoacan, Mexico.

*Stage 2.* Strawberry and mango remnants from agro-industries were collected, where they were considered: strawberry pulp and stem, on the other hand mango seeds were collected, the raw material was stored in sterile plastic bags, later they were transferred to a desiccator (Novatech), with the aim of dehydrating the biomass.

*Stage 3.* Extractions of essential oils. For the development of this stage, an adaptation was made to the methodology proposed by Sánchez I. & Huertas K. (2012), which consisted of: 1) dehydrating the biomass of both fruits, 2) grinding the mango seeds and the dehydrated strawberry pulp, and 3) the soxhlet method (KIMAX brand) was used, which consisted of pouring 200 ml of isopropyl alcohol (MEYER), subjecting it to a constant temperature and stirring of 300°C and 1,400 rpm, for 15 cycles. Afterwards, a rotoevaporator was used to separate the solvent from the essential oil and finally the transesterification method was carried out, which was carried out by centrifuging the essential oil for 30 minutes at 6,000rpm and eliminating the degumming or residues to be able to be mixed with the concentration. to 1% of the potassium iodide solution (Reasol brand) with an addition of 3% (p/p) of distilled water and place on the grill to keep stirring for 30 minutes at 60°C to finish it was brought to the centrifuge at 6,000rpm for one hour.

*Stage 4.* Characterization of biodiesel. Biodiesel was characterized by Fourier transform infrared spectroscopy (FT-IR), Perkin Elmer Frontier model in the 4,500-400cm<sup>-1</sup> region and by Perkin Elmer Lambda 25 model UV-VIS spectrophotometry, in the absorbance region of 300-800nm.

#### 4. Results and discussions

Sampling points for agro-industry waste were identified. Once the samples were prepared, the fruits were taken to the drying oven, in which they were dehydrated with the aim that a biomass screening could be carried out (Fig. 1).

Fig.1. Fruits considered as waste in agro-industries in Zamora-Jacona. a) Decaying fruits of *Mangifera indica spp*, b) Decaying fruits of *Fragaria spp*. and c) Screening for *Mangifera indica spp*.

Subsequently, the extraction of essential oils was carried out (Fig. 2), carrying out an adaptation to the methodology proposed by Sánchez I. & Huertas K. (2012). It started by obtaining essential oils using the Soxhlet method (Fig. 2a and 2b), having the essential oils biodiesel was synthesized (Fig. 2c) which was subjected to refining with the purpose of reducing impurities (Fig. 2d).

Once the biodiesel was obtained, it was characterized by both UV-VIS and FT-IR (Fig. 3 and Fig. 4). Regarding the characterization by UV-VIS, the band corresponding to the reading of mango biodiesel (MD2), presents a greater intensity and absorbance, compared to the band of strawberry biodiesel (FD2), this is attributed to the fact that in the upper part mango seed stores a greater amount of oil.

Fig. 2. Conversion of essential oils to biodiesel. a) and b) Essential oil of *Mangifera indica* spp and *Fragaria* spp, c) and d) Refined biodiesel.

Fig. 3. UV-VIS characterization of strawberry (FD2) and mango (MD2) biodiesel.

Regarding the characterization by FT-IR (Fig.4), it was possible to identify the functional groups, characteristic of the absorption bands of strawberry biodiesel, within the identified groups are: OH, CH<sub>2</sub>, CH and PH.

In the same way, a proposal was developed where this technology can be migrated on an industrial scale, for which the design at the industry level is proposed (Fig. 5).

Fig. 4. FT-IR characterization identify the absorption bands of strawberry biodiesel

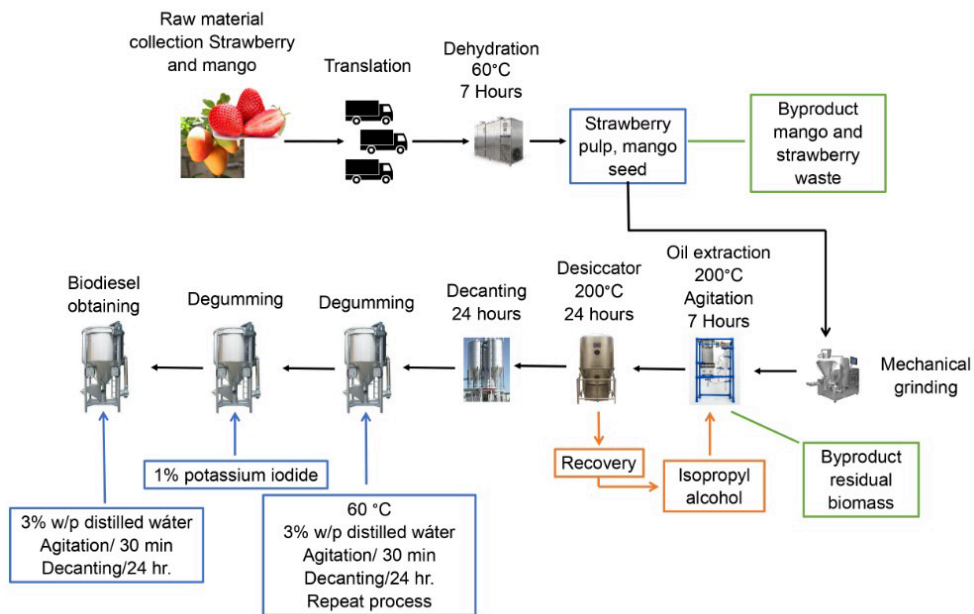

Fig. 5. Biodiesel production scheme from agro-industry remnants.

In the year 2021 the state of Michoacan had a production of 180,871.84 tons of mango, for the proposed methodology only the residual part due to the processing of the fruit is considered, in the case of mango only the interior seed that corresponds to 17.5% is considered of the fruit. In this sense, considering mango production, there are 31,652.57 tons of residual biomass. Based on the data obtained at the experimental level and the process proposed in Fig. 5, it is possible to obtain  $7.0339 \times 10^5$  Lt of biodiesel. In the case of strawberries, in 2021 a production of 326,191.10 tons was obtained, in this case the largest amount of the fruit is pulp, so the residual biomass obtained during

processing corresponds to 10% of the total available. Therefore, a total of 32,619 tons of residual biomass is available. From this flow, it is possible to obtain a total of  $1.63 \times 10^5$  Lt of biodiesel. Through the residual biomass it is possible to obtain a total of  $8.664 \times 10^5$  Lt of biodiesel, considering an approximate price of \$1 dollars, a profit of  $\$8.664 \times 10^5$  USD.

## 5. Conclusions

The remnants generated in the agro-industries can be possible sources of infection for society, in such a way it is necessary to identify ways of using such residues, in this way the alternative of using the obtaining of biofuels and these biofuels can be used by society. The highest yield and production of biodiesel occurs in the mango; this is due to the fact that a greater amount of residual biomass is generated during its processing. The strawberry presents a considerable production, since it is one of the fruits with the highest production and demand in Mexico.

Instrumentation, Rua XV de Novembro 1452, 13560-970, São Carlos, SP, Brazil.

## Abstract

The purpose of using Life Cycle Assessment (LCA) in this work was to evaluate the cellulose nanocrystals (CNCs) production in sugarcane biorefineries, identifying hotspots that can direct to process design changes to reduce environmental footprint. Modeling and simulation of an incremental unit for CNCs production from sugarcane bagasse (the main residue from the sugarcane industry) was carried out. In order to proceed the LCA, an inventory of raw-materials, products and emissions was made. The analysis employed the cradle-to-gate approach. The Global Warming Potential (GWP) metric was estimated using the SimaPro<sup>®</sup> software and using the EcoInvent v.3.3 database. LCA results showed that daily production of 7.73 ton of CNCs occurred with accumulated GWP of 23.6 tons of CO<sub>2</sub> equivalents. Ethanol from organosolv pretreatment, sulfuric acid from hydrolysis, and sugarcane bagasse burning for steam and energy generation were the main contribution inputs for GWP. An estimated GWP of 0.23 kg of CO<sub>2</sub> equiv. per kg of dry equiv. CNCs (or 13.43 g of CO<sub>2</sub> equiv. / MJ of process outputs) were accounted after energetic allocation. In other impact categories aside from GWP, the environmental impacts of H<sub>2</sub>SO<sub>4</sub> were generally the most relevant, especially in the abiotic depletion.

**Keywords:** Life Cycle Analysis, Cellulose Nanocrystals, CNCs, Sugarcane Biorefineries.

## 1. Introduction

Life Cycle Assessment (LCA) is a standardized tool to quantify the environmental sustainability performance of emerging technology products along all phases of their life cycles, allowing the comparison of different process designs (ÖGMUNDARSON et al, 2020a; ÖGMUNDARSON et al, 2020b; FOROUGHİ et al., 2021). If the methodology is used during a new product development phase, especially during the process methodology planning, it can indicate the process stages or technologies with the highest environmental impacts, and thus provide a guide for improvements in the implementation of the technology (IBICT, 2014). ISO 14040:2006 and ISO 14044:2006 established a methodological framework for conducting LCA studies.

With the implementation of the carbon credits market, the quantification of the Global Warming Potential (GWP) and of other metrics of environmental impacts have now also a strong impact on investment decision-making, once high environmental impact

production methodologies will be neglected due to environmental and economic aspects as well (ÖGMUNDARSON et al., 2020a). Nanocellulose is an example of an emerging, still under development material for which a reduced environmental impact is expected when comparing to other existing materials (ARVIDSSON et al., 2015; PICCINNO et al., 2018). Cellulose nanocrystals (CNCs) are crystalline and highly ordered materials of small diameter, elongated length, and high surface area whose main applications are as reinforcement in polymeric materials and the applications in biomedicine. Consisting in a high added-value renewable biocomposite, but still in limited availability and presenting low yields of obtainment and isolation, the nanocellulose market is in continuous and strong growth (MARKETS AND MARKETS, 2021).

Due to some challenges such as data unavailability and limitations related to the end-of-life applicability and the solvent recycle treatments in lab-scale processes, there are only a few LCA studies related to nanocellulose products. A cradle-to-gate environmental impacts study of three production routes for cellulose nanofibrils (CNFs) was carried out by ARVIDSSON et al. (2015). The authors used wood pulp as feedstock, and three production routes investigated were: enzymatic pretreatment, carboxymethylation pretreatment and no previous pretreatment. The results obtained showed that processes without pre-treatment and using enzymatic treatment had relatively low environmental impact in terms of GWP (0.79 and 1.2 kg of CO<sub>2</sub> equiv. / kg of CNFs produced, respectively). NASCIMENTO et al. (2016) evaluated the LCA of the CNCs production from coconut fibers by extraction with high powered ultrasound, while using the residual lignin as power source for energy cogeneration to the process. The authors quantified the GWP of the process as 0.207 g of CO<sub>2</sub> equiv. / g of CNC produced. Still, to the best of our knowledge, the technical-environmental analysis of the production of CNCs from sugarcane biorefinery residues is a topic not yet well investigated in literature. Thereby, the purpose of using LCA in this work was to simulate CNCs production in sugarcane biorefineries attached to a second-generation ethanol (E2G) biorefinery, and to quantify the GWP of this nanocellulose unit in a 100-year horizon through LCA, identifying hotspots that can direct to process design changes to reduce environmental footprint.

## 2. Methodology

The simulated methodology of production proposed in this work employed sugarcane bagasse as feedstock. The process started with organosolv treatment (190 °C, 2h, 1:1  $V_{\text{ethanol}}/V_{\text{water}}$ , 1:10 dry mass / volume of solution) with ethanol recycle by flashing and distillation, followed by purification with H<sub>2</sub>O<sub>2</sub> (50 °C, 1 h, H<sub>2</sub>O<sub>2</sub> 7% vol, NaOH 5% vol, 10:1 m/m relative to input) and subsequent acid hydrolysis with H<sub>2</sub>SO<sub>4</sub> (45 °C, 45 min, 10:1 m/m relative to dry nanocellulose output, 70% yield). After washing and filtering of the produced CNCs, sulfuric acid was recycled by a system of evaporators operating in three stages, two of which operate at vacuum pressure (1atm, 300 mbar and 100 mbar). The nanocrystals downstream process then proceeded with residual H<sub>2</sub>SO<sub>4</sub> neutralization, dialysis, sonication, and drying of the material to purity of 95% in a spray-dryer. The annual sugarcane bagasse utilization as feedstock was set at 72000 tons per year. The mass and energy balances for discontinuous equipment were discretized, i.e., the input and output streams had mass and energy contents distributed over the time of the equipment usage cycles. Organosolv pretreatment with ethanol was selected over other treatment options because it provides high rates of removal of lignins and residual

hemicelluloses, whilst being environmentally less aggressive than the chemical processes (NASCIMENTO et al., 2016). In its turn, complementary alkaline delignification was selected for its high effectiveness in removing residual lignin content, generating biomasses with high-purity cellulose. Acid hydrolysis by concentrated  $H_2SO_4$  was chosen because it is the state-of art hydrolysis process in the CNCs production (VANDERFLEET & CRANSTON, 2021).

Several sources of literature data, external sources and laboratory data were used as input parameters of the Case Studies analyzed in this work. Mass and energy balances were performed on Microsoft Excel<sup>®</sup> electronic spreadsheets. In the energy balances, the thermodynamic calculations for the equipment were performed using the Aspen Plus<sup>®</sup> software and the results were transposed to the electronic spreadsheets. The NRTL thermodynamic model was used to represent the non-idealities of liquid phase mixtures in each analyzed system. The vapor phases were considered ideal due to the low pressure in the processes. Thermodynamic data related to sugarcane biomasses that was absent in the Aspen Plus<sup>®</sup> were inserted into this simulator using values obtained in DOMALSKI et al. (1986). Figure 1 shows a box diagram that represents the simulated process.

In order to proceed the LCA, an inventory of raw-materials, products and emissions were made based on the process modeling stage. The analysis employed the cradle-to-gate approach, and the functional unit was considered as 1 kg of cellulose nanomaterials produced. The GWP coefficient quantified the Greenhouse Gas Emissions (GHG) as grams of equivalent  $CO_2$  emitted per each produced kg of CNCs for 100 years of operation. The carbon intensity of residues from any process stage was equaled to zero in the cradle-to-gate approach.

In addition to the GWP metric, other environmental assessment categories were also evaluated, as the *CML-IA Baseline v3.04 2000* method was selected in *SimaPro<sup>®</sup> 9.0.0.35 PhD* software and using the *EcoInvent<sup>®</sup> v.3.3* database. For the allocation of environmental impacts to the product and the by-product from the process (lignin), energetic allocation was carried out as the impact's distribution factor.

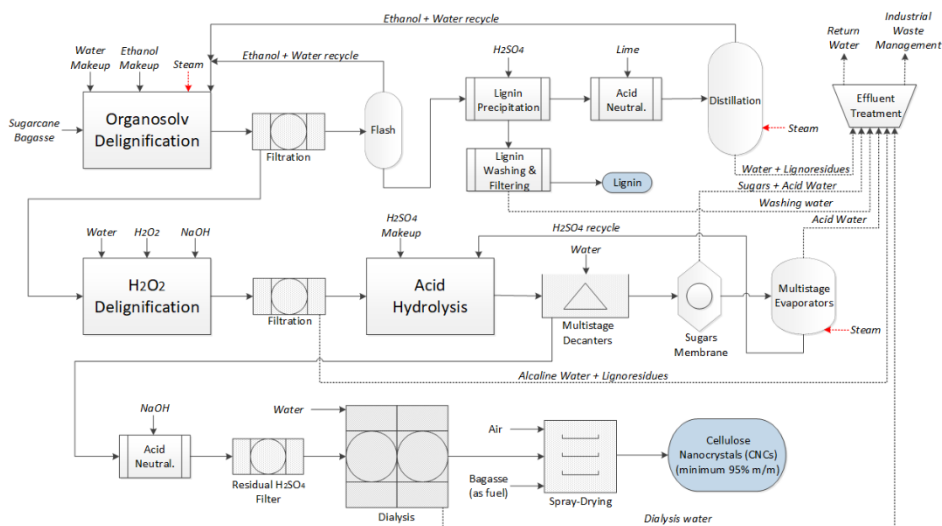

Figure 1 - Block diagram for the CNCs production methodology proposed in this work.

### 3. Results and Discussion

Modeling and simulation results showed that the CNCs production from sugarcane bagasse was water-use intensive, as 209 m<sup>3</sup> water / ton CNCs were consumed. LCA results showed that daily production of 7.73 ton of CNCs occurred with accumulated GWP of 23.6 tons of CO<sub>2</sub> equivalents. Ethanol from organosolv pretreatment, sulfuric acid from hydrolysis, and sugarcane bagasse burning for steam and energy generation were the main contribution inputs for GWP.

An estimated GWP of 0.23 kg of CO<sub>2</sub> equiv. per kg of dry equiv. CNCs were accounted after energetic allocation. This result corresponds to 13.43 g of CO<sub>2</sub> equiv. / MJ of process outputs. In other impact categories aside from GWP, the environmental impacts of H<sub>2</sub>SO<sub>4</sub> were generally the most relevant, especially in the abiotic depletion (96% of the total 1.37 kg of Sb equiv. per day of production), ozone layer depletion, soil acidification (52.8% of total 683 kg of SO<sub>2</sub> equiv. per day of operation) and water ecotoxicity (Figure 2), indicating that research studies may be directed to optimize the use of this acid in the nanocellulose production chain. Other compounds for acid hydrolysis (as organic acids) may represent a hindrance in the economics of the process but are also alternatives to be environmentally analyzed.

Life Cycle Assessment to produce nanocellulose varieties using recycled hydrolysis solvents are scarce studies in literature. Previous works that evaluated LCA of nanocellulose production, such as those by HOHENTHAL et al. (2012) (750 - 3100 g of CO<sub>2</sub> equiv. / kg of CNCs by TEMPO oxidation / high-pressure homogenization of sulfite pulp) presented higher GWP impacts per kg of nanocellulose produced. The relatively low GWP values when compared to processes that use derivatives of fossil fuels (and other biochemicals) indicate that the CNCs production from sugarcane bagasse is an option of interest for industries in the sector that aim to expand their portfolio with a high added-value product while reducing the emission of environmental impacts.

Biochemical production faces economic and environmental challenges that need to be overcome to enable a viable and sustainable bioeconomy. There are combined analysis frameworks indicated in literature (ÖGMUNDARSON et al., 2020b) that consistently combine environmental and economic indicators to support optimized biochemical production at early development stages. These frameworks propose the monetization of environmental impacts that, added to the economic indicators of the process, can generate process indexes that be used in the investment analysis. Given the global appeal for government policies to reduce environmental damage, it is expected that the adoption of this type of combined framework will be important for the expansion of bioeconomy.

### 4. Conclusions

Producing biochemicals from renewable resources is a key driver for moving towards a sustainable society where energetic efficiency and the use of agricultural residues are performance indicators (ÖGMUNDARSON et al., 2020b). A LCA of a nanocellulose production unit annexed to a sugarcane biorefinery was performed. The results showed that the GWP potential of the proposed process is concentrated in specific steps as the organosolv pretreatment and the sulfuric acid from hydrolysis. The identification of these steps can orientate future researchers for the demand of new methods of lignocellulosic biomass purification which can be environmentally friendly withal economically competitive for the nanocellulose production.

## Abstract

Several decarbonization strategies have been proposed for the cement sector including fuel switching (FS), carbon storage (CS), and carbon recycling (CR). FS and CS are expected in the short-term whereas CR is expected by 2050. Between the CR options, electrochemical reduction (ER) provides the opportunity to close the anthropogenic CO<sub>2</sub> cycle producing chemicals while promoting industrial symbiosis (IS). However, it requires high penetration of renewables. This study evaluates three decarbonization scenarios emphasizing the IS benefits provided by ER. Since ER is at low TRL, we elucidate the prospects to ensure its environmental feasibility within the European cement sector. We analyze the prospects of ER performance to compete with FS, which is viable even under low TRL. However, ER cell energy efficiencies are higher than 50% and methanol concentrations higher than 40%wt. are needed to compete with CS. From the defossilization perspective CR exhibits a wider margin of opportunity to compete even with CS.

**Keywords:** carbon dioxide, electrochemical reduction, decarbonization, defossilization, cement

## 1. Introduction

Since the consequences of climate change become more apparent, industries, scientists, and governments are committed to meet stringent greenhouse gas (GHG) emissions targets. These climate goals together with the recent geopolitical and energy market reality require us to drastically accelerate the energy transition increasing Europe's energy independence from unreliable suppliers and volatile fossil fuels.

Cement, which is an important building material, will pave the way to achieve a climate-resilient infrastructure. However, the success of the energy transition hinges on the effectiveness of its decarbonization. During cement production, carbon dioxide (CO<sub>2</sub>) is emitted directly from the chemical conversion process of clinker production (calcination) but also because of fossil fuel combustion (mainly petcoke, coal, and oil). Given the nexus of cement production with the world's population, cement demand has been projected to increase by 2 or 3 times during the next few decades (Favier et al., 2018). This trend will lead to drastic consequences in terms of CO<sub>2</sub> emissions and fossil resource depletion.

Today, the decarbonization of energy-intensive industries as the cement sector is not straightforward. It employs extremely high temperatures, which can be achieved cost-effectively only by burning fossil fuels. The challenge of finding new, carbon-free approaches to produce low-carbon cement is just as complicated as well as expensive.

The recent cement decarbonization roadmap has predicted an amount of 7.7 Gt CO<sub>2</sub> of cumulative direct CO<sub>2</sub> savings by 2050 under the proper application of reduction strategies (International Energy Agency, 2018). This could be only achieved through improving energy efficiency, fuel switching (FS) to those that are less carbon-intensive, reducing clinker content in cement, and implementing innovative technologies such as Carbon Sequestration (CS) and/or Carbon Recycling (CR). In this sense, innovative CR technologies have arisen in the last decade as promising options to boost the so-called industrial symbiosis (IS) concept. The IS concept was introduced in the fifth Assessment Report from the Intergovernmental Panel on Climate Change (IPCC) as a way to reduce raw material consumption while mitigating GHG emissions on a process level, industry park level, and national level. CR implementation in the cement sector as an IS strategy can contribute not only to reaching the projected cumulative CO<sub>2</sub> emissions reduction but also to reducing the consumption of fossil fuels elsewhere.

The present study evaluates the benefits of the CR strategy in the cement sector in comparison with FS and CS. We have chosen methanol as the CO<sub>2</sub> conversion product given its market capacity and potential uses as fuel and chemical (Olah, 2005). Several CO<sub>2</sub> conversion pathways to methanol have been proposed in the latest decades, including catalytic conversion (CC), thermochemical (TC), and electrochemical reduction (ER) (Roh et al., 2020). We have selected ER route given its potential scalability, mild temperature, and pressure conditions, as well as the final possibility of using sunlight directly in the long-term. In a previous environmental assessment carried out by the authors (Rumayor et al., 2019), it was analyzed the influence of the selected key performance parameters (KPPs) in the methanol carbon footprint (CF), concluding that the feasibility of the ER technology is still hampered by the low methanol production rates, low current densities, and Faraday efficiencies. This fact results in high-energy requirements and therefore, CO<sub>2</sub> savings are restricted to the utilization of a low-carbon electricity source. This study aims to provide a comprehensive perspective on the technical prospects of ER technology to maximize the decarbonization/defossilization synergy in the European cement sector including the renewable requirement. The findings can promote the development of CR within the climate and defossilization transition.

## 2. Methodology

The present study aims to elucidate the environmental trade-offs for a feasible implementation of a CR strategy based on the electrochemical reduction (ER) of CO<sub>2</sub> into methanol within the European cement sector. The assessment is conducted in terms of carbon footprint (CF), fossil abiotic depletion (f-ADP) as well as renewable electricity requirements. The proposed CR scenario is compared with two scenarios, which are expected in a shorter timeframe. These are based on: i) FS; and ii) CS. As the objective is to emphasize the IS benefits involved in the co-production of cement and methanol in the CR scenario, the combined conventional production of both cement and methanol is used as a benchmark for comparison purposes. A Life Cycle Assessment (LCA) tool is applied according to international standards (“ISO 14040:2006,” 2006b; “ISO 14044:2006,” 2006). The LCA is conducted using the software GaBi v9.5 (Sphera) and the Ecoinvent database v3.8. The functional unit (FU) is set as 1 ton of cement plus 429 kg of methanol, which is the stoichiometric amount of methanol that can be converted from the direct emissions of cement (672 kg CO<sub>2</sub>/ton cement) by ER. Figure 1 shows the system boundary of the scenarios analyzed in the present study. The baseline scenario considers the production of 1 ton of cement and the conventional synthesis of 429 kg of methanol according to their Ecoinvent datasets. Briefly, the production of 1 ton of cement

involves the consumption of resources such as limestone, gypsum, metals, and fossil fuels including natural gas (0.158 m<sup>3</sup>), heavy fuel oil (23 kg), petcoke (3.53 kg) and hard coal (32 kg). The CO<sub>2</sub> direct emissions associated with the process account for 672 kg of CO<sub>2</sub>. The production of 429 kg of methanol involves mainly natural gas (280 m<sup>3</sup>), which is the main raw material, together with metals and water, being 2.8 GJ the heating needs that come from natural gas. The CR scenario captures CO<sub>2</sub> assuming membrane separation technology, which has a 90% of efficiency and an energy requirement of 300 kWh/ton CO<sub>2in</sub> (Giordano et al., 2018). The ER of CO<sub>2</sub> yields methanol by direct CO<sub>2</sub> reduction with water and electricity. ER process comprises 4 steps: 1) capture of the CO<sub>2</sub>; 2) electroreduction of CO<sub>2</sub> into methanol and subproducts (O<sub>2</sub> and H<sub>2</sub>); 3) recovery of unreacted CO<sub>2</sub>; and 4) distillation of methanol up to commercial grade. The inventory for the electroreduction is obtained by a mathematical process model described in previous studies (Rumayor et al., 2019, 2020). Given the low technology readiness level (TRL) of the ER route into methanol at its current stage, we have carried out a series of sensitivity analyses. The energy efficiency of the ER cell is ranged between 10% (current) and 90% (optimistic) while the methanol concentration at the outlet stream of the ER cell ranges between 10%wt. and 60%wt. The bivariate analyses show the influence in the categories of CF and f-ADP for the selected FU. It is expected a rapid installation of wind/PV solar in projected national plans as well as the economic incentives for carbon reduction in industries. Therefore, the analyses are conducted using two electricity impacts: i) EU-PV solar mix (2021); and ii) EU-wind-mix (2021). Their impacts may be representative of the environmental performance of renewable electricity in the medium and long-term timeframes, respectively.

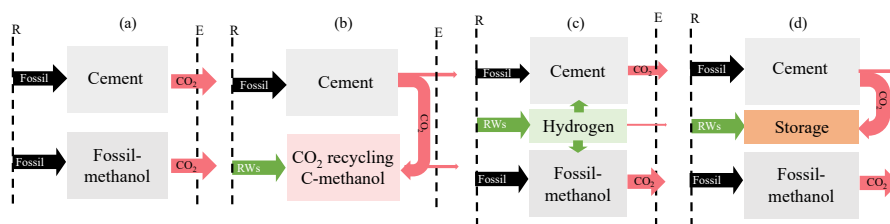

Figure 1. System boundary of a) Baseline; b) CR; c) FS; and d) CS

In the FS scenario, electricity is assumed renewable and the heat to produce 1 ton of cement (3.8 GJ) and 426 kg of methanol is considered to be supplied by 100% green H<sub>2</sub>. Green H<sub>2</sub> production is proposed to be synthesized by the polymer electrolyte membrane (PEM) technology, which is currently at the commercial stage. The electricity consumption of PEM is fixed at 50 kWh/kg H<sub>2</sub>, which is an optimistic value for the medium term. It must be considered that other resources such as limestone, gypsum, metals, and natural gas, which are used as raw materials, are the same that those considered in the Baseline. The CS scenario includes the capture of CO<sub>2</sub>, the compression and its sequestration. Energy consumption for the compression and injection is 117 kWh/t of CO<sub>2</sub> according to the literature (Koornneef et al., 2008). Note that the production of 429 kg of methanol will be kept as in the Baseline. Authors will display FS and CS in the result section only as benchmarking, being the prospective exploration of a combination of CCUS out of the scope of the present study because of the differences in TRL of the proposed technologies. Finally, it is calculated the resources and carbon emissions of an hypothetical decarbonized scenario. This scenario assumes the decarbonization of 10% of EU cement production by the proposed CR pathway. For a fair comparison, the impacts

are also calculated for the Baseline scenario (conventional). Therefore, the resources and impacts are calculated for 10% of the overall EU cement capacity (20 Mton/yr from the overall 200 Mton/yr). The decarbonized scenario is performed according to the figures of merits found in the sensitivity assessment as they will ensure the feasibility of the proposed CR pathway.

### 3. Results and discussion

Figure 2 displays the CF and f-ADP results obtained from the sensitivity analysis for the FU (1 ton of cement+429 kg of methanol) in the CR scenario. Since ER conversion in the CR scenario consumes a significant amount of electricity, the carbon intensity of the electricity to power the conversion process is critical. The CF and f-ADP results include the influence of the environmental impacts of renewable electricity to power the processes using the EU-PV solar mix (Figure 2 (a) and (c)) and the EU-Wind mix (Figure 2 (b) and (d)). There are also shown the CF and f-ADP of the CS (orange line) and FS (yellow line) scenarios as a function of the environmental impacts of renewable electricity. Furthermore, the baseline scenario is presented as a white dashed line and it is calculated keeping fixed the current EU grid mix. It should be mentioned that the contribution of the electricity to the overall CF value per FU (1120 kg CO<sub>2</sub>e) as well as to the overall f-ADP per FU (16500 MJ) in the Baseline are negligible. On one hand, direct CO<sub>2</sub> emissions are the main contributor to the overall CF value representing 85% according to the datasets. On the other hand, natural gas, which is the raw material in methanol production, is the main contributor to the overall f-ADP. From the CF perspective (Figure 2 (a) and (b)), the CR pathway exhibits a wide margin of opportunity to compete with the baseline scenario. CR may be competitive with the FS scenario using renewable electricity with a carbon intensity lower than 0.07 kgCO<sub>2</sub>e/kWh for methanol concentrations higher than 40%wt and energy efficiencies higher than 40%. However, the window of opportunity to compete with CS is narrower. The results indicate that CR may be competitive with CS only using renewable electricity with a CF lower than 0.01 kg CO<sub>2</sub>e/kWh and efficiencies higher than 50%. Note that the current energy efficiency of CO<sub>2</sub> ER is near 10-15%. As can be seen in Figures 2 (c) and (d), the benefits in the f-ADP are clearer. The results indicate a wider window of opportunity even under low-TRL performance of the ER technology compared with Baseline and CS scenarios. Note that 280 m<sup>3</sup> of natural gas is saved in the CR scenario as the amount of methanol (429 kg) is synthesized from the CO<sub>2</sub> direct emissions from the production of 1 ton of cement. According to the results, energy efficiencies higher than 40% and 50% and methanol concentrations higher than 40% could be a positive scenario to compete with CS and FS, respectively.

Figure 3 shows an overview of the resources, in terms of f-ADP, and the carbon emissions, in terms of CF, of the current cement production. It has also analyzed a hypothetical decarbonized scenario based on CR. The values shown in the figure correspond to the production of 10% of the overall EU cement capacity (20 Mton/yr from the overall 200 Mton/yr). The decarbonized scenario is performed according to the figures of merits found in the sensitivity analysis. It is assumed a methanol concentration of 40%wt. and a cell energy efficiency of 50%. EU-Wind-mix electricity impacts have been used to calculate the environmental impacts of the CR plant. According to the results, f-ADP could be reduced by a percentage of 70% with the CR strategy because of the resource savings (natural gas) within the conventional methanol production. On the other hand, CF is reduced by around 80% because CO<sub>2</sub> recycling substitutes natural gas in methanol production. Since ER is an electricity-intensive process, the decarbonization of

10% of EU cement production would require  $15 \cdot 10^{13}$  kWh of low-carbon renewable electricity.

Figure 2. Influence in the CF and f-ADP (per FU) during the sensitivity analysis of CR scenario using electricity based on EU-PV-Mix (a, c) and EU-Wind-Mix (b,d)

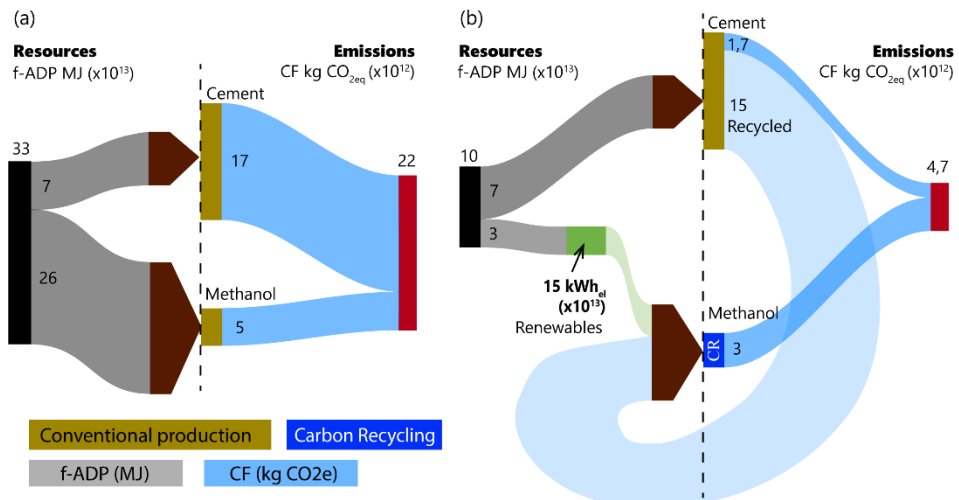

Figure 3. Environmental impacts (f-ADP and CF) of: (a) conventional production; and (b) decarbonized scenario considering 10% of European cement capacity

## 4. Conclusions

This work has provided the environmental prospects that CR strategy through ER could bring to the EU cement sector within the climate and defossilization transition. We have applied a prospective life cycle assessment tool to compare the CF and f-ADP of CR with FS and CS strategies. Since ER conversion is an electricity-intensive process, the environmental impacts of renewable electricity to power the conversion process is critical. In the nearer term, implementing CS seems more beneficial to reach the decarbonization goal of the cement sector. However, the CR strategy, which is an industrial symbiosis approach may boost the circular economy. The pathway involves a 70% of fossil resource savings and a reduction of 80% of carbon emissions.

## Abstract

Ammonia synthesis is the biggest emitter of carbon dioxide among chemical processes. Emission regulations will become even stricter over the coming decades and call for innovative sustainable pathways to meet the decarbonization targets. An answer to such a transition may be retrofitting (*i.e.* hybridization) the existing plants by implementing low- or zero-emission technologies. One of the most promising retrofits is introducing green hydrogen from electrolyzers into the synthesis loop. This paper compares the operational expenditures (OPEX) of a conventional gray ammonia plant and a 10%-decarbonized electrolysis-based hybrid-green ammonia plant. The OPEX terms depend primarily on natural gas costs, renewable electric energy prices, and carbon tax values. Specifically, hybrid-green ammonia proves to be competitive at current EU natural gas quotations, which have increased more than five-fold since the first semester of 2021 due to the ongoing Russia-Ukraine war.

**Keywords:** decarbonization; hybridization; electrolysis; renewables; hydrogen.

## 1. Introduction

Ammonia synthesis is the most carbon-intensive process in the chemical industry, with emissions above 440 Mt<sub>CO<sub>2</sub>eq</sub>/y in 2020 (Isella and Manca, 2022). Indeed, current ammonia synthesis heavily relies on fossil fuels to produce the hydrogen needed in the ammonia converters and generate the heat and compression required for the process. This explains the blooming of decarbonization strategies to mitigate the carbon footprint of conventional “gray” ammonia. Among them, we have: (i) blue ammonia, which implements various solutions of carbon capture and utilization or storage (CCUS); (ii) green ammonia, which fully decouples the ammonia production from fossil feedstocks (*e.g.*, hydrogen production through an electrolyzer powered by renewable electricity); (iii) hybrid-green ammonia, which consists in revamping the existing conventional plants by installing an electrolyzer to replace part of the gray, fossil-based hydrogen feedstock with a green, water-based one (MPP, 2022). Concerning the latter technology, it is worth clarifying that within the perspective of a fully decarbonized ammonia scenario, such a production method should be considered a transitional technology due to its reduced CO<sub>2</sub> abatement potential, which is partial by nature. Nonetheless, until near-zero-emissions paths become commercially ready in the following decades, an available-to-date alternative such as hybrid-green ammonia can be the best way to meet emissions

reduction in ammonia synthesis. The main purpose of the paper is to identify the price volatility of hybrid-green ammonia. Specifically, its market trends are reproduced and compared with the far more widely-known and better-characterized conventional ammonia prices. Indeed, the cost of hybrid-green ammonia is shown to be, just as its gray counterpart, a function of several market variables (*e.g.*, the price of fossil fuels and electrical energy). To our knowledge, this assessment is unprecedented in the scientific literature and represents a first attempt to formally describe the market evolution of hybrid-green ammonia. Moreover, the global geopolitical conditions given by current events (*in primis*, the Russia-Ukraine war), add even more novelty to our study.

## 2. Simulation of the hybrid-green ammonia plant

A medium-high capacity 2000 t/d stand-alone natural gas-based ammonia plant was simulated in UniSim® Design R491 to assess its economic hybridization potential. The decarbonization target was set to 10% (a distinctive value of such plants resulting mainly from design considerations, as discussed in the following). The injection of green hydrogen from an alkaline electrolyzer (AEL) powered by renewable electric energy can achieve that target. Indeed, this strategy aims to reduce the “front-end” (*i.e.* the whole of the reforming, shift, and syngas purification sections) load and, consequently, to lower both the natural gas fuel and feed demands of the process (see Figure 1).

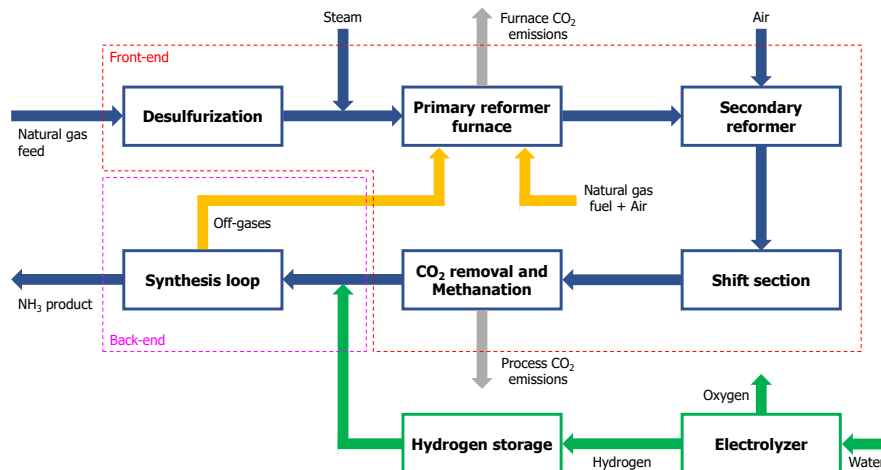

Figure 1: Block flow diagram of the simulated hybrid-green ammonia plant.

An equivalent amount of hydrogen fed to the ammonia synthesis loop must be generated by electrolysis, assuming a 10% average reduction in carbon dioxide emissions ( $\text{DeCO}_2 = 10\%$ ). However, the hydrogen production capacity of the electrolyzer is strongly affected by the fluctuating trends of renewable electric energy profiles. Indeed, renewable energy production is firmly susceptible to the varying availability of energy sources (such as sunlight and wind in the case of solar and wind farms). Since the electrolyzer converts such fluctuating electricity profiles into hydrogen flows that are thus intermittent, it follows that the target green hydrogen productivity should be considered as an average of the oscillations that span from a minimum of zero (when no green electricity is available) to a maximum, which is strictly related to the capacity factor of the renewable power station (that determines the peak power available to the user) and also to some design considerations, precisely the reformers' load. Indeed, considering to keep constant the ammonia productivity of the plant, the injection of an excessive amount

of green hydrogen into the synthesis loop results in substantial drops in the front-end flow rates (*i.e.* the ones linked to the conventional gray route), which may affect a few critical aspects, such as the operability of the fired tubes in the primary reformer and the rise in the temperature of the secondary reformer. To tackle this, hydrogen storage is needed downstream of the electrolyzer to set the maximum amount of green hydrogen fed to the synthesis loop. Specifically, it was assumed that the upper limit of green hydrogen input should be such to require a decrease in the front-end “throughput” (*i.e.* its total processed flow rate) to 80% maximum turndown to ensure reliable operative conditions of the primary reformer. Respecting such a directive leads to an instantaneous decarbonization degree of about 20% ( $\text{DeCO}_2 = 20\%$ ) at the highest. This is a somewhat limiting constraint since, by ignoring all the above design recommendations and basing the calculations exclusively on the peak availability of green electricity (which depends only on the capacity factor of the renewable power source), the maximum achievable decarbonization degree could be, in principle, higher.

Table 1 reports the leading process variables of the simulated hybrid-green ammonia plant in its three main operating conditions: S0, which corresponds to the minimum (*i.e.* null) green hydrogen availability; S1, which corresponds to the average working conditions (which should guarantee a 10% decarbonization target, as requested); and S2, which corresponds to the upper limit of green hydrogen input.

Table 1: Process variables of the simulated hybrid-green plant in its three main operative conditions. The electrolyzer has a specific electricity consumption of 4.5 kWh/Nm<sup>3</sup>H<sub>2</sub>, a specific water consumption of 0.9 kgH<sub>2</sub>O/Nm<sup>3</sup>H<sub>2</sub>, and a hydrogen output temperature and pressure of 35 °C and 30 bar, respectively (Nel Hydrogen, 2021). Note that a natural gas-to-electricity conversion factor of 3 MWh<sub>LHV</sub>/MWh<sub>el</sub> was used to evaluate the net plant energy consumption.

<i>Process variable</i>		<i>Status “S0”</i>	<i>Status “S1”</i>	<i>Status “S2”</i>
		(0% DeCO <sub>2</sub> )	(10% DeCO <sub>2</sub> )	(20% DeCO <sub>2</sub> )
<i>Primary reformer throughput</i>	[t/h]	163	146	129
<i>Natural gas feed to the front-end</i>	[t/h]	38.0	33.9	29.9
<i>Natural gas fuel to the furnace</i>	[t/h]	12.9	11.9	10.7
<i>Green hydrogen production</i>	[t/h]	0	1.74	3.55
<i>Green electricity consumption</i>	[MW]	0	86.8	177
<i>Net plant energy consumption</i>	[MWh <sub>LHV</sub> /tNH <sub>3</sub> ]	8.14	10.4	12.9
<i>Furnace CO<sub>2</sub> emissions</i>	[t/h]	38.9	34.8	30.7
	[tCO <sub>2</sub> /tNH <sub>3</sub> ]	0.467	0.418	0.368
<i>Process CO<sub>2</sub> emissions</i>	[t/h]	97.4	87.9	78.1
	[tCO <sub>2</sub> /tNH <sub>3</sub> ]	1.17	1.06	0.937
<i>Total CO<sub>2</sub> emissions</i>	[t/h]	136.3	122.7	108.8
	[tCO <sub>2</sub> /tNH <sub>3</sub> ]	1.64	1.48	1.31

As expected, an increase in the green hydrogen input to the ammonia synthesis loop leads to a significant decrease in both the furnace and process carbon dioxide emissions at the

expense of the net energy consumption of the plant. Indeed, as the heating demand associated with natural gas streams declines, electricity demand rises significantly. However, also other implications occur, namely: (i) the increase in the operating temperature of the secondary reformer (from 996 °C in S0 to 1043 °C in S1 and 1104 °C in S2) and (ii) the drop in the methane slip (from 0.244 mol% in S0 to 0.098 mol% in S1 and 0.032 mol% in S2) and the inert gases content (from 11.7 vol% in S0 to 8.92 vol% in S1 and 7.28 vol% in S2) in the ammonia synthesis loop. Consequence (i) is mainly due to the choice of keeping the process air flowrate constant (to meet the nitrogen demand of the plant and guarantee the stoichiometric  $H_2/N_2$  ratio at the inlet of the first ammonia converter). This leads to an increase in the oxygen-to-carbon molar ratio at the secondary reformer inlet (from 0.757 in S0 to 0.848 in S1 and 0.963 in S2) and, therefore, in its operative temperature. Concerning consequence (ii), instead, it is strictly related to the first one, (i). Indeed, such a result is due to the higher temperatures in the secondary reformer, which shift the steam reforming reaction towards the products. Finally, it is worth noting that while consequence (i) is very detrimental, as excessive overheating of the secondary reformer and the downstream process boiler must be avoided, consequence (ii) is beneficial to the process as it reduces compression costs and improves the reaction thermodynamics and kinetics in the ammonia converters.

### 3. Gray and hybrid-green ammonia production costs

Through the previous simulations, hybrid-green ammonia proves to be an available-to-date, feasible (although conspicuously electricity-demanding) technique to decarbonize ammonia synthesis. However, the actual testing benchmark to assess the competitiveness of an alternative production route to the conventional one is the cost of the final product. Indeed, since the cheapest process is expected to be the most appealing, the present section focuses on evaluating both gray and hybrid-green ammonia production costs. Precisely, the following assumptions hold:

- both facilities operate 8000 h/y;
- the hybrid-green plant has an average annual decarbonization target of 10%;
- the costs for cooling and demineralized water are 0.04 and 0.75 €/m<sup>3</sup>, respectively (Intratec, 2022);
- the revenues from the medium-pressure steam production within both plants are estimated by considering the natural gas duty that an auxiliary boiler would need for the same task (Noelker and Ruether, 2011). Specifically, using pure water at 35 °C and 40 bar leads to a steam energy export equal to 0.13 MWh<sub>LHV</sub>/t<sub>NH<sub>3</sub></sub> from both facilities;
- the decarbonization degree of the hybrid-green plant is assumed to fluctuate in the 0-20% interval, depending on the instantaneous availability of renewable electricity;
- the installed electrolyzer capacity must be 177 MW to meet the hydrogen demand at the peak of green electricity availability (see Table 1, S2). On top of this, such power capacity value is oversized by 10%;
- the electrolyzer capital expenditures (CAPEX) must be accounted for. Indeed, since the electrolyzer is the most expensive unit that the hybridization retrofit calls for, its cost affects the price of the final product. Specifically, the electrolyzer exhibits a 10-year depreciation time and a fixed fee of 700 €/kW<sub>el</sub> (including engineering, housing, and balance-of-plant components such as the compression and the water and hydrogen purification units). This is a rather low (yet conservative) value compared to the average ones reported in the literature (which typically span from 800 to 1000 €/kW<sub>el</sub>).

Indeed, it is recognized that the economy of scale notably affects AEL modules with an installed power capacity higher than 100 MW (Fraunhofer ISE, 2021). It is worth noting that the main contributions to the final prices of both gray and hybrid-green ammonia are given by natural gas, carbon tax, and (only for the hybrid plant) renewable electricity, whose values are continuously changing at rather high rates. This aspect is very significant since specific fluctuations of such variables affect the costs of both production pathways, eventually overturning their mutual relationship. For example, decreasing renewable power purchase agreement (PPA) costs and increasing values of carbon taxes are expected to promote the shift to environmentally mitigating technologies despite the conventional, carbon-intensive (and otherwise far cheaper) ones. Anyway, the aspect that has predominantly affected the recent evolution of the price trends in ammonia production is the runaway behavior of natural gas quotations. Indeed, with the outbreak of the Russia-Ukraine war, its already rising trend, which started in the summer of 2020, reached extraordinary peaks in a few weeks. Specifically, the remarkable surge in natural gas prices made the hybrid-green ammonia production pathway cheaper than the conventional gray one. Indeed, the reduced fossil fuel consumption in the hybridized facility makes it less susceptible to changes in natural gas quotations.

Figure 2: Gray and hybrid-green ammonia production costs and carbon tax values (left y-axis); natural gas and renewable PPA prices (right y-axis) for the A-H scenarios. The percentages at the top of the bars quantify the difference between the hybrid-green vs. gray ammonia total production costs. Input data from Trading Economics (2022), for natural gas and carbon tax, and LevelTen Energy (2022), for PPAs.

To follow the ever-changing panorama of incidents that significantly affected the main prices/costs of both process typologies, we identified eight scenarios that occurred in the last three years (see also Figure 2):

- A. Pre Covid-19 era (30-Sep-19);
- B. After 6 months of Covid-19 (30-Sep-20);
- C. After 18 months of Covid-19 (30-Sep-21);
- D. Start of Russia-Ukraine war (24-Feb-22);
- E. One week into the conflict (03-Mar-22);
- F. One month into the conflict (24-Mar-22);

- G. Highest peak of natural gas price (26-Aug-22);
- H. First EU protective measures (30-Sep-22).

Figure 2 shows the economic assessment, where the prices of gray and hybrid-green ammonia were considered by utilizing as input data the values of natural gas price, renewable PPA price, and carbon tax for the European market at the A-H scenarios. As previously mentioned, the sensitivity of ammonia production prices to market fluctuations is so elevated that the remarkable increase in natural gas quotations has made hybrid-green ammonia cheaper than gray ammonia in the recent C-H scenarios (*i.e.* since 30-Sep-2021). Indeed, hybrid-green ammonia has gradually become cheaper than gray ammonia, despite starting from a 34% higher price than the conventional route in the pre Covid-19 era. This is still true after the highest recorded peak in natural gas quotations (on 26-Aug-2022), with a discounted price of 4.2% to gray ammonia.

#### 4. Conclusions

This paper introduced a novel method to evaluate ammonia market price, aimed at discussing the economic attractiveness of hybrid-green vs. gray ammonia production. The simulation of a 2000 t/d hybridized ammonia plant highlighted the main problems related to the operating limits of that facility. These are the significant demand for renewable power and operability issues in the reformers as far as excessively high decarbonization degrees are concerned. Regarding the economic assessment, the production costs of gray and hybrid-green ammonia proved particularly sensitive to market fluctuations, primarily to natural gas quotations. The steep increase in the natural gas price due to the outbreak of the Russia-Ukraine war made the hybrid-green production route cheaper than the gray one, although being far more expensive just a few months before. This outcome matches the increased adoption of electrified technologies to decarbonize ammonia synthesis.

## Abstract

The constant development of new alternatives to treat waste aids in closing material loops towards the circular economy and improving sustainability through the use of new renewable materials and energy. This fact leads to the increasing need for decision-making tools for process synthesis and assessment, which can be addressed with an integrated framework that employs ontologies for knowledge management and optimization tools to perform a hierarchical assessment of alternatives. The systematization of these procedures raises the need for tools to automate techno-economic and life cycle analyses. In this work, such a challenge is addressed through the additional integration of add-on modules such as the CapEx-Opex estimation tools and surrogate modeling within this framework. A case study on plastic waste is proposed with the inclusion of several pyrolysis and gasification alternatives. Results show pyrolysis, followed by the subsequent purification of its products, as the best alternative and helped identify main drivers for technologies feasibility such as feedstock purity and energy consumption.

**Keywords:** circular economy, integrated modeling, sustainable development, machine learning, economic optimization.

## 1. Introduction

The Circular Economy appears as a subject of paramount importance toward economically, environmentally, and socially sustainable development. Thus, many entities across the world are working hard to find alternatives that not only bring economic profit but also are environmentally benign and socially responsible. One of the most urgent matters is waste management and, in this specific line, many technical efforts are currently devoted to finding new waste-to-resource processes, recovering valuable resources, and closing material loops. Consequently, decision-makers face the challenge to determine which alternatives are most suitable for each kind of waste. To address this task, Pacheco-López et al., (2022) developed a framework of integrated tools to connect waste sources with valuable products and find the best routes to close material loops. The

application of this framework requires performing economic and environmental analyses and developing models suitable for each one of the alternatives included. To undertake these tasks more systematically, this contribution aims to integrate new tools to make the framework more versatile and minimize the required human intervention for synthesizing and assessing new sustainable approaches. Within the proposed framework, the ontology is used to manage the information and data that are needed as inputs on each module, as well as storing the outputs, therefore centralizing all the knowledge required and produced in the system (orange arrows represent information exchange in Figure 1).

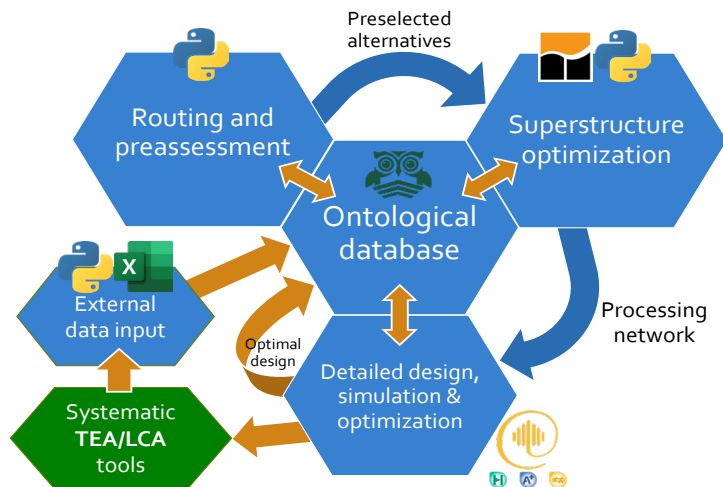

Figure 1. Schematic representation of the proposed framework with an additional module (green).

## 2. Methodology

The methodology used in this contribution is an extended version of a previously proposed one, in which several synthesis, assessment, and optimization tools were integrated to build a decision-making framework (Pacheco-López et al., 2022). There, a sequential approach is used to build alternative paths between waste materials and marketable products and to assess them from several points of view as well as to find the optimal configuration. First stage uses a new proposed algorithm and metric based on different objectives to pre-select alternatives, then a second stage consisting on a Multi-objective network optimization to find best routes based on each objective (for more details of this procedure see (Somoza-Tornos et al., 2021)). One of the identified challenges in this work was the need to perform previous techno-economic (TEA) and life cycle (LCA) assessments manually for every single process in order to introduce their results in the framework to be used by the other modules. To address this challenge, the need for systematization tools was identified to reduce human intervention and standardize the results. In this direction, some tools were already developed and are being implemented in the framework. Prifti et al. (2022) developed a CapEx-OpEx Robust Optimizer (CORO) framework that was intended to assess the cost evaluation of a plant including some sustainability targets, thus, it provides the framework with more dynamism and systematization in the TEA tasks. CORO automatically takes a simulation file (Hysys or ProII) as an input and generates the capital and operational expenditures for each process. Using this tool, the cost estimations for all processes in the ontology have been performed in order to obtain standardized results. Figure 1 shows the original methodology and the proposed additional module for techno-economic/life-cycle systematic assessment tools.

As of now, only systematic TEA is implemented for illustrative purposes, although future developments are intended to include LCA systematization in the same way.

On the other hand, process simulation is also a critical step for the design and optimization of new processes, which, in turn, may require considerable computational effort. Surrogate modeling offers the possibility to speed up simulation convergence times by substituting rigorous models with machine learning methods (Granacher et al., 2021), as the one proposed by Galeazzi et al., (2022) to predict the behavior of several process variables of existing steady-state digital twins of industrial plants. This tool can be accessorially used in the third stage of the methodology to ease the simulation step or to study the processes' sensitivity to variations in feed composition or operating conditions.

Table 1. Deployed process paths for MPW treatment, outputs, and GPI for 24 alternatives. ### 3. Case Study

The framework is tested on a case study dealing with the recovery of plastic waste materials and the conversion/purification of the resulting products into other valuable carbon-based products. New alternatives are added to the set of alternatives available in the ontology from previous implementations using the same assumptions as presented in Pacheco-López et al., (2022). These new processes consist of gasification followed by methane reforming and conversion to obtain methanol as a final product, either using

traditional energy sources or electrified ones (Prifti et al., 2021). A total of 66 processes (see Figure 2) are implemented in this case, where 200 paths were created and assessed, from which 24 were selected in the first stage (see Table 1).

The preselected alternatives were sent to the multi-objective network optimization module obtaining a set of configurations along with the representation with the corresponding Pareto fronts. The newly added alternatives are compared against those already available in the ontology. The feedstock considered corresponds with a mixture of plastic waste with the following mass composition: 45% polyethylene, 32% polypropylene, 20% polystyrene, and 3% of PVC. A plant to treat an annual amount of 20,000 tonnes of MPW (2.5 tonnes/hour for a plant operating 8000h a year) was considered and all processes were scaled accordingly.

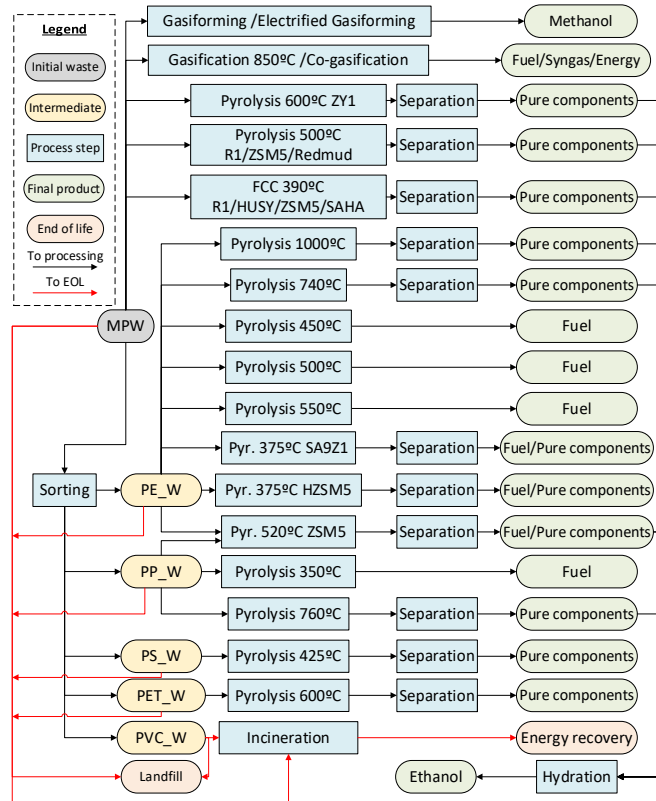

Figure 2. Implicitly generated graph in the pre-assessment stage with all tentative connections. PE: polyethylene, PP: polypropylene, PS: polystyrene, PET: polyethylene terephthalate, PVC: polyvinyl chloride; Pyr.: Pyrolysis; EOL: End of life.

#### 4. Results

After updating the ontology with all the current and new process parameters, the algorithm is run and all the possible connections are made with an input-output matching procedure, resulting in a graph as seen in Figure 2. With the assessment procedure presented in Pacheco-López et al., (2021), all the paths are built and a list of prioritized alternatives is obtained and preselected according to their global performance indicator (see Table 1, for brevity similar routes have been combined). This prioritized list of alternatives is passed to the network optimization stage where a multi-objective

optimization is performed. A set of different process configurations is obtained according to different objectives and intermediate alternatives as well as a set of Pareto points using the  $\epsilon$ -constraint method. As an example, the configuration with the best economic performance is shown in Figure 3 along with the Pareto fronts obtained for the economic profit against each one of the environmental endpoint indicators as shown in Figure 4.

Figure 3. Configuration obtained for maximized profit. Point number 10 in Figure 4.

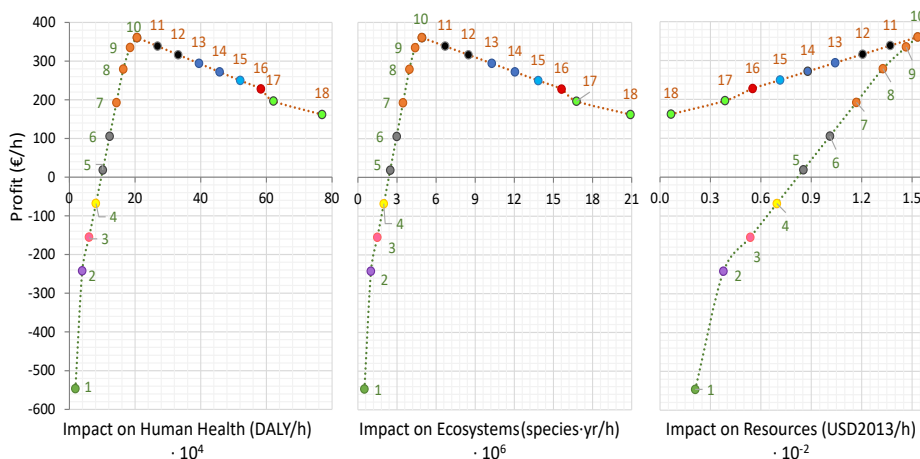

Figure 4. Pareto fronts for the trade-off between profit and the three environmental endpoint indicators. The points are numbered and color-coded to represent different configurations. Each point (as the one seen in Figure 3) consists of a different combination of processes from Figure 2.

Results in this contribution were consistent with those obtained in previous runs of the algorithm (Pacheco-López et al., 2022, 2021). Newly introduced gasification alternatives were selected in the first stage in the positions 9<sup>th</sup>, for the traditionally powered route, or Gasiforming<sup>TM</sup>, and 20<sup>th</sup>, for the Electrified Gasiforming<sup>TM</sup>. In addition, they were not among the best-performing alternatives in the second stage for any of the four obtained anchor points, which may suggest they need further development and more efficient and economically competitive energy sources. It was identified that capital expenditures play an important role in the implementation of these technologies. Electrical energy consumption has been also identified as a critical part since it entails most of the operating expenditures. On the other hand, results show that pyrolysis of mixed plastic waste with or without catalysts at a temperature of 500°C is still among the best-performing alternatives for most objectives since they are the most economically and environmentally competitive or beneficial options for this kind of waste.

## 5. Conclusions

Results show the framework's ability to synthesize and assess routes for the upcycling of waste accounting for economic and environmental objectives. The capability of the framework to be easily expanded and complemented with the integration of other tools to satisfy processes modeling, design, and assessment needs has also been proven. The use of the CapEx-OpEx Robust Optimizer (CORO) has aided in systematically generating the economic performance indicators for all the processes asserted in the ontology, providing a standardized procedure to avoid user-introduced errors and keeping the assessment parameters consistent among all alternatives. The third stage of the methodology, detailed simulation, and design of a chosen alternative is one of the most work-intensive tasks of the framework and stays out of the scope of this study. The use of surrogate modeling has been envisaged as a useful alternative to ease this stage and might be implemented in future developments to study the effect of feedstock composition changes on the economic and environmental performance of the upcycling technologies. Some identified challenges have been approached with the inclusion of new ideas and tools that help advance the automation and systematization of the framework, mainly in terms of TEA/LCA and simulation efforts. The possible inclusion of carbon emission credits has also been included as a potential source of income, therefore improving the overall economic performance of the considered alternatives.

## 6. Acknowledgments

Financial support received from the Spanish "Ministerio de Economía, Industria y Competitividad" and the European Regional Development Fund, both funding the research Project CEPI (PID2020-116051RB-I00) is fully acknowledged. A.P-L thanks the financial support received from the "Ministerio de Ciencia e Innovación" (grant ref. PRE2018-087135) and the Erasmus+ programme of the EU 2021-27 (KA131 call).

## Abstract

Livestock manure contributes to around 18% of global greenhouse gas (GHG) emissions, while the mishandling of manure further pollutes water and soil. As such, the valorisation of these wastes becomes vital for the mitigation of global warming impact. In this context, anaerobic digestion (AD) is commonly used to generate biogas and digestate from manure; however, pyrolysis has recently emerged as a viable alternative to AD for producing cleaner products in much shorter processing times. Therefore, this study investigates the pyrolysis of four types of livestock manures including poultry (PM), dairy (DM), camel (CM) and sheep manure (SM). The air-dried manure samples are characterised with reference to literature reported data, while the process is simulated using existing empirical prediction models. In addition, the process performance in terms of economic feasibility and environmental impact is evaluated from cradle to gate for different manure feedstocks. A mathematical optimisation model is then developed to evaluate optimal blending of manure for the commercial production of bio-oil, considering different operating conditions, manure compositions and availability in the State of Qatar. The model is solved to fulfill seven different objectives independently. The results revealed that PM is linked to the highest amount of bio-oil (41%) at 600°C, while the lowest yield is associated to CM. Finally, the optimal manure blending ratio for highest bio-oil yield and lowest cost is achieved at 52% PM: 2% DM: 3% CM: 43% SM. Whereas the optimal blending ratio for lowest carbon footprint is realised at 42% PM: 21% DM: 30% CM: 7% SM. The designed model provides a thorough insight on optimal technical and environmental valorisation of livestock manures by pyrolysis.

**Keywords:** Pyrolysis; Livestock manures; Optimisation; GHG; Bio-oil; Biochar.

## 1. Introduction

Several billion tonnes of livestock waste/manure are produced worldwide every year. The mismanagement and misuse of manure is severely polluting the environment and contaminating the water supply. As a matter of fact, the livestock sector is estimated to contribute 18% of total Greenhouse gas (GHG) emissions globally (Moran and Wall, 2011). Biomass, including livestock manure, has piqued the interest of many because its carbon neutrality offers a strategic measure to reduce GHG emissions. Biological treatment of livestock manures, such as anaerobic digestion (AD), has traditionally been used. The use of pyrolysis method to convert livestock manure into energy has been emerging as a viable alternative to AD because they can be used to produce value-added

products in a much shorter timeframe than AD. Pyrolysis also significantly reduces waste volume and eliminates pathogens.

This study considers four types of livestock manures: poultry (PM), dairy (DM), camel (CM), and sheep (SM). Due to the large numbers of aforementioned livestock raised in the State of Qatar, these manures were considered. The study also attempts to find an optimal blending ratio of the aforementioned manures for commercial production of bio-oil, considering different operating conditions, manure compositions, and availability in the State of Qatar

In order to predict the pyrolysis product distribution, researchers have created a number of models. In the current study, pyrolytic kinetics model proposed by Song is applied (Song, 2016). The model represents the general trends in product distribution using empirical equations that cover mass and energy balances as well as empirical relationships (based on temperature). Only a few empirical models are based on both feedstock attributes and pyrolysis operation parameters, with the majority of models being based solely on the properties of feedstock materials (Abhijeet et al., 2020; Al-Rumaihi et al., 2022). One of the few studies that considers both the pyrolysis conditions and feedstock qualities is the current one (Parthasarathy et al., 2022). Prediction model-based economic analysis is uncommon, as such, this study is distinctive as it concentrates on both technical and economic assessment. The commercialisation of bio-oil will benefit from the techno-economic analysis of the pyrolysis of the aforementioned manures.

## 2. Methodology

### 2.1. Materials and methods

The proximate and ultimate analyses results of the manures under study are provided in **Table 1**.

**Table 1:** Proximate and ultimate analyses findings of the feedstock manures.

Analysis	PM	DM	CM	SM
Moisture content (%) (as-received basis)				
Moisture	40.00	85.00	58.00	50.00
Proximate analysis (% wt.) (Dry basis)				
Volatile matter	63.58	57.18	60.51	57.30
Fixed carbon*	13.31	10.11	22.74	15.56
Ash	23.09	32.69	16.73	27.13
Ultimate analysis (% wt.) (Dry and ash free basis)				
Carbon	36.67	27.61	37.11	33.14
Hydrogen	5.33	3.48	4.07	4.48
Nitrogen	3.54	1.88	2.27	2.65

Sulphur	0.73	0.41	0.24	0.37
Chlorine	0.00	0.00	0.00	0.00

\*Calculated by difference

### 2.2. Model Development

**Figure 1** depicts a simplified process flow diagram of the pyrolysis process. The following assumptions are made for the development of the prediction model. Feedstocks are pyrolysed in an isothermal reactor with a nitrogen environment. As a pre-treatment, the feedstocks are dried, and then they are pyrolysed and transformed into water, bio-oil,

tar, pyrogas (CO<sub>2</sub>, CO, CH<sub>4</sub>, H<sub>2</sub>, hydrocarbons, etc.), biochar, and ash, as denoted by **equations 1-3** (Swagathnath et al., 2019). Further, as the temperature proceeds, the bio-oil is further decomposed into gas components.

$$\text{Bio - char yield} = 0.106 + 2.43 * \exp(-0.66 * T * 10^{-2}) \quad (1)$$

$$\text{Bio - oil yield} = Y_{\text{bio-oil},F} + Y_{\text{H}_2\text{O},F} + \text{samples' moisture composition} \quad (2)$$

$$\text{Pyrogas yield} = Y_{\text{CO}_2,F} + Y_{\text{CO},F} + Y_{\text{H}_2,F} + Y_{\text{CH}_4,F} \quad (3)$$

**Figure 1.** Process flow diagram of the pyrolysis process.

### 2.3. Economic Analysis

The economic analysis of pyrolysis is investigated based on the assumptions listed in **Table 2**. The primary pyrolysis equipment costs and labor requirements have been adapted from previous technical reports (Humbird et al., 2011). Using the Chemical Engineering Plant Cost Index, all prices are scaled up and inflated to the year 2019 (Chemical Engineering Plant Cost Index (CEPCI)).

**Table 2:** Economic analysis assumptions.

Parameters	Values
Pyrolysis plant location	Qatar
Plant capacity	20 t/h
Analysis base year	2019
Plant lifetime (years)	25
Discount rate (%)	20
Feedstock price (USD \$/t)	50

### 2.4. Environmental Analysis

Environmental analysis covers the concept of carbon footprint, which is the total amount of CO<sub>2</sub> emissions that have been generated over the lifecycle of bio-oil, from cradle to gate.

### 2.5. Optimisation

Using the objective functions and the constraints presented below, an optimisation model is created using Excel Solver. For the selection of optimal blends of the four different manures for the pyrolysis process, 7 objectives are adopted independently. The objectives seek to maximise the yields of bio-oil, syngas, and biochar, maximise the heating value of bio-oil and syngas, and minimise cost and carbon footprint. Additionally, the blending must use no less than 10% no more than 50% of each available manure, considering the plant's capacity.

**Objective functions:**

$$\begin{aligned}
 \text{Bio-oil yield } (Z_1) &= \text{Max } \sum_{i=1}^4 BO_i X_i \\
 \text{Syngas yield } (Z_2) &= \text{Max } \sum_{i=1}^4 SG_i X_i \\
 \text{Biochar yield } (Z_3) &= \text{Max } \sum_{i=1}^4 BC_i X_i \\
 \text{Bio-oil HV } (Z_4) &= \text{Max } \sum_{i=1}^4 BHV_i X_i \\
 \text{Syngas HV } (Z_5) &= \text{Max } \sum_{i=1}^4 SHV_i X_i \\
 \text{CO}_2 \text{ emissions } (Z_6) &= \text{Min } \sum_{i=1}^4 E_i X_i \\
 \text{Bio-oil Cost } (Z_7) &= \text{Min } \sum_{i=1}^4 C_i X_i
 \end{aligned}$$

**Constraints:**

$$\begin{aligned}
 \sum_{i=1}^4 X_i &= 1 \\
 \sum_{i=1}^4 Q_i X_i &\leq \text{feed capacity} \\
 0.5 &\geq X_i \geq 0.1
 \end{aligned}$$

Where:  $X_i$ : blending ratio % of manure ( $i$ );  $Q_i$ : available quantity (t/y) of manure ( $i$ );  $BO_i$ : bio-oil yield (t/y) for manure ( $i$ ),  $SG_i$ : syngas yield (t/y) for manure ( $i$ );  $BC_i$ : biochar yield (t/y) for manure ( $i$ );  $BHV_i$ : Bio-oil heating value (GJ/t) via manure ( $i$ );  $SHV_i$ : syngas heating value (GJ/t) via manure ( $i$ );  $E_i$ : process emissions in kg CO<sub>2</sub>-e /kg manure ( $i$ );  $C_i$ : Bio-oil cost (\$/kg) using manure ( $i$ );  $i=1-4$  represent manure types, whereby: 1: Poultry manure, 2: Dairy manure, 3: Camel manure, 4: Sheep manure.

**3. Results and Discussion**

*3.1. Products Distribution*

**Figure 2.** depicts the effect of temperature on the distribution of pyrolysis products in feedstock samples. In terms of bio-oil and syngas yields, increasing the temperature from 300 to 600°C increased the bio-oil and syngas yields in all feedstocks. However, the increased temperature resulted in a decrease in the biochar yield of all feedstocks. The highest bio-oil and syngas yields were achieved at 600°C, while the highest biochar yield was achieved at 300°C. Among the feedstocks, CM produced the most syngas (55%), DM produced the most biochar (33%), and PM offered the highest bio-oil yield (41%).

**Figure 2.** Effect of temperature on the distribution of pyrolysis products.

*3.2. Bio-oil Levelised Cost*

The bio-oil levelised cost of all manures with respect to temperature is presented in **Figure 3a**. The levelised cost for the bio-oil production from CM is not considered since the bio-oil production from the manure is little. For all manures, the levelised cost for the production of bio-oil is minimum at 500°C, whilst the cost is maximum at 300°C. Of all the manures, PM contributed for the lowest bio-oil levelised cost (0.34 USD/kg of bio-oil). This suggests that pyrolysing PM would result in greater financial gain than pyrolysing other manures.

Figure 3a. Bio-oil levelised cost of the manures.

Figure 3b. Carbon footprint of the manures.

### 3.3. Carbon Footprint

Figure 3b. illustrates the carbon footprint (kg CO<sub>2</sub>-e/kg Bio-oil) of all manures in relation to different temperatures. The carbon footprint value for all manures is lowest at 300°C and highest at 600°C. Because the CM produces a meagre amount of bio-oil, the carbon footprint of the manure is negligible. DM had the lowest carbon footprint of the feedstocks, while SM had the highest carbon footprint. This suggests that DM pyrolysis is less polluting than other manures.

### 3.4. Optimal Blend

The effect of manure blending ratio with respect to products' yields, heating value, carbon footprint, and production cost is illustrated in Figure 4. The best manure blending ratio for the maximum bio-oil yield and the lowest cost is achieved at 52% PM: 2% DM: 3% CM: 43% SM. The optimal blending ratio for the lowest carbon footprint is accomplished at 42% PM: 21% DM: 30% CM: 7% SM.

Figure 4. Optimal blending ratios for achieving 7 objectives.

#### 4. Conclusion

The pyrolysis of four different types of livestock manures—poultry (PM), dairy (DM), camel (CM), and sheep manure is examined in this study (SM). The process is simulated using empirical prediction models that are already well established. Additionally, the process performance for the manure feedstocks is assessed from cradle to gate in terms of economic viability and environmental impact. The best manure blend for commercial bio-oil production is then evaluated using a mathematical optimisation model that considers various operating conditions, manure compositions, and availability in the State of Qatar. According to the findings, PM is connected to the highest yield of bio-oil (41%) at 600°C, while CM is responsible for the lowest yield. Finally, 52% PM: 2% DM: 3% CM: 43% SM is found to be the ideal manure blending ratio for the highest bio-oil yield and lowest cost. While 42% PM: 21% DM: 30% CM: 7% SM is the blend that results in the lowest carbon footprint. The created model offers a thorough understanding of the pyrolysis's ideal technical and environmental valorisation of livestock manures.

# Investigating the feasibility of biomass integrated gasification combined cycle (BIGCC) as a power alternative in Gaza Strip

Rawan Shihada,<sup>a</sup> Rania Salem,<sup>a</sup> Amanda Munia,<sup>a</sup> Nashat Naim,<sup>a</sup> Mohammad Alherbawi<sup>b\*</sup>

<sup>a</sup> Faculty of Engineering and Information Technology, Al-Azhar University, Gaza, Palestine.

<sup>b</sup> College of Science and Engineering, Hamad Bin Khalifa University, Qatar Foundation, Doha, Qatar

\*[malherbawi@hbku.edu.qa](mailto:malherbawi@hbku.edu.qa)

## Abstract

Gaza strip suffers from severe electricity deficit of 62%, due to the lack of fuel needed to operate the local power plant. As a result, local authorities adopted a rationing plan, through which the power is often cutoff during half of the day. Meanwhile, more than 2,000 tonnes of wastes are generated every day in Gaza, while its municipal capabilities to recycle wastes are limited, leading to the landfilling of most of the generated wastes in a highly populated region. Therefore, this study explores the feasibility of the biomass integrated gasification combined cycle (BIGCC) in Gaza scenario in utilising local wastes and independently generating power at reasonable costs. The BIGCC plant is simulated using the advanced system for process engineering software (Aspen Plus<sup>®</sup>). Furthermore, an economic feasibility analysis is conducted considering the actual costs of similar existing units, as well as local operating costs. The obtained results are encouraging, where the designed BIGCC plant was able to generate ~207 MW, which can fulfill 46% of Gaza's electricity demand, and 86.25% of its current power deficit. The levelised cost of electricity (LCOE) is estimated at 0.045 \$/kWh, which represents 26% only of the current market price. The proposed scenario may contribute to diversifying the power supplies in Gaza and compensate for the power deficit. In addition, a diversion from landfilling can be achieved through wastes valorisation, which reduces the associated land and carbon footprints.

**Keywords:** IGCC; Techno-economics; Clean power; LCOE; Aspen Plus; Gaza.

## 1. Introduction

Gaza Strip has been suffering from a severe electricity shortage since 2007 due to the lack of diesel fuel. The present demand is approximately 450 MW, while the current supplies are no more than 210 MW, ending up with more than 60% shortage of power (PENRA 2022). However, there are 8,900 TJ/year of biomass potential in the Gaza Strip, where considerable amount of biomass is produced every day, including municipal waste (MSW), agricultural residues, and sewage sludge (Al-Najjar et al. 2020). More than 2,000 tonnes of MSW are generated every day, which is expected to reach 2,660 tonnes during the year 2025 (MDLF 2017).

Therefore, this study investigates the feasibility of BIGCC establishment in Gaza to utilise local biomass for the generation of electricity to fill up the current power shortage. In comparison to existing coal power plants, BIGCC plants are known to have a higher thermal efficiency as they convert biomass into syngas and then use its flue gas and heat to generate electricity through a heat-integrated system (Zang et al. 2020).

Considering local biomass, a BIGCC plant is modelled and evaluated in Aspen Plus (V.9), while an economic assessment is conducted based on local prices of materials and international equipment costs.

The model in hand may provide insights on power generation alternatives in developing countries through the utilisation of local waste at reasonable costs. Nevertheless, the deployment of BIGCC technology may also contribute towards land filling diversion and emissions mitigation.

## 2. Methodology

### 2.1. Model Development

An integrated gasification combined cycle using municipal solid waste (MSW) is modelled in Aspen Plus V.9. A simplified process flow diagram is shown in Figure 1. Throughout the simulations of BIGCC, mass and energy balance and chemical equilibrium were observed, considering an isothermal and steady state systems.

**Figure 1:** Process flow diagram of BIGCC.

MSW is introduced into the model based on its proximate and ultimate analysis reported in Table 1 (Phyllis 2022). The gasification part of the model was simulated using four Aspen Plus blocks based on Alherbawi et al. (Alherbawi, AlNouss, et al. 2020) model. The process starts by processing the feedstock in a drying unit (RStoic) to reduce its moisture content. The dry MSW which is defined with zero moisture was then passed through an RYield reactor for pyrolysis, where non-conventional components are converted into their equivalent conventional elements and compounds (i.e.,  $H_2$ ,  $N_2$ ,  $O_2$ , C, S, ash). To simplify the model, ash is separated using a solid separator, while useful components are processed along with a gasifying agent (i.e., steam) into two consecutive blocks representing the oxidation and reduction processes following the reactions in Table 2. The reactor calculates the syngas composition by minimising the Gibbs free energy to achieve a chemical and state equilibrium (Alherbawi, Al-Ansari, and Mckay 2020).

**Table 1:** Proximate and ultimate analyses of MSW.

Proximate analysis	(wt. %)	Ultimate analysis	(wt. %)
Moisture	7.56	Carbon	48.23
Ash	17.8	Hydrogen	5.16
Volatile matter	57.99	Nitrogen	1.21
Fixed Carbon	24.21	Oxygen	27.31
		Sulfur	0.29

**Table 2:** Key gasification reactions.

Reaction	Equation	No.
Carbon oxidation	$C + O_2 \leftrightarrow CO_2$	(1)
Partial oxidation	$C + \frac{1}{2} O_2 \leftrightarrow CO$	(2)
Steam generation	$H_2 + \frac{1}{2} O_2 \leftrightarrow H_2O$	(3)
CO oxidation	$CO + \frac{1}{2} O_2 \leftrightarrow CO_2$	(4)
Boudouard reaction	$C + CO_2 \rightarrow 2CO$	(5)
Methanation	$C + 2H_2 \rightarrow CH_4$	(6)
Steam gasification	$C + H_2O \rightarrow CO + H_2$	(7)
Methane reforming	$CH_4 + H_2O \leftrightarrow CO + 3H_2$	(8)
Water gas shift reaction	$CO + H_2O \leftrightarrow CO_2 + H_2$	(9)
Ammonia formation	$N_2 + 3H_2 \rightarrow 2 NH_3$	(10)
Hydrogen sulfide formation	$S + H_2 \rightarrow H_2S$	(11)

Following the gasification reaction, traces of unconverted char are separated from the syngas using solid separator. While a flash unit is used to remove tar and water contents before processing the raw syngas into a methanol-based absorption unit (Alherbawi et al. 2021). To remove CO<sub>2</sub>, NH<sub>3</sub> and H<sub>2</sub>S, cool methanol is introduced into a RadFrac absorber against the flow of syngas, where gas impurities are dissolved in methanol and then stripped in a regenerator column at a higher temperature.

The power generation stage is simulated as a combined cycle system to further utilise the generated heat into electricity production. Where syngas is pumped into a combustion chamber, in which the relevant combustion reactions are defined with adequate flow of air to observe a complete combustion.

The hot and high-pressure gas resulting from the combustion is introduced into a gas turbine and a generator to generate power. In parallel, the combustion's resulting heat is utilised to create steam using a boiler feedwater, where the high-pressure steam is passed through a steam turbine to generate additional power.

### 2.2. Economic Assessment

An economic analysis is conducted based on pre-COVID19 values. An BIGCC plant located in Gaza (Palestine) is considered with a feed capacity of 2000 tonnes/day. The analysis is conducted based on the given parameters and assumptions listed in Table 3. The biomass collection charges, wages, raw materials and utility prices are quoted locally. As for capital expenses (capex), the key equipment prices are adapted from high-level technical reports (National Energy Technology Laboratory 2007; National Renewable Energy Laboratory 2011), scaled up and inflated to the base year of analysis using the Chemical Engineering Plant Cost Index (CEPCI) as expressed in Equation 12 and 13. While the minimum selling price of electricity is calculated using Equation 14.

**Table 3:** Economics parameters and assumptions used in this study.

Parameter	Value/ assumption
Location	Gaza strip (Palestine)
Analysis year	2019
Currency	U.S. \$
Plant feed capacity	2000 t/d
Feedstock gate price	30 \$/t
Water- price	0.26 \$/m <sup>3</sup>
Waste disposal charges	30 \$/t
Electricity price	0.14 \$/kWh
Operating	25% of the labour
Maintenance	2% of equipment
Overhead	60% of the labour
Discount rate	10%
Taxes	25%
Insurance	1.5% of total installed cost (TIC)

$$Cost_{desgin} = Cost_{base} \cdot \left( \frac{Capacity_{desgin}}{Capacity_{base}} \right)^{Scaling\ Factor} \quad (12)$$

$$Cost_{desgin} \$ 2019 = Cost_{desgin} \$ i \cdot \left( \frac{CEPCI_{2019}}{CEPCI\ i} \right) \quad (13)$$

$$LCOE \left( \frac{\$}{kWh} \right) = \frac{Capex + \sum_1^{Lifespan} (Opex(1+Discount\ Rate)^{-Lifespan})}{\sum_1^{Lifespan} generated\ power (1+Discount\ Rate)^{-Lifespan}} \quad (14)$$

### 3. Results and Discussion

#### 3.1. Technical Analysis

At gasification stage, an enhanced syngas is generated with a molar ratio of hydrogen to carbon monoxide at 1.3. A small amount of methane is produced (<0.1%). While the gas impurities (CO<sub>2</sub>, NH<sub>3</sub>, H<sub>2</sub>S) are perfectly removed using methanol absorption. The final molar and mass composition of cleaned syngas is presented in Table 4.

In addition, at combined-cycle power generation stages, 207 MW is generated a year, where 80% of the generated power is obtained from the gas turbine, while the steam turbine contributed with the remaining 20%. The attained power can fulfill 46% of Gaza's electricity demand, and 86.25% of its current power deficit.

**Table 4:** Cleaned syngas composition.

Component	Mass fraction	Mole fraction
H <sub>2</sub>	8.3%	55.7%
CO	88.5%	43%
CO <sub>2</sub>	2.2%	0.6%
Others	1%	0.7%
<b>Sum</b>	<b>100%</b>	<b>100%</b>

3.2. Economic Analysis

The key findings of the BIGCC economic analysis are presented in Table 5. The capital expenses (capex) are estimated at 608 M U.S.\$, while the plant requires annual operating expenses (opex) of 16.5 M U.S.\$\$. Whereas 190 M U.S.\$ of profit (after tax) can be attained. The return on investment is at 31%, while the investment cost can be paid in 3.2 years. Furthermore, the levelised cost of electricity is achieved at 0.045 \$/kWh, which represents only 26% of the current market price.

Figures 2 and 3 reveal the breakdown of capex and opex, where purchased equipment occupied 40% of capex, while opex is dominated by raw materials cost at 42%.

**Table 5:** Key economics parameters of Gaza’s BIGCC project.

Item	Value	Unit
Levelised cost of electricity	0.045	\$/kWh
Project capex	608,229,938	\$
Project opex	16,489,484	\$/y
Capacity	207.13	MW
Sales	254,018,100	\$/y
Annual profit	237,528,616	\$/y
Profit after tax	190,022,893	\$/y
Payback time	3.2	years
ROI	31	%

**Figure 2:** Breakdown of Gaza’s BIGCC capex.

**Figure 3:** Breakdown of Gaza’s BIGCC opex.

#### 4. Conclusion

This study has investigated the feasibility of BIGCC establishment in Gaza Strip which is suffering from severe power shortage. The plant was assumed to operate based on local solid waste at 2000 tonnes per day and was simulated and evaluated in Aspen Plus software. The proposed plant generated 207 MW a year, which may fulfill nearly 50% of net Gaza's power demand, and 86% of the present power shortage.

The economic analysis indicated that the plant requires an investment cost of around 600 M U.S.\$, and that it can generate power at a minimum cost of 0.045 \$/kWh, which represents quarter of the current market price.

The model provides insights on local resources-based power generation as a feasible and clean alternative for countries suffering from severe fossil fuel shortage.

# The Infinity Reactor: A new conceptual design for a more cost-efficient CO<sub>2</sub> to methanol route

Hilbert Kestra, Edwin Zondervan, Wim Brilman

University of Twente, Drienerlolaan 5, 7522 NB Enschede, The Netherlands

## Abstract

With conventional methanol reactor designs for CO<sub>2</sub>-based methanol synthesis, there is the risk of rapid catalyst deactivation with commercial Cu/ZnO/Al<sub>2</sub>O<sub>3</sub> catalysts at high water partial pressures, related to the use of CO<sub>2</sub> as carbon feed. As catalyst reactivity and exothermicity are influenced by the switch to a CO<sub>2</sub>-rich feed, also heat integration options are affected. A new reactor/process design, the Infinity Reactor, is proposed to both improve catalyst lifetime and reduce catalyst usage. The Infinity Reactor is a shell and tube type of reactor, with catalyst on both sides, utilising the difference in temperature between the inlet and outlet of the reactor to operate as a quasi-gas-cooled reactor. The gas loops over both sides of the reactor, with intermediate cooling and condensation. This modelling study shows around 35% savings in catalyst volume in comparison with adiabatic operation.

**Keywords:** methanol, intensification, infinity, reactor, CO<sub>2</sub>

## 1. Introduction

Methanol serves as an important feedstock for about 30% of industrial chemicals<sup>1</sup>. Methanol is commercially synthesized from fossil-derived syngas (a mixture of CO, CO<sub>2</sub> and H<sub>2</sub>) via the hydrogenation of CO<sub>2</sub> (Equation 1), which is an exothermic reaction. The role of CO at high conversions is to remove excess water via the water-gas shift reaction (WGS) (Equation 2), thereby enhancing CO<sub>2</sub> conversions to methanol<sup>2,3</sup>. However, this mechanism also increases the exothermicity of the process.

Many companies have understood that developing CO<sub>2</sub>-utilizing technologies are an essential step towards a sustainable industrial world<sup>4-6</sup>. However, using

pure CO<sub>2</sub> as a feedstock (e.g. obtained from flue gases to reduce CO<sub>2</sub> emissions) reduces the contribution of the WGS reaction. This reduces the exothermicity of the system but also increases water production during methanol synthesis.

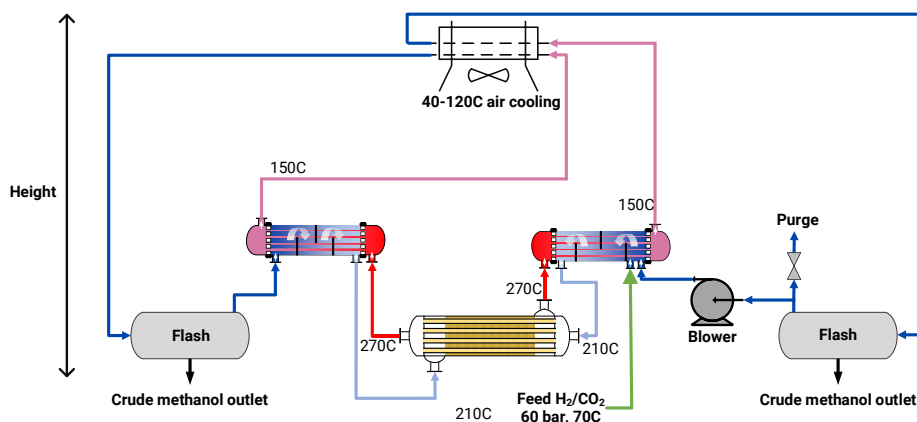

Catalyst deactivation is one of the major hurdles in green methanol production due to a higher water concentration in the process that induces ZnO agglomeration and ZnAl-spinel formation<sup>7,8</sup>. Whereas commercial catalysts have a lifetime of 4-6 years<sup>3,9,10</sup> with CO-rich syngas-based feeds, methanol production with CO<sub>2</sub>-rich feeds suffers from more rapid deactivation in terms of a few months or even weeks<sup>7,11,12</sup>. It is anticipated that this is especially related to higher water partial pressures at high temperatures. Model-based tools like process simulations are necessary for investigating and comparing performances and costs. Therefore, this study has investigated new plant configurations and reactor concepts to improve catalyst lifetime, reduce catalyst usage, and make, through this, the CO<sub>2</sub> to methanol process more cost-efficient.

## 2. Methods

Boiling water reactors (BWR) and quench reactors are the most utilised reactors in commercial methanol synthesis<sup>13,14</sup> and were therefore used as a starting point for this study. Marlin et al.<sup>15</sup> from Carbon Recycling International (CRI) utilise a tube-cooled reactor as a way to save on capital investment because the reaction is less exothermic and progresses slower compared to syngas-based methanol production. The effective wall area for heat exchange between the cooling medium and reaction gas can be decreased by using larger tubes and, thus, heat transfer rates are reduced while still sufficient to remove excess reaction heat.

The models of all the above plant configurations were simulated in Aspen HYSYS and first validated with available plant data from Lurgi<sup>14,16</sup>, which utilises a BWR, and Johnson Matthey<sup>14,17</sup> (formerly ICI), which uses the quench design. All simulations include a recycle stream, heat exchanger, cooler, and flash unit for separating the liquid product mixture.

In this work, an improvement to the above existing reactor concepts and plant configurations is proposed, using in-situ direct heat integration between two different catalyst zones in one (shell and tube) reactor unit to intensify the process, enabled by a lower exothermicity when using CO<sub>2</sub>. Two gas-gas heat exchangers, a combined air cooler, two flash vessels, and a blower complete the (Infinity) reactor loop. Detailed reactor calculations for this reactor were done using Python.

**Figure 1.** Proposed flowsheet of the methanol synthesis loop for the Infinity Reactor.

**Figure 2.** Sketch of an Infinity Reactor. The reactor has catalyst (not drawn) on both sides of the tubes and consists of two stationary heads and two rear heads. The overall flow contacting pattern is counter-current.

In the proposed flowsheet, the fresh feed is mixed with recycle gas and fed to a heat exchanger where it is heated up to 210 °C and then sent to the reactor. The reactor inlet is heated up by the hot reactor outlet (270 °C) of the gas stream on the other side of the tubes, thereby accelerating the reaction rate at the cold feed side and preventing too high temperatures at the hot side. At the other end of the reactor, the reverse happens. Therefore, the reactor is a type of gas-cooled reactor, effectively utilising the temperature gradients inside the reactor. The hot reactor outlet streams are used in a separate heat exchanger to preheat the cold recycle stream from the condenser. The cooled reactor effluent with an outgoing temperature of ~150 °C is subsequently cooled down in a combined air cooler. Any condensed product will be separated in a flash vessel from the unreacted gas. The process can be designed for a low pressure drop to enable the use of a blower instead of a recycle compressor for the recirculation of unconverted syngas.

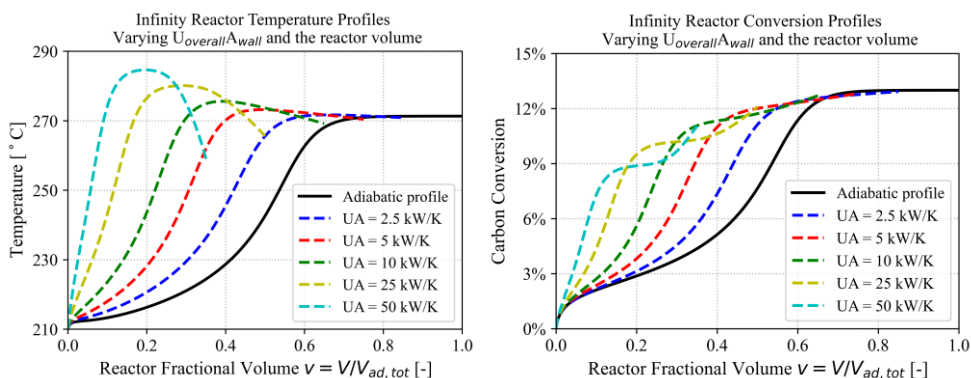

### 2.1. Model development

The kinetic model of Vanden Bussche and Froment<sup>18</sup> (VBF) was chosen because it is one of the most utilised models and serves as a benchmark in the industry<sup>14,19</sup>. Due to input restrictions in Aspen HYSYS, the equilibrium constants as proposed by Graaf et al.<sup>20</sup> were refitted as Arrhenius equations. The kinetic model was first validated with data from VBF<sup>18</sup> and industrial plant data<sup>16,17,21,22</sup>. For heat transfer calculations the lumped value  $UA$  was used, which is the combination of the overall heat transfer coefficient  $U_{ov}$  ( $W/m^2.K$ ), multiplied by the tubular wall area  $A_{wall}$  ( $m^2$ ).

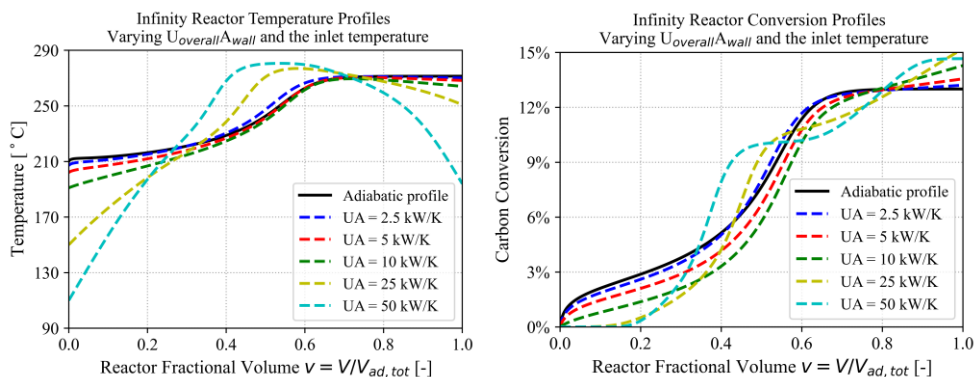

**Table 1.** Main process parameters used in the simulations.

Operating pressure (bar)	60
Cooling temperature ( $^{\circ}C$ )	70
Molar flow rate (kmol/hr)	957
$H_2/CO_2$ ratio	3
Catalyst particle diameter (mm) <sup>14,21</sup>	5.7
Catalyst particle density ( $kg/m^3$ ) <sup>18</sup>	1775
Bed voidage <sup>14,21</sup>	0.39

### 3. Results & discussion

**Figure 3.** Temperature and conversion profiles for the Infinity Reactor with varied  $UA$  and reactor volume but constant inlet temperature. For the adiabatic profile  $V_{tot}=V_{ad,tot}$ ,  $UA=2.5$  kW/K has  $V_{tot}=0.85V_{ad,tot}$ ,  $UA=5$  kW/K has  $V_{tot}=0.75V_{ad,tot}$ ,  $UA=10$  kW/K has  $V_{tot}=0.65V_{ad,tot}$ ,  $UA=25$  kW/K has  $V_{tot}=0.5V_{ad,tot}$ ,  $UA=50$  kW/K has  $V_{tot}=0.35V_{ad,tot}$ .

**Figure 4.** Temperature and conversion profiles of the Infinity Reactor with varied UA and inlet temperature but constant reactor volume. For the adiabatic profile  $T_{in}=210$  °C, UA=2.5 kW/K has  $T_{in}=207$  °C, UA=5 kW/K has  $T_{in}=202$  °C, UA=10 kW/K has  $T_{in}=191$  °C, UA=25 kW/K has  $T_{in}=150$  °C, UA=50 kW/K has  $T_{in}=110$  °C.

Figure 3 shows that the required catalyst amount can be drastically lowered if there is sufficient tube wall area for heat transfer. The average temperature in the reactor is increased and, therefore, the reaction rate is higher on average, resulting in less catalyst required to reach equilibrium. However, too much area for heat transfer will result in a higher peak temperature due to the added heat and results in faster catalyst degradation. Figure 4 shows that the inlet temperature can be lowered while slightly increasing conversions. However, if the temperature is lowered too much, the reaction rate is nearly zero and then it acts only as a cooling medium to lower the reactor outlet temperature of the other reactor. Conversions are ~13% per pass in the Infinity Reactor and adiabatic reactor at the simulated conditions while the BWR and quench reactor are ~20%. Therefore, the water partial pressure is ~35% lower in the proposed concept.

Case-specific conditions and parameters	
Inlet temperature (°C) of the BWR	240
Boiler feed water temperature (°C)	250
UA (kW/K) of the BWR	263
Inlet temperature (°C) of the other designs	210
UA (kW/K) of the Infinity Reactor	10
4-bed volume ratio of the quench reactor	0.2-0.23- 0.23-0.34

**Figure 5.** Space-time yield per simulated reactor concept and the case-specific assumptions.

Figure 5 shows that the Infinity Reactor has a higher catalyst utilisation compared to the other simulated reactor concepts. For the chosen conditions and parameters, catalyst savings are 35% compared to adiabatic operation, 20% compared to BWR, and ~80% compared to a 4-bed quench reactor. In addition, the catalyst lifetime is improved due to the lower water partial pressure compared to a BWR and quench reactor as the single-pass conversion is lower (13% compared to 20%). Furthermore, a multi-stage design with water removal reduces the recycle size and, thus, reduces operational costs.

#### 4. Conclusions

The Infinity Reactor requires significantly less catalyst than adiabatic, boiling water, and quench reactors. It is expected that this will translate to a lower pressure drop, lower investment and lower operational costs. The operational costs are lower due to a smaller gas recycle ratio, caused by a higher conversion per full cycle of the gas loop, related to the two reactor passes per cycle. The somewhat lower single pass conversion leads to a lower water partial pressure inside the reactor compared to the boiling water and quench reactor concepts, by which the catalyst lifetime is improved.

## Abstract

Biohydrogen is considered as an alternative to replace fossil fuels and is being researched as a possible alternative to reduce conventional non-renewable hydrogen technologies. Towards a circular economy, microbial electrolysis cells have been suggested as a tool to both reduce organic pollutants from wastewater as well as to produce desirable hydrogen gas. Research efforts have focused on experimental design and computational simulation. The work presented here aims to develop an optimization model capable of estimating an optimal design and operational criteria to maximize cell's hydrogen output.

**Keywords:** microbial electrolysis cell, hydrogen, modeling, optimization

## 1. Introduction

The Microbial Electrolysis Cell (MEC) is a fairly new technology that has emerged and got scientific attention. The cell exploits the conductor-like properties of electrogenic microorganisms that catalyze the electrochemical oxidation of organic substrate, converting electrical energy into chemical energy stored in the H<sub>2</sub> molecule that is produced through the electrochemical reduction of the protons of the electrolytic medium. The main advantage of this technology is the ability to both treat wastewater effluents (source of organic matter) and synthesize biohydrogen. Numerous wastewater effluents have been demonstrated as potential substrate sources for MEC operation with varying degrees of efficiency in both organic-waste removal and hydrogen generation.

MEC-reactor design is known to be influenced by effluent's substrate concentration, reactor geometry and sizing, electrode material and configuration, anode-cathode distance, presence of a separator between them, composition of the electrolytic medium, as well as the microbial communities in the anodic chamber (Rousseau, 2021). Experimental studies have been performed to comprehend and optimize the processes occurring in these systems, however, so far there is no consensus to determine a feasible reactor configuration that would lead to competitive hydrogen production rates.

One approach that could be used to oversee these hindrances is mathematical modelling, to which fewer studies have been carried out. The first model proposed for a MEC was reported by Pinto *et al.* in 2011. This work studied the effect of several microbial communities: electrogenic, methanogenic, acetoclastic and hydrogenotrophic distributed in bioanode layers to understand their competition for the substrate in a continuous MEC. Later, Karimi, *et al.* in 2015 reported a generalized model that assumes coexisting microbial populations and the effects of a dynamic biofilm growth on substrate-potential distribution within it considering a conduction-based biofilm model in a batch reactor. A

similar model was proposed by Flores-Estrella, *et al.*, in 2019 considering a continuous operation MEC. Hernández-García, *et al.*, in 2020 reported a model that considers the influence of geometry with primary and secondary current-substrate distributions in 2D, and was re-studied, in 3D considering the effects of hydrodynamic behavior in a fed-batch reactor. Other works have developed models, which include stability and sensibility analysis and process control. As for optimization, some studies have been performed by trial-error and online methods, with little focus in a mathematical problem statement. Design optimization is an engineering tool that utilizes a mathematical formulation of a design problem to support the selection of an optimal design among several alternatives. This work proposes a process model for a MEC based in a conduction-based bioanode considering operational and topological constraints, stated as discrete decision variables in order to find a design that maximizes hydrogen production rate.

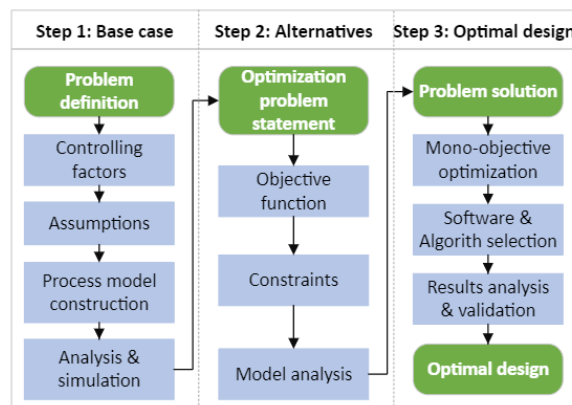

## 2. Methodology

### 1.1. Modeling framework

A systematic modeling approach has been adapted from Aguiñaga-Morales *et al.* (2017) which allows the construction of a process model that will be set as equality constraint in an optimization model, described in Figure 1.

### 1.2. Problem statement

A Microbial electrolysis cell (MEC) consisting of two chambers, separated by a cation exchange membrane, contains acetate as substrate in the anodic chamber, a carbonaceous material anode colonized by electroactive bacteria and an abiotic platinum cathode. The electrodes are linked by an external circuit. The Ag/AgCl/KCl<sub>(sat)</sub> system is used as the reference electrode. The substrate oxidation releases CO<sub>2</sub>, electrons, and protons, which will be electrochemically reduced at the cathode. The system is illustrated in Figure 2.

**Figure 1.** Modeling approach adopted to solve the optimal MEC design problem.

#### 1.2.1. Identification of limiting factors and assumptions

(1) Substrate mass transport is mediated by diffusion, here described in 1D from and to the bioanode. (2) The biofilm acts as a porous conductor with conductivity  $\kappa_{bio}$ . (3) Electroactive bacteria exhibit extracellular electron transfer mechanisms through conductive pili and cytochrome C in their cell wall. (4) Cell operates in batch mode with uniform substrate distribution in bulk liquid. (5) Biofilm is mediated by advection. (6) Cathodic chamber is free of microorganisms. (7) An external power supply provides

**Figure 2.** Schematic representation of phenomena in the modeled MEC. On the bioanode the model substrate (acetate) is diffused and oxidized by electroactive bacteria for cell growth. The generated protons go through the membrane to be reduced at the cathode.

the cell with a voltage that drives the electrochemical production of  $H_2$ . (8) The substrate oxidation generates the electrons needed to reduce the protons at the cathode, in terms of produced current or consumed electric charge. (9) This model is limited to hydrogen generation only, and does not consider methane production by other bacteria.

### 1.3. Construction of process model

#### 1.3.1. Substrate mass balance in biofilm domain

Substrate accumulation in biofilm is mediated by diffusion and the consumption term, expressed as the following equation:

$$\frac{\partial S_d}{\partial t} = D_{S,f} \frac{\partial^2 S_d}{\partial z^2} - X_{f,a} q \quad (1)$$

With boundary conditions in anode surface ( $z=0$ ) and biofilm-liquid interface ( $z=L_f$ ):

$$D_{ED,f} \frac{\partial S_d}{\partial z} \Big|_{z=0} = 0$$

$$D_{ED,f} \frac{\partial S_d}{\partial z} \Big|_{z=L_f} = \left(\frac{D_{S,l}}{L}\right)(S_{d,l} - S_{d,n})$$

Where  $S_d$  is the substrate concentration,  $D_{S,f}$  is the substrate diffusion constant at the biofilm,  $X_{f,a}$  is the electroactive biomass density and  $q$  is the substrate consumption rate.  $q$  is expressed as Monod-like kinetics derived from the Nernst equation, named Nernst-Monod kinetic equation:

$$q = q_{max} \phi_a \frac{S_d}{S_d + K_S} \frac{1}{\exp[-F\eta/RT] + 1} \quad (2)$$

$q_{max}$  is the maximum rate of substrate consumption,  $\phi_a$  is the volumetric fraction of electroactive biomass,  $F$  is the Faraday constant,  $T$  is the anodic chamber temperature and  $\eta$  is the local potential, and  $K_S$  is the Monod's half-saturation constant.

#### 1.3.2. Charge balance in biofilm

Electron transfer through the biofilm matrix is allowed by the local potential difference across the biofilm; the biofilm potential's change over time is expressed by this conduction (derived from the Ohm's law) and the addition of electrons generated by substrate oxidation and endogenous respiration:

$$\frac{\partial \eta}{\partial t} = \kappa_{bio} \frac{\partial^2 \eta}{\partial z^2} + \frac{F\gamma_1}{\tau} L_f f e^0 X_{f,a} q + \frac{F\gamma_2}{\tau} L_f X_{f,a} r_{res} \quad (3)$$

With boundary conditions in anode surface ( $z=0$ ) and biofilm-liquid interface ( $z=L_f$ , no conduction):

$$\eta|_{z=0} = V_{anode} \quad \frac{\partial \eta}{\partial z}|_{z=L_f} = \frac{j|_{z=L_f}}{\kappa_{bio}} = 0$$

Here  $\eta$  is the local potential,  $\kappa_{bio}$  is the biofilm's conductivity,  $\gamma_1$  is the yield of electrons from substrate oxidation,  $L_f$  is the biofilm thickness,  $X_{f,a}$  is the biomass density,  $f e^0$  is the fraction of electrons used for electrosynthesis,  $\gamma_2$  is the electron yield from endogenous respiration,  $F$  is the Faraday's constant,  $\tau$  is the time conversion and  $r_{res}$  is the endogenous respiration rate:

$$r_{res} = b_{res} \frac{1}{\exp[-F\eta/RT]+1} \quad (4)$$

### 1.3.3. Biomass balance in biofilm

The microbial population exists as a consortium of electroactive bacteria, capable of metabolic extracellular electron transfer, and non-electroactive bacteria, which are capable of substrate consumption. In volume terms, the sum of their fractions is given by:

$$\phi_a + \phi_i = 1 \quad (5)$$

$\phi_a$  and  $\phi_i$  are the electroactive fraction and the non-electroactive fraction, respectively. Their mass balances are stated as:

$$\frac{\partial \phi_a}{\partial t} + \frac{\partial(v\phi_a)}{\partial z} = Yq - r_{res} - r_{rina} = \mu_a \quad (6)$$

Which represents the transient electroactive fraction with respect to its position (a function of the advective velocity),  $v$ , by metabolic growth, loss by endogenous respiration and loss by inactivation.

$$\frac{\partial \phi_i}{\partial t} + \frac{\partial(v\phi_i)}{\partial z} = \frac{X_{f,a}}{X_{f,i}} r_{rina} = \mu_i \quad (7)$$

This equation gives the transient volumetric fraction of non-electroactive biomass, and its growth is given by the rate of inactivation,  $r_{rina}$ , which is stated as:

$$r_{rina} = b_{ina} \phi_a \quad (8)$$

Where  $b_{ina}$  is the inactivation constant. The advective velocity may also vary on biomass growth, so we can state:

$$\frac{\partial v}{\partial z} = \mu_a + \mu_i \quad (9)$$

This can be integrated along the biomass specific growth rate to get the advective velocity at any point  $z'$ , considering that the net growth enhances the advective velocity.

The biofilm growth is thus a function of the advective velocity and the detachment phenomenon (which reduces biofilm's thickness) and can be formulated as:

$$\frac{dL_f}{dt} = v(t, L_f) - b_{det} L_f \quad (10)$$

Where  $b_{det}$  is the detachment constant.

### 1.3.4. Mass balances in liquid bulk

The substrate fed to the cell is accumulated on its volume, and fluxes to the biofilm domain as it's also consumed. The macroscopic mass balance can be stated as:

$$\frac{d(S_l V_b)}{dt} = A_s \frac{D_{S,l}}{L} (S_{d,n} - S_l) - V_b q_b \quad (11)$$

Here  $S_l$  represents the substrate concentration in the bulk liquid,  $V_b$  is the liquid volume in the anodic chamber,  $A_s$  is the anode surface area,  $D_{S,l}$  is the diffusion coefficient in the liquid,  $L$  is the thickness of the diffusion layer,  $S_{d,n}$  is the substrate concentration in the biofilm's surface and  $q_b$  is the substrate consumption rate by suspended biomass.

For the suspended biomass, we express:

$$\frac{dx_b}{dt} = Y_b q_b - b_b x_b \quad (12)$$

$x_b$  is the biomass concentration in the anodic chamber,  $b_b$  is the death rate and  $Y_b$  is the substrate/biomass yield. The consumption rate law for suspended biomass, which doesn't contribute to electron transport, is:

$$q_b = q_{max,b} x_b \frac{S_l}{K_{s,l} + S_l} \quad (13)$$

### 1.3.5. Current generation and hydrogen productivity

The anode potential is function of the applied cell potential by the external power supply.

$$V_{an} = V_1 V_{app} + V_2 \quad (14)$$

Where  $V_{an}$  is the anode potential,  $V_{app}$  is the applied potential, and  $V_1$  and  $V_2$  are constant relationships of linear applied potential.

By Ohm's Law, the current density ( $j$ ) might be stated as the product of the biofilm's conductivity times the quotient of the potential/biofilm thickness gradients, and the cell current ( $I$ ) is known by the product of the anode's surface area times  $j$ :

$$j = -\kappa_{bio} \frac{\Delta \eta}{\Delta z} \quad \text{and} \quad I_{MEC} = A_s j \quad (15)$$

So, we can state the hydrogen productivity as a function of the cell current that conducts to the cathode:

$$Q_{H_2} = \frac{RT}{V_b P} \left( \frac{\tau I_{MEC} Y_c}{nF} \right) \quad (16)$$

$Q_{H_2}$  is the hydrogen volumetric productivity ( $\text{m}^3 \text{H}_2 \text{m}^{-3} \text{anode day}^{-1}$ ) and  $Y_c$  is the cathode's dimensionless efficiency.

## 1.4. Analysis and simulation

Kinetic and electrochemical parameters are obtained from previous MFC and MEC modeling works (Pinto, 2011; Karimi, 2015). To implement, discretize (1) and (3) and their B.C., in space through finite differences, solve non-linear system through Newton's method. Calculate advective velocity (9) by numerical integration (trapezoid rule) then solve for biofilm thickness (10). Biomass balances (5, 6, 7) at the biofilms are solved by Backward-Euler. Subtract detachment rate from biofilm thickness. Interpolate the remaining biomass onto a new grid and iterate. Use a similar approach for (11) and (12).

## 2.5. Optimization problem statement

### 2.5.1. Objective function

The present work aims to optimize the energy efficiency of an MEC considering spatial and operational factors. The cell efficiency is stated as the energy load achieved by hydrogen gathered, a function of its enthalpy of combustion *versus* the applied energy (applied electric potential) and any other applied energy sources as mixing and pumping. We can express this mathematically as:

$$\eta_{H_2} = \frac{W_{H_2}}{W_E} = \frac{Q_{H_2} \rho_{H_2} \Delta H_{H_2}}{I_{MEC} V_{app}}$$

Thus, we can state our objective function as:

$$\max \eta_{H_2} = \frac{Q_{H_2} \rho_{H_2} \Delta H_{H_2}}{I_{MEC} V_{app}}$$

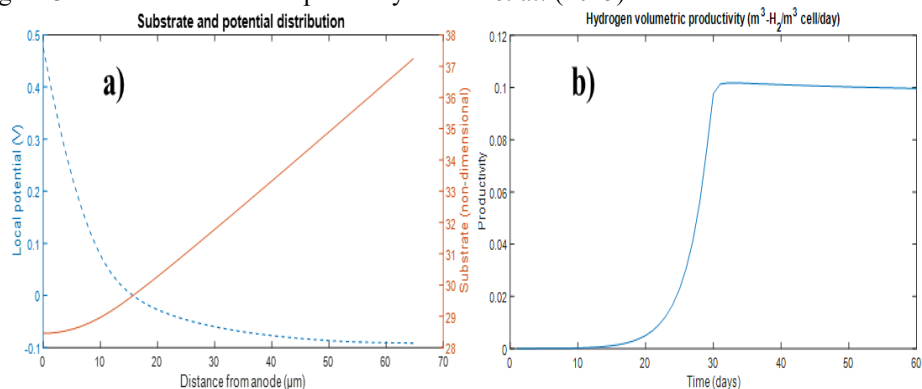

s. t.  $\mathbf{h}(\mathbf{x}, \mathbf{y}) = \mathbf{0}$  (equality constraints);  $\mathbf{g}(\mathbf{x}, \mathbf{y}) \leq \mathbf{0}$  (inequality constraints)

$\mathbf{x} \in \mathbf{X} \subseteq \mathbb{R}^n$ ;  $\mathbf{y} \in \mathbf{Y}$  integer

## 3. Process model simulation results

Thus far, the process model returns spatial distributions of substrate, voltage, and current density in the  $z$  direction across the biofilm. Figure 3 shows that the substrate concentration is highest in biofilm's vicinity with liquid, opposite to the potential which decreases with biofilm length, while the current density behaves similarly, achieving a current density of  $2.9 \text{ A/m}^2$  at tested substrate load of  $1.5 \times 10^{-3} \text{ mol/L}$ . The max. current reached in the  $10 \text{ cm}^2$ -bioanode is  $3.1 \times 10^{-4} \text{ A}$ , so the max. hydrogen productivity is  $0.102$

$\text{m}^3\text{H}_2/\text{m}^3\text{cell day}$  at 32 days, when microbes reach stationary phase and substrate starts depleting. For validation, potential/substrate distribution and  $\text{H}_2$  productivity profiles in Figure 3 are similar to those reported by Karimi *et al.* (2015).

**Figure 3.** (a) Distribution of potential (dashed) and substrate (solid) across biofilm at max length 70  $\mu\text{m}$ . Simulated time, 60 days, initial substrate concentration:  $1.5 \times 10^{-3}$  mol Acetate/L. (b) Hydrogen productivity, reached max. at 32 days.

#### 4. Conclusions

The developed process model is suitable to be formulated as an equality constraint for the objective function and may be tested in different parameter scenarios. It demonstrates microbial processes are limiting to MEC performance. Further alternative analysis will be carried out to complete the optimization problem formulation.

## Abstract

A low-cost and highly exergetic efficient drying process assures a sustainable transformation of Brewer's Spent Grains (BSGs) into value-added product. This work aims to perform an exergoeconomic analysis at a level component of the convective simulated drying process of BSGs. To validate the simulated process, characterization, and a drying kinetic study of BSGs obtained from a factory in Guayaquil, Ecuador, were carried out. The simulated drying process was validated, reaching a maximum relative error of 4.64%. The exergy destruction rate varied from 12.6 MJ/kg to 3.42 MJ/kg when the air inlet temperature varied from 60 °C to 120 °C. Results suggest that the increment of the air inlet temperature could reduce the specific cost of the dry BSGs up to a 68.3% and increase the exergetic efficiency by 24.6%.

**Keywords:** kinetic study, exergoeconomic analysis, process simulation, modeling, Brewer's Spent Grains (BSGs)

## 1. Introduction

Currently, reducing waste is considered a critical need in the brewing industry. The main waste in this production process is the brewer's spent grains (BSGs) (Rachwał et al., 2020). Usually, it is necessary to dry the BSGs due to the high moisture levels before converting them into value-added products (Mallen & Najdanovic-Visak, 2018). Hence, the drying process needs to be sustainable and have low operating costs. The exergoeconomic analysis is considered a vital decision-making tool to reduce production costs and increase the sustainability of a process by reducing the exergy destruction rate (Bejan & Tsatsaronis, 2021). Although there are some drying experimental studies of this waste at temperatures from 40 °C to 95 °C (Capossio et al., 2022) (Castro et al., 2022), these studies do not analyze the best-operating conditions to diminish the exergy destruction rate and the operating cost of the drying process. Thus, there has been no exergoeconomic analysis of the drying process of BSGs. In this context, this work presents an exergoeconomic analysis of a convective drying process of BSGs. The characterization and drying kinetic study were performed using BSGs from a factory located in Guayaquil, Ecuador. The drying process was simulated using Aspen Plus V12.1, and the obtained experimental data was used to validate the process simulation.

The exergetic, economic, and exergoeconomic balances were performed for the dryer using Engineering Equation Solver (ESS) software following the methodology from (Bejan et al., 1996). The exergy destruction rate, investment and operational costs were determined for drying temperatures from 60 °C to 120 °C.

## 2. Materials and Methods

### 2.1. Experimental Studies

#### 2.1.1. Characterization of BSGs

The BSGs were obtained from a brewing company in Guayaquil, Ecuador. The samples were dried at 105°C based on ISO 18123:2015. The proximate analysis (ash and volatile material (VM)) was done according to ISO 18122:2015, respectively. The difference between ash and volatile material determined the fixed carbon (FC) in dry basis. The ultimate analysis was performed by a CHNS Elemental Analyzer (Elementar). The particle size distribution was analyzed according to the ASTM D1511-10 procedure.

#### 2.1.2. Drying Kinetics

The drying kinetic study was carried out at temperatures 60, 70, 80, 90, 105, and 120°C. Higher temperatures were not selected, because a previous study shows that the degradation rate increases (Mishra et al., 2017). Dry BSGs were submerged in distilled water at room temperature during 2 h to reach their initial moisture (Cuevas et al., 2019). Samples were placed on a plate up with thickness of 1.30 cm inside a convective dryer (UNB 500, Memmert, Germany). Periodically the samples were removed from the dryer, weighing them on digital balance in order to measure their average water content.

The critical moisture was determined as transition moisture, where the first constant speed dry deviation was observed. The equilibrium moisture was estimated as the constant behavior for an extended period (Srikiatden & Roberts, 2007). The effective diffusivity was determined from the slope of the natural logarithm of the moisture ratio ( $M_R$ ) versus drying time according to the second diffusion Fick Law for the infinite dry plate (Cuevas et al., 2019). The heat and mass coefficients were determined from the dimensionless numbers based on Incropera et al. (Incropera et al., 2007).

### 2.2. Process Simulation

Figure 1 shows the BSGs simulated drying system. It consists of an air preheater (HX-101) and a batch-type convection drying chamber (D-101). Flue gases at 300 °C (stream 6) with a mass composition of 18.5% CO<sub>2</sub>, 6.8% H<sub>2</sub>O, 7.09% N<sub>2</sub>, and 3.8% O<sub>2</sub> enter the HX-101. Then, ambient air enters the HX-101 with a relative humidity of 73% at 25 °C (stream 1) and exits at the drying temperature (stream 2), which varies between 60 °C to 120 °C. Then, the flue gases exit the HX-101 (stream 7) and they are discharged to the environment. The hot air enters the D-101 to remove the water from the BSGs (stream 3), and the moist air exits the dryer (stream 4). After the process, the dry BSGs (stream 5) is discharged.

Figure 1. Process flow diagram of the drying system

The process simulation was performed in Aspen Plus V12.1. BSGs were simulated as an unconventional component. The ultimate and proximate analysis results obtained in section 2.1 were entered into the HCOALGEN and DCOALIGT models. First, the ideal thermodynamic model was used since it worked at atmospheric pressure, and the MIXCNCPD for handling unconventional solids configured the flow class. Next, the dryer was simulated using a convective dryer. Finally, the simulation was configured in batch mode, where the total drying time was set as the maximum iteration and operation time. Drying data such as heat and mass transfer coefficients, drying curve, equilibrium, and critical moisture were defined in the component.

2.3. Model Validation

The absolute moisture of the BSGs obtained in the simulation was compared with the results obtained experimentally for each drying air temperature. The same operating conditions were maintained to ensure the validity of the modeled process.

2.4. Exergoeconomic analysis

The exergoeconomic analysis was developed according to the methodology offered by (Bejan et al., 1996) using equations Eq.(1)-(4). Engineering Equations Solver (EES) software was used to determine the thermophysical properties for the calculation of enthalpy and entropy of each state.

$$\begin{aligned} \dot{E}_{D,k} &= \dot{E}_{F,k} - \dot{E}_{P,k} \quad (1) & \dot{C}_{F,k} + \dot{Z}_k &= \dot{C}_{P,k} \quad (3) & PEC_{HX-101} &= 1900 + 2500 \cdot S \quad (5) \\ \dot{Z}_k &= \dot{Z}_k^{O\&M} + \dot{Z}_k^{CI} \quad (2) & \dot{C}_{D,k} &= c_{F,k} \dot{E}_{D,k} \quad (4) & PEC_{D-101} &= 10000 + 7900 \cdot S^{0.5} \quad (6) \end{aligned}$$

The economic analysis was carried out following the revenue requirement method. The economic parameters were taken from a previous study by authors (Tinoco-Caicedo et al., 2021). The purchase equipment costs (PEC) of the HX-101 and the D-101 were determined using Eq. (5)-(6) (Towler & Sinnott, 2012), respectively, for 2010 (CEPCI of 532.9). Where S is the area of each tray from the dryer (20 m<sup>2</sup>) and the heat exchange area for the HX-101 (obtained in the simulator). The chemical engineering plant cost index (CEPCI) of 607.5 was used to adjust the PEC for 2019.

Table 1 shows the fuel exergy ( $\dot{E}_F$ ), product exergy ( $\dot{E}_P$ ), fuel cost ( $\dot{C}_F$ ), product cost ( $\dot{C}_P$ ) and auxiliary equations at the component level.

Table 1. Equations used for the exergoeconomic analysis

Component	$\dot{E}_{F,k}$	$\dot{E}_{P,k}$	$\dot{C}_{F,k}$	$\dot{C}_{P,k}$	Auxiliary equation
HX-101	$\dot{E}_6 - \dot{E}_7$	$\dot{E}_2 - \dot{E}_1$	$\dot{C}_6 - \dot{C}_7$	$\dot{C}_2 - \dot{C}_1$	$c_6 = 0$ $c_1 = 0$
D-101	$\dot{E}_2 - \dot{E}_4 + \dot{E}_3$	$\dot{E}_5$	$\dot{C}_2 - \dot{C}_4 + \dot{C}_3$	$\dot{C}_5$	$c_3 = 0$
Overall System	$\dot{E}_F = (\dot{E}_6 - \dot{E}_7) + \dot{E}_3 + (\dot{E}_2 - \dot{E}_4)$ $\dot{E}_P = \dot{E}_5$				

3. Results and Discussion

3.1. Experimental studies

The characterization and drying kinetic study was done for the BSGs. Table 2 shows the results obtained for the ultimate and proximate analysis and the particle size distribution.

Table 2. BSGs characterization required for convective dryer simulation

	Ultimate analysis (% in dry basis)	Proximate analysis (% in dry basis)	Particle size distribution (mm, %)	
C	47.55	Ash	4.03	PS>2 68.48

H	8.09	VM	88.31	1.4<PS<2	16.24
N	5.56	FC	7.66	1<PS<1.4	6.03
O	38.13	Moisture (wb)	81.77	0.85<PS<1	1.28
S	0.67			PS<0.85	7.97

Figure 2 a) shows the drying kinetic of BSGs in a batch type convective dryer at different drying temperatures between 60 °C and 120 °C. The drying time reduction from 4 to 1.25 hours was observed when the temperature increased from 60 °C to 120 °C. This change occurs because the increase in temperature causes a faster water evaporation rate from 0.43 to 2.45 g/kg-s, which can be graphically seen in the slope of the curve from the first period of constant rate. The critical and equilibrium moistures vary from 53.9 % to 72.4 % and 0.63 % to 3.86 % in wet basis, respectively.

Figure 2 b) shows the mass and heat transfer coefficients estimated from the results of the drying kinetic study. It is observed that the heat and mass transfer coefficients increased at high temperatures because the increase in the inlet drying temperature intensifies the water evaporation rate (Beigi et al., 2017a). Similar results were obtained using a tray dryer for pumpkin (Guiné et al., 2012) in which the mass transfer coefficient increased from  $0.1 \times 10^{-5}$  m/s to  $4.1 \times 10^{-5}$  m/s when the inlet air drying temperature increased from 30 °C to 70 °C.

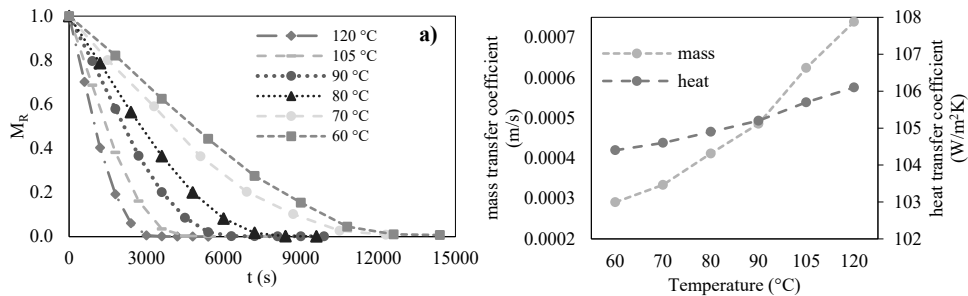

Figure 2. a) Drying kinetic curves for BSGs, b) mass and heat transfer coefficients at different temperatures.

### 3.2. Model validation

The drying process was simulated in Aspen Plus using the data obtained from the characterization of the BSGs and the kinetic drying study. The final moisture obtained in the simulation and in the drying experiments were compared to validate the model developed for the dryer. Table 3 shows that the simulation results have relative errors between 3.0 and 4.6%. Therefore, the developed drying model can describe the behavior of the drying process between 60 °C and 120 °C.

Table 3. Model validation of the batch type convective dryer.

Temperature (°C)	Moisture (wet basis)		Relative Error (%)
	Experiment	Simulation	
60	2.610	2.729	4.56
70	3.861	3.979	3.05
80	0.635	0.656	3.28

90	0.819	0.856	4.55
105	0.715	0.749	4.64
120	1.231	1.279	3.90

### 3.3 Exergoeconomic Analysis

The exergoeconomic indicators of the simulated BSGs convection drying process at different drying air temperatures were determined. Figure 3 a) shows that the exergetic efficiency increases significantly between 70 °C and 80 °C, while exergetic efficiency varies insignificantly at higher temperatures. This behavior is similar to the overall exergy destruction rate. The greatest reduction of destroyed exergy (52.3%) occurs between 70 °C and 80 °C because the required drying air flow decreases by 66%, according to Figure 3

b). Moreover, at higher temperatures, less drying air is required. Therefore, the drying airflow is directly proportional to the destroyed exergy rate. (Beigi et al., 2017b) obtained similar results, where rice is dried in a convective dryer and the exergetic efficiency increased from 33% to 68% when the drying temperature increased from 40 °C to 60 °C.

Figure 3. The effect of drying temperature in a) global exergy destruction and exergetic efficiency per component, b) air to BSGs ratio, c) exergy destruction, investment, operational and maintenance cost rates of the drying system, and d) specific biomass cost.

Figure 3 c) shows that at 120 °C the operating costs are the lowest and the cost per destroyed exergy. This change occurs because, at 120 °C, the lowest air/flue gas ratio was used. Thus, there is a need to burn less fuel for flue gas production. Also, previous studies have demonstrated that implementating other technologies, such as microwave-assisted dryers, would reduce operating costs (Ranjbaran & Zare, 2013). Furthermore, (Agbede et al., 2020) recommended implementating renewable energy sources such as solar energy in the air heater of drying processes due to their lower energy requirement. (Atalay, 2019)

compared conventional heat pump drying with solar-assisted heat pump and found that this reduces investment and operating costs by 20.3% and 34.5%, respectively. Figure 3 d) shows that the specific cost of biomass decreases significantly with the temperature increment. At 120 °C, it is possible to reduce the cost of dry biomass by 69.3%. This cost reduction responds to the low operating costs achieved at 120 °C. The minimum cost of BSGs was \$0.95/kg, which is half that obtained in a previous study for dry spent coffee grounds (Tinoco-Caicedo et al., 2021).

#### 4. Conclusions

This study aimed to simulate and perform an exergoeconomic analysis of a batch type convective dryer of BSGs based on experimental studies, carried out for air drying temperatures between 60 °C to 120 °C. This research shows that the exergetic efficiency varies between 66.4% and 88.0% when increasing the temperature from 60 °C to 120 °C. Production costs can be reduced by 69.1% by increasing the temperature from 60 °C to 120 °C. The specific cost of biomass varies between 3.00 \$/kg and 0.95 \$/kg and is at 120 °C when the lowest cost is reached. Finally, the results suggest that convective drying should operate at high temperature because it benefits exergetic efficiency and operating costs. Future studies should focus on experimental studies using other drying technologies that increase the drying rate and reduce both costs and the rate of destroyed exergy.

## Abstract

The ongoing climate crisis requires the reduction and removal of carbon to avoid global catastrophic consequences to the environment. As such, efforts presently focus on understanding the impact of negative emissions technologies in actively removing carbon dioxide from the atmosphere. While these emerging technologies bring a distinctive set of feasibility challenges, their integration into existing systems is essential due to the inability of decarbonization strategies to solely mitigate greenhouse gas emissions. The objective of this work is to develop strategies for integrating negative emissions technologies with carbon capture utilization and storage options, spurred by the increasing relevance of circular economies. The multi-period resource integration approach will determine the optimal technology portfolios best suited to a specific industrial landscape to achieve net-zero emissions in the presence of environmental policy instruments across time. The analysis will provide decision makers with a preliminary understanding of the viability of these technologies and the progress needed in regulatory frameworks to enable their effective implementation. The applicability of the proposed approach is demonstrated through the deployment of negative emissions technologies, such as bioenergy carbon capture and storage, direct air carbon capture and storage, enhanced weathering of minerals, and utilization of biochar, in an oil and gas based industrial setting. The optimal strategies determined indicate that carbon caps and taxes are fundamental in reducing the creation of emissions, while carbon credits encourage the active removal of carbon dioxide from the atmosphere.

**Keywords:** Negative emissions technologies, Process integration, Optimization, Carbon management

## 1. Introduction

With the climate crisis at the forefront of the sustainable development agenda, oil and gas economies that account for 15-20% of global greenhouse gas emissions (Gatto et al., 2021) will play a critical role in achieving net-zero emissions by 2050. To meet these targets, negative emissions technologies or NETs will need to be integrated into these economies along with more rampant decarbonization efforts that focus on the improvement of process efficiencies, transition to renewable energy, and deployment of carbon capture and storage (CCS) options. NETs fundamentally remove greenhouse gases from the atmosphere through various mechanisms, with their primary target being carbon dioxide (CO<sub>2</sub>) (McLaren, 2012). Some examples of NETs include technological solutions such as bioenergy with carbon capture and storage (BECCS) and direct air carbon capture and storage (DACCS), natural solutions such as afforestation and

reforestation, and enhanced natural solutions such as the use of biochar and enhanced weathering (IEA, 2020). Recently, these technologies have gained significant traction in industrial and academic research and development domains due to the major roles they play in the scenarios analyzed by integrated assessment models towards attaining carbon neutrality, where both carbon removal and reduction are of paramount importance (Tavoni & Socolow, 2013).

A significant portion of the extensive literature in this direction belongs to BECCS and DACCS, detailing the critical feasibility challenges that prevent their large-scale deployment and the measures to overcome them. Of the two, DACCS shows promising potential for deployment in oil and gas economies due to their large energy reserves, which can power the capture process and provide a means through the depleted reserves to store the captured carbon (Babonneau et al., 2022). While storage concerns for BECCS can also be managed similarly, there are concerns surrounding the sustainable procurement of the biomass required that additionally needs to be addressed. However, if obtained in a viable manner, the bioenergy it produces is a valuable commodity that can provide power for various operations such as those of other NETs, as suggested by Abraham et al. (2022c), who investigated the feasibility of such synergistic exchanges between NETs. Alternatively, instead of storing the carbon removed in geological storage sites, principles of circular economy suggest that it can be redirected for utilization in CCUS options (Abraham et al., 2022a). Therefore, to create an integrated system that embodies circular economy, all material and energy resources in a system must be analyzed. Towards enabling such circularity in systems, Abraham et al. (2022b) developed a multi-period optimization approach based on the resource integration method proposed by Ahmed et al. (2020) for designing processing clusters. This work adopts the multi-period resource integration approach to analyze the viability of integrating NETs with CCUS options and policy instruments in energy-rich economies to further devise deployment strategies over time where the carbon removed is specifically stored in environmental compartments in their customary sense to achieve net-zero emissions.

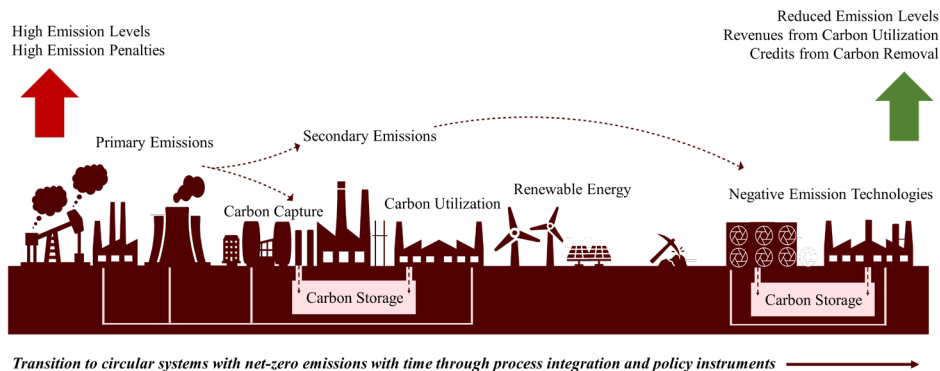

Figure 1: Overview of the proposed strategy for net-zero emissions

## 2. Approach

The multi-period resource integration model adopted in this work modifies the approach proposed by Abraham et al. (2022b) to develop planning strategies set to achieve carbon neutrality using networks of NETs and CCUS options. The model formulation takes the form of a mixed-integer linear program (MILP) to develop an integrated deployment strategy where further synergistic opportunities that are unapparent when solely focusing

on carbon can be explored. For a given carbon removal and reduction target, it identifies the optimal network that achieves the maximum net present value (NPV) over a planning horizon as given by Eq(1):

$$NPV_{Deployment\ strategy} = \sum_{Period} \frac{\sum_{Process} Revenue - Operating\ Cost - Capital\ Cost}{(1 + Discount\ Rate)^{Number\ of\ periods\ considered}} \quad (1)$$

The optimization determines which processes become active in a period and the capacities they operate at to meet the specified target. The carbon removal and reduction options are each represented as processes that consume certain resources to produce certain others using explicit resource parameters. Each of the resources is then represented through a resource line defined by a unique set of specifications to facilitate integration between processes that share common resources. The total costs incurred depend on the capital and operating costs of the processes, along with any stipulated inflation rates, resource penalties, and credits considered. Furthermore, equality and inequality constraints can be placed on the operational capacities and resource flows throughout the network according to the specific details of the scenario analyzed, along with resource balances that monitor the flow of resources to, from, and between processes.

### 3. Illustrative Example

To illustrate the application of this approach, a hypothetical scenario is investigated over a planning horizon that consists of three periods spanning 10 years each. The processes considered for capturing, storing, utilizing, and removing CO<sub>2</sub> are listed in Table 1, along with their reference products and CAPEX parameters. The process parameters for the carbon removal options, namely, the BECCS, biomass pelletization unit, biochar production unit, DACCS, and EW mineral processing unit, were retrieved from Abraham et al. (2022c), while those of the sequestration unit and the production and capture units of methanol and urea, were determined from Ahmed et al. (2020). Each process operates at a maximum capacity of 25 million tons of their respective reference products in the first period, after which the capacities of the NETs and biomass pelletization unit increase by 20% from the previous period.

Table 1: Reference products and CAPEX parameters

Processes (Process ID)	Reference Product	CAPEX Parameter (Million \$)
Bioenergy Carbon Capture and Storage (BECCS)	CO <sub>2</sub> removed	2,478
Biomass Pelletization Unit (BMP)	Biomass pellets	130
Biochar Production Unit (BCP)	CO <sub>2</sub> removed	1,601
Direct Air Carbon Capture and Storage (DACCS)	CO <sub>2</sub> removed	2,175
EW Mineral Processing Unit (EW)	CO <sub>2</sub> removed	71
Fischer-tropsch Unit (FTU)	Fischer-tropsch fuels	248
Methanol Production Unit (MPU)	Methanol	262
Methanol Carbon Capture Unit (MCC)	CO <sub>2</sub> captured	7
Synthetic Natural Gas Production Unit (SNG)	SNG	39
Sequestration (SQU)	CO <sub>2</sub> captured	12
Urea Production Unit (UPU)	Urea	135
Urea Carbon Capture Unit (UCC)	CO <sub>2</sub> captured	7

The data for the SNG production unit was obtained from Chauvy et al. (2021), while those for the FT unit were obtained from Panahi et al. (2018) and Al-Yaeshi et al. (2020). The resource parameters for these processes are summarized in Table 2, along with the prices of their associated resources. The prices per ton of the resources not listed here were set at \$294 for ammonia, \$1,383 for biochar, \$112 for biomass pellets, \$509 for calcium carbonate, \$14 for low pressure steam, \$305 for methanol, \$484 for propane, \$24 for

residues, \$26 for rock in, and \$288 for urea. All prices were set to vary at an inflation rate of 5%.

Table 2: Resource parameters of the FT and SNG units along with their prices (2020 US\$)

Processes (Resource unit)	FT Unit	SNG Production Unit	Prices (\$/ Resource unit)
CO <sub>2</sub> emitted (tons)	3.85	-	-
CO <sub>2</sub> utilized (tons)	-2.07	-2.41	-
Cooling water (tons)	-	-23.69	0.03
Electricity (kWh)	-	-17.14	0.03
FT Fuels (tons)	1.00	-	1,029
High pressure steam (tons)	3.88	-	16
Hydrogen (tons)	-	-0.45	1,178
Medium pressure steam (tons)	4.70	3.71	15
Natural gas (tons)	-2.01	-	100
Saturated steam (tons)	-3.56	-	15
Synthetic natural gas (tons)	-	1.00	100
Wastewater (tons)	-	23.69	-
Water (tons)	-	-3.71	5
Water out (tons)	4.22	1.86	-

Certain resources in the processes considered contain CO<sub>2</sub> that must be accounted for to ensure climate targets are met in time. As such, the compositions of these resources, specified in Table 3, will also be incorporated into the overall carbon flow analysis.

Table 3: CO<sub>2</sub> compositions of the carbon carrying resources

Resource	CO <sub>2</sub> Composition
CO <sub>2</sub> emitted, captured, utilized, removed	1.00
Methanol process emissions	0.30
Methanol capture unit emissions	0.06
Urea process emissions	0.26
Urea capture unit emissions	0.03

Two cases were investigated with this setup to maximize the NPV of the deployment strategy analyzed at a discount rate of 10%. Every period receives a feed of CO<sub>2</sub> captured from various industrial processes associated with the oil and gas industry. With each period, this feed decreases at a rate of 25% as changes to conventional processes are expected to lower the emissions they release. To achieve net-zero emissions at the end of the planning horizon, constraints are placed on the overall flow of CO<sub>2</sub> from the system. While the first period has no specific constraints, the CO<sub>2</sub> that leaves the network in the second and third periods, defined as the difference between the carbon created and removed by it, are constrained with carbon caps, as specified in Table 4.

Table 4: Carbon feed and cap limits over the three periods

Periods	Period 1	Period 2	Period 3
CO <sub>2</sub> fed (tons)	175,000,000	131,250,000	98,437,500
CO <sub>2</sub> cap (tons)	No constraint	65,625,000	0

The processes activated for the two cases and their operational capacities in each period are given in Table 5. In the first case, net-zero emissions are achieved by transitioning from focusing solely on carbon utilization to additionally incorporating carbon removal. The optimal strategy determined has an NPV of \$32 billion and removes nearly 128 million tons of CO<sub>2</sub> using the BECCS, DACCS, and EW processes. These NETs only become active when constraints are placed on the emissions leaving the system. In contrast, periods such as the first, without any constraints, focus on generating revenues through carbon capture and utilization through the production of FT fuels, methanol, and

urea. In later periods, there is a decrease in carbon utilization processes with high operating costs, such as SNG production, and those which lead to further emissions, like methanol production. This decrease, when simultaneously implemented with an increase in carbon removal through NETs, permits the system, over time, to lower sequestration capacities and leads to the cumulative release of about 295 million tons of CO<sub>2</sub>.

Table 5: Operational capacities in million tons of the reference product determined for the three cases in each period and their set carbon tax and credit rates

Case	Case 1			Case 2		
	tp1	tp2	tp 3	tp1	tp2	tp 3
Time periods	tp1	tp2	tp 3	tp1	tp2	tp 3
Carbon tax	0	0	0	150	300	450
Carbon credit	0	0	0	200	400	600
<b>Processes</b>						
BMP	-	22.21	26.65	18.51	22.21	26.65
BECCS	-	30.00	36.00	25.00	30.00	36.00
DACCS	-	-	27.10	25.00	27.12	27.10
EW	-	1.26	33.66	25.00	30.00	36.00
FTU	25.00	25.00	25.00	25.00	0.10	0.10
MPU	25.00	25.00	17.95	25.00	25.00	25.00
MCC	-	2.56	1.84	2.56	2.56	2.56
SNG	14.98	0.10	0.10	16.69	19.92	6.31
SQU	25.00	21.23	0.10	25.00	25.00	25.00
UPU	25.00	25.00	25.00	25.00	25.00	25.00
UCC	0.10	1.66	1.66	1.66	1.66	1.66

In the second case, carbon taxes and credits that doubled and tripled from their rates in the first period are implemented as described in Table 5, along with the emission caps detailed previously. The increasing carbon tax rates further limit the release of emissions, while the increasing carbon removal credits incentivize the deployment of NETs with the overall network emitting and removing about 99 and 261 million tons of CO<sub>2</sub>, respectively. Over time, emissions were drastically reduced from 97 million tons in the first period to nearly only a million tons of CO<sub>2</sub> in the second and third periods. The reduction was realized by decreasing carbon utilization in the FT unit, increasing carbon capture from the two capture units, and increasing sequestration to operate at its maximum capacity throughout the periods considered. The operations of the FT unit were specifically reduced while methanol and urea production remained constant as these processes have capture units to manage the emissions they create. On the other hand, the NETs operating at or near their maximum capacities enable the network to achieve the increased carbon removal required. The only exception here is the biochar process, which fails to be deployed in any period as it releases some emissions. An overview of the different CO<sub>2</sub> flows in the two cases explored through the proposed approach is illustrated in Figure 2.

Figure 2: Overview of CO<sub>2</sub> flows (a) without and (b) with policy instruments

With time, the carbon caps ensure that the amount of carbon removed from the atmosphere increases while carbon utilization decreases as it still leads to the creation of emissions. Additionally, the carbon tax and credit implemented in the second case further reduce emissions and promotes the deployment of NETs. Of the policy instruments in place, the carbon credits were particularly pivotal in achieving net-zero emissions and generating profits in the second case with an NPV of \$45 billion. On further analysis, the network can break even with carbon credits set as low as \$53.37 per ton CO<sub>2</sub> removed in the first period. Furthermore, with the great uncertainty encompassing the capital required for the NETs and their associated processes, adjusting these carbon credit rates appropriately can encourage their deployment. In fact, with their CAPEX parameters doubled, the second case can break even at rates as low as \$68.73 per ton CO<sub>2</sub> removed in the first period.

#### 4. Conclusion

The approach described in this work enables the assessment of policy instruments such as carbon caps, taxes, and credits with CCUS and NETs options while identifying potential for material and energy integration between them. Future work should integrate renewable energy with these technologies and additionally consider their land and supply chain feasibility. Furthermore, the non-linear expressions used in pricing the carbon taxes and credits can be simplified to allow for the analysis of more network configurations to achieve climate targets. Thus, the multi-period multi-resource approach described here allows policymakers to propose guidelines to achieve net-zero emissions.

## Abstract

The production of edible mushrooms generates two types of waste: the spent substrate from growing mushrooms and a loss of non-marketed mushrooms. Currently, great interest has been placed in the recovery of the spent substrate through the development of biorefineries for bioethanol production, mainly. However, the use of non-marketable mushrooms as raw material has not been extensively investigated. Therefore, the main objective of this work is the proposal for the synthesis, design and evaluation of a biorefinery of non-marketable edible mushrooms to obtain chitin, citric acid and animal feed, as high value-added products. The methodology proposes a technical-economic-environmental evaluation for decision-making. As a result, a viable conceptual design is obtained, with positive profitability and reduction of environmental impact factors.

**Keywords:** biorefinery, edible mushrooms, waste valorization, process simulation.

## 1. Introduction

Edible mushrooms constitute a functional food with nutritional and medicinal properties that promote health, which can strengthen food security in times of crisis. Their production has increased more than 30 times since 1978, reaching a world production of 34 million tons (Royse et al., 2017). The most widely cultivated edible mushroom worldwide is *Agaricus bisporus* (common white mushroom), followed by *Lentinus edodes*, *Pleurotus spp.* and *Flammulina velutipes* (Kumar et al., 2021), which are regulated according to different standards to guarantee organoleptic qualities and consumer satisfaction. Depending on its quality, there is an amount of non-marketable waste that ranges between 5 - 20% of the production.

It is important to highlight that there are proposals for the use of waste lignocellulosic substrates (such as cereal straws) employed in mushroom cultivation (Awasthi et al., 2022), but there are no biorefineries that take advantage of mushroom waste, since they are currently used directly as animal feed or fertilizer. Thus, the objective of this work is to design a biorefinery to produce high value-added products from these (non-marketable) edible mushroom residues, under a circular economy perspective.

Agro-industrial residues are unavoidable and should be considered as a new opportunity for their reuse within a biorefinery, using environmentally friendly and profitable bioprocess technologies. In such a way that these wastes from biorenewable resources can be used for the production of food, animal feed, fertilizers, fuels, energy, amino acids, biopolymers, among other industrial chemical products. From a review of the literature, it was found that the product with the highest value that can be obtained from edible

mushrooms is chitin, which, together with its derivatives, show low immunogenicity and therefore have a great use in biomedical applications. As a second product of the biorefinery, citric acid is considered due to its wide use as an additive in the food, pharmaceutical, cosmetic, and cleaning industries. And since citric acid can be processed by microbial culture, then the biomass resulting from cell growth with high nutritional value can be processed for animal feed.

In this work, first, a biorefinery conceptual design is proposed for the waste valorization of non-commercialized edible mushrooms to produce chitin, citric acid and animal feed. Then the biorefinery flowsheet diagram is implemented and evaluated in a modular process simulator. Afterwards, a parametric sensitivity analysis is performed, considering equipment dimensions, amount of waste fed, design configurations, etc., as a result: the technical evaluation demonstrates the feasibility of using the waste, while the economic evaluation presents a positive profitability of the proposal using as indicators the unit production cost, the return on investment and its payback time; and the environmental impact is evaluated considering the consumption of water, utilities and energy.

## 2. Methodology

The methodology consists first of determining the composition of the edible mushroom residues, then identifying the best reaction routes to obtain value-added products, then determining a process flow diagram, and finally evaluating the biorefinery in a comprehensive manner considering technical, economic and environmental impact aspects. Each of these stages is briefly described below.

### 2.1. Mushroom composition

The bodies of the fruits of *A. bisporus* are rich in proteins (29.14%), carbohydrates (51.05%) and fats (1.56%); and also include proteins, lipids, vitamins and minerals (Ahlawat et al., 2016). For simulation purposes, the composition is established according to the compounds of interest (chitin and glucans present), while the rest of the compounds were grouped under the name of other solids. Therefore, the composition used was: 90% water, 0.47% chitin, 1.01% glucans, and the rest of other solids (Nitschiske et al., 2011; Khan et al., 2017).

### 2.2. Conceptual design of the biorefinery

A biorefinery is proposed to obtain three high-value products, through the following processing stages:

- (a) Conditioning of the mushroom waste, which consists of washing, drying, grinding and sieving the mushrooms to obtain dry flour.
- (b) Chitin extraction, where the deproteinization process is first carried out by enzymatic hydrolysis using proteases. Immediately a thermal hydrolysis allows extracting compounds such as lipids, minerals, vitamins and remaining proteins. As a result, supernatant rich in soluble glucans and a precipitate rich in chitin are obtained (Urbina-Salazar et al., 2020). The latter is sent to dry to obtain the chitin.
- (c) Saccharification and fermentation, where first the soluble glucans are converted to glucose by enzymatic hydrolysis. Then, glucose is converted to citric acid by fermentation with *Aspergillus niger*. Subsequently, the solid phase (residual biomass) is separated, and the liquid phase is subjected to a citric acid recovery process.
- (d) Animal feed production, by using the residual biomass from fermentation, which is dried and packaged for its sale.
- (e) Production of citric acid, where this product is first precipitated as calcium citrate, then treated with sulfuric acid and the gypsum precipitate formed (calcium sulfate) is

removed. Finally, the recovery of the product is carried out through a crystallization process to obtain dry crystals of citric acid.

Figure 1 shows the process flow diagram for the biorefinery of non-marketable edible mushrooms, according to this proposed conceptual design. Here it is important to mention that all liquid waste is sent to a wastewater treatment plant (WWT), which is not included but is considered in the evaluation.

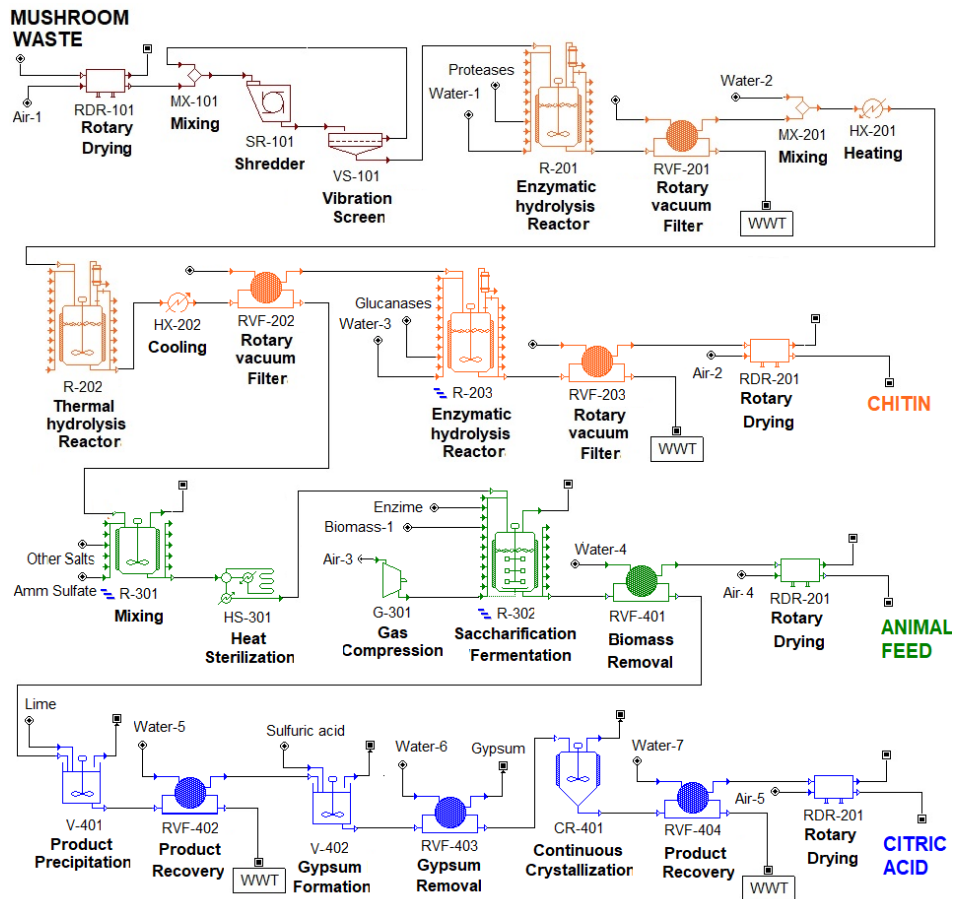

Figure 1. Process flow diagram of the proposed biorefinery.

### 2.3. Biorefinery assessment

The comprehensive evaluation of the biorefinery includes technical, economic and environmental aspects, as detailed below.

#### 2.3.1. Technical evaluation

The implementation of the conceptual diagram of the biorefinery considers technical and design aspects for an industrial scale, with which the mass and energy balances are evaluated taking into account the reactions in the processes and their conversions; the sizing of equipment and its efficiency; the working times of the equipment and processing cycles; as well as the installed capacity of the plant in terms of the amount of raw material fed and products generated.

### 2.3.2. Economic evaluation

Undiscounted cash flow profitability criteria provide an immediate assessment of process economics and are often used for the early stages of process synthesis and design (Seider et al., 2009). So, in this work, the economic criteria used to determine if a project is profitable are the unit production cost (UPC), the return on investment (ROI) and the payback time (PT) of the investment.

### 2.3.3. Environmental evaluation

A successful economic development also depends on the rational use of resources and the reduction of the adverse environmental impact of the development project (Dixon and Pagiola, 1998). Therefore, this work evaluates (a) the consumption of water in the process, due to problems of water scarcity and damage to ecosystems; (b) energy consumption, as it is a key element in climate change; and (c) the demand for heat transfer agents, such as steam and cooling water.

## 3. Results

The biorefinery flow diagram was implemented in *SuperPro Designer*, a modular process simulator to evaluate the mass and energy balances that allow to calculate the technical-economic-environmental criteria. It is important to mention that the evaluation of the economic criteria depends on the unit production revenues, which were estimated at 200, 2.0, 0.2 USD/kg for chitin, citric acid and animal feed, respectively (Pighinelli et al, 2019; Heinzle et al. al., 2017; Anaya-Reza and Lopez-Arenas, 2018). With the purpose of carrying out a profitability analysis of the biorefinery, first, the feeding of edible mushroom waste was set at 50 T/batch, and later, a sensitivity analysis was carried out based on the number of reactors installed.

### 3.1. Base Case

Considering a 50 T/batch mushroom feed and an annual operating time of 336 days, the recipe batch time was calculated at 14.7 days, processing 50 batches per year and producing 301.6 kg of chitin, 21.3 kg of animal feed and 178.6 kg of citric acid per batch. The direct fixed capital, working capital, and startup cost were estimated as 13 176 000, 212 000, and 659 000, USD, respectively, giving a total investment of 14 047 000 USD for the biorefinery installation. The calculated value for UPC was 390.13 USD/kg, which was too high compared to the unit production revenue, so the ROI was -2.88% and it was not possible to assess the PT. The latter are summarized in the first line of Table 1.

Table 1. Profitability analysis based on the number of reactors installed in R-203, 301 and 302

Number of reactors	UPC (USD/kg)	ROI (%)	PT (years)	Amount of mushroom waste (T/year)
1	390	-2.9	NA	2 500
2	305	2.6	37.8	4 950
3	278	6.7	15.0	7 450
4	261	9.6	10.4	9 900
5	252	11.9	8.4	12 400
6	256	10.7	9.4	12 450

### 3.2. Profitability analysis

Since the initial base case was not profitable, the equipment occupancy was analyzed and it was determined that the reactors R-203, R-301 and R-302 generate a bottleneck as shown in Fig. 3(a). So, a sensitivity analysis was carried out increasing the number of these reactors installed, managing to increase the profitability of the biorefinery as shown

in Table 1. As can be seen by increasing the number of reactors it is possible to increase the profitability of the process, achieving a maximum with 5 reactors. The increase in profitability is explained by the fact that dead times decrease, reaching an optimal equipment occupancy with 5 reactors. The comparison of processing times for 1 and 5 reactors can be seen in Fig. 3. So, increasing to 6 reactors, a bottleneck starts again and the annual amount of mushroom waste increases little (as observed in the last line of Table 1), so that cost effectiveness tends to decrease.

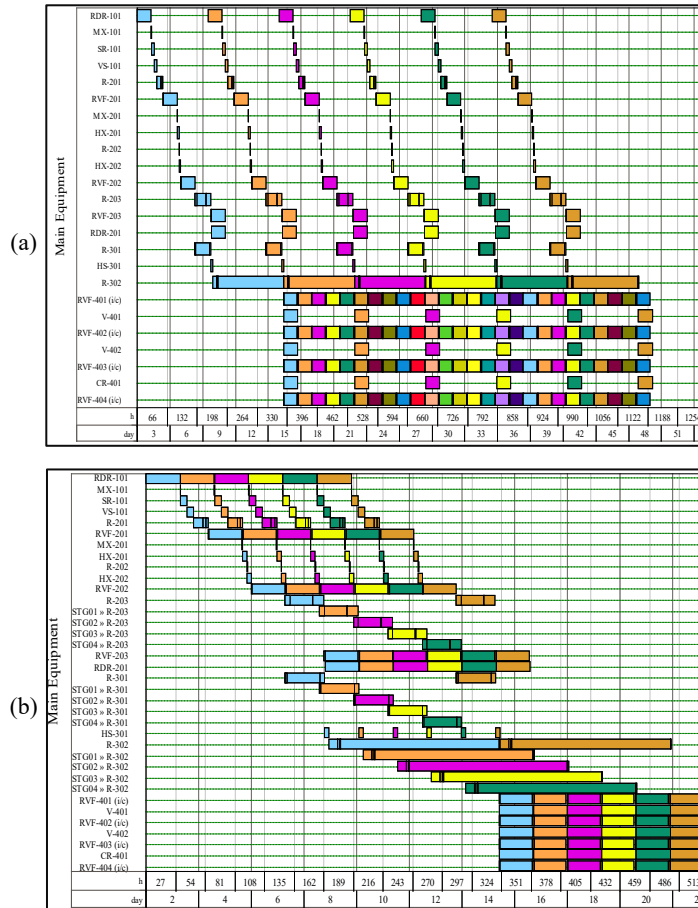

Figure 3. Equipment occupancy (R-203, R-301, R-302) considering (a) one and (b) 5 reactors..

### 3.3. Environmental results

Regarding the environmental impact indicators, Table 2 shows the values obtained for the base case (with 1 reactor) and the improved case (with 5 reactors). According to these results, it can be seen in general that a large amount of utilities is required, however, by increasing the number of reactors it was possible to reduce the use of heat transfer agent resources and energy consumption. Regarding the process water, it is important to highlight that although this water is required for all processing, the residual water is sent to a WWT plant and later recirculated. Therefore, the consumption of water after start-up is minimal, only to recover losses due to venting and evaporation.

Table 2. Environmental criteria for the base and improved cases.

Case study	No. reactors	Process water (T/kg chitin)	Utilities		
			Steam (T/kg chitin)	Cooling water (T/kg chitin)	Std. power (kW-h / kg chitin)
Base	1	349	0.45	22.8	51.5
Improved	5	271	0.35	17.3	46.4

#### 4. Conclusions

The need to create alternatives for the synthesis, design, and operation of biorefineries for the processing of high value-added products from non-commercialized edible mushrooms is a promising, profitable, and sustainable alternative. In this work, a conceptual design of a biorefinery has been proposed, and a comprehensive evaluation methodology has been presented that allows decision-making at an early design stage. Although the results show a positive profitability of the project, there are still various aspects to be studied, such as the modification of the installed capacity, the synthesis of other bioproducts (for example, lactic acid instead of citric acid), mixing various types of edible mushroom waste, alternatives to reduce the consumption of utilities (such as heat integration), etc.

## Abstract

The aviation industry is responsible for 2% of the total GHG emissions and 10% of the fuel consumption worldwide and sustainable aviation fuel (SAF) is considered a key step towards achieving net-zero aviation. In this work, we carry out an enviro-economic comparison of a one-step Fischer-Tropsch process (1sFT), based on a novel Mn-Fe-K catalyst, whereby CO<sub>2</sub> and H<sub>2</sub> are directly converted to liquid hydrocarbons, with a two-steps FT process (2sFT), in which a reverse water gas shift reactor is used to produce syngas, followed by a conventional FT process. Our analysis considers 1 MJ of liquid fuel as functional unit and the following key performance indicators: levelized cost of production, global warming potential, and monetized end-point environmental impacts. Our results suggest that the fuel blend from 1sFT has a minimum selling price 20% lower than the fuel blend from 2sFT, due to a lower capital cost and a higher selectivity towards liquid hydrocarbons. 1sFT is also found to be superior to 2sFT from an environmental point of view, with 30% lower GWP and 70% lower externalities cost.

**Keywords:** sustainable aviation fuel, technoeconomic analysis, LCA, Fischer-Tropsch

## 1. Introduction

Decarbonisation of the transport sector is a key challenge in the path towards net-zero and a sustainable future. The aviation industry is responsible for 2% and 10% of the global GHG emissions and fuel consumption, respectively. Sustainable aviation fuel (SAF) is called upon to play a pivotal role in a net-zero aviation, with up to 80% GHG emissions reduction (IEA 2022a). According to IEA (2020) low-carbon hydrogen-derived liquid fuels will gain significant market share in the sector, as batteries and hydrogen are not feasible alternatives, especially for long-range flights, due to the low energy content per unit of mass and volume respectively (Karadotcheva *et al.* 2021). Moreover, hydrogen-fuelled aircrafts would require a complete redesign and advanced materials to avoid hydrogen embrittlement and leakage (Airbus 2020).

Fischer-Tropsch (FT) synthesis is a well-established chemical route to produce hydrocarbons of different chain length distributions from syngas, a mixture of CO and H<sub>2</sub>, and can produce a drop-in alternative fuel for the aviation industry. However, syngas is nowadays produced from steam methane reforming or coal gasification, carries a high environmental burden. Significant research efforts have been devoted to identifying routes to use CO<sub>2</sub> as the carbon source in the FT process and deliver sustainable fuels. One option is to convert CO<sub>2</sub> and H<sub>2</sub> in a reverse water gas shift (RWGS) reactor and use

the resulting syngas in a traditional FT process (Zang *et al.* 2021). The main limitations of this two-step approach are: (i) RWGS reaction requires high temperatures to achieve a good conversion (600–1000 °C); and (ii) the production of wax, a mixture of heavy hydrocarbons, requires additional upgrading units, such as a hydrocracking (HC) reactor to improve the yield of liquid fuels. The direct hydrogenation of CO<sub>2</sub> to liquid fuels in a single step is more appealing, but the selectivity towards liquid fuels is usually low, and the formation of short chain hydrocarbons is favored (Chen *et al.* 2018; Gao *et al.* 2017). Recently, Yao *et al.* (2020) synthesized a novel Mn-Fe-K based catalyst capable of converting CO<sub>2</sub> and H<sub>2</sub> with excellent yield and selectivity towards liquid hydrocarbons in the jet fuel range (C<sub>8</sub>–C<sub>16</sub>) and minimal wax production.

The main objective of this paper, therefore, is to conduct a comparative assessment of one-step (1sFT) and two-step (2sFT) FT synthesis from CO<sub>2</sub> and H<sub>2</sub> to produce liquid fuels, also with a fossil-based alternative, in terms of economic and environmental performance. The methodology is described in the next section, followed by results and discussions, before concluding the paper.

## 2. Methodology

Figure 1 presents block flow diagrams of the two processes considered in this paper, which are designed to utilize 100 t/h of CO<sub>2</sub> coming from a direct air capture (DAC) plant and H<sub>2</sub> from water electrolysis. We further assumed that the fuel blend is sent to an existing refinery.

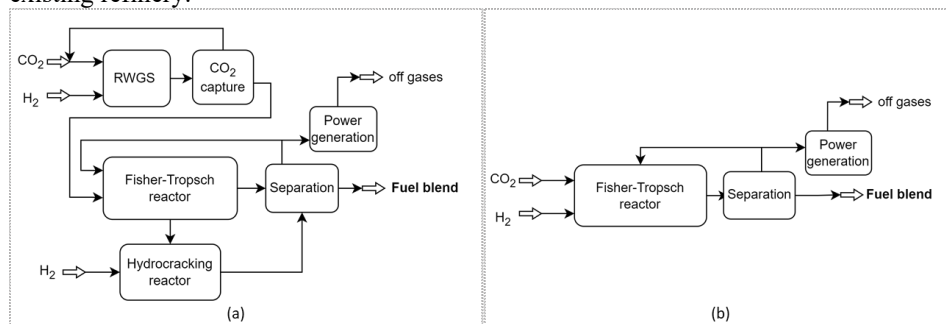

Figure 1: block flow diagrams of the two-step FT synthesis (a) and one-step FT synthesis (b). A wastewater stream is produced by both processes but is not represented in the diagram.

### 2.1. Process simulation and economic analysis

Flowsheet of both 1sFT and 2sFT routes were developed using Aspen HYSYS (version 11) and simulated in steady state, considering the Peng Robinson fluid package. Heat integration was performed using the Aspen Energy Analyzer. In the following the processes are described in more details.

**Feed streams.** We consider CO<sub>2</sub> from DAC as carbon source, available at 25 °C and 1 bar. According to IEA (2020), the cost of DAC CO<sub>2</sub> capture ranges between 135–345 \$/tCO<sub>2</sub> (note that all costs throughout the paper are expressed in US\$<sub>2021</sub>), in our base case the cost is 160 \$/tCO<sub>2</sub> as reported in Keith *et al.* (2016). H<sub>2</sub> is obtained from water electrolysis using wind energy, and it is available at 20 bar and 25 °C (Al Qahtani *et al.* 2021). The H<sub>2</sub> price is 4.2 \$/kg as reported in IRENA (2019) for wind-based water electrolysis. Both feed streams are assumed to have no impurities. An optimistic best-case scenario is also briefly discussed, considering 2050 predicted prices to compute the raw material costs (1.5 \$/kg<sub>H<sub>2</sub></sub>, IRENA 2019; 50 \$/tCO<sub>2</sub>, IEA 2022).

**One-step FT synthesis (1sFT).** The FT reactor uses the new Mn-Fe-K based catalyst and operates at 260 °C and 10 bar (Yao *et al.* 2020). A two-stage compressor with intercooling is used to bring the CO<sub>2</sub> at 10 bar, while no compression is needed for H<sub>2</sub>. The H<sub>2</sub> is fed to the process in a H<sub>2</sub>:CO<sub>2</sub> molar ratio of 3:1. The outlet stream enters a sequence of two 3-phase separators operating at 70 °C and 40 °C under 10 bar. A small (2%) fraction of the gaseous stream coming out of the second separator is burned to produce heat and electricity in a gas and steam cycle, while the rest is recycled to the FT reactor. The other two streams from the 3-phase separators are wastewater and liquid hydrocarbons. The liquid hydrocarbons are mixed, expanded to 1 bar and cooled down to 35 °C. Lastly, the vapor phase from a flash separator (CO<sub>2</sub> and C<sub>1</sub>–C<sub>4</sub> hydrocarbons) is burned to produce additional electricity, the liquid phase contains the fuel blend product to be sent to the refinery. This blend contains 29%<sub>wt</sub> gasoline, 48%<sub>wt</sub> SAF, 19%<sub>wt</sub> diesel, 2.5%<sub>wt</sub> light hydrocarbons, and traces (<1%<sub>wt</sub>) amount of wax.

**Two-step FT synthesis (2sFT).** The RWGS reactor operates at 600 °C under 30 bar (Zang *et al.* 2021). A three-stage compressor with intercooling is used to bring the CO<sub>2</sub> to 30 bar, and a single stage compressor is used for the H<sub>2</sub> feed. An amine-based capture system is used to capture and recycle the unreacted CO<sub>2</sub> (Danaci *et al.* 2020). The hydrogen inlet flowrate is adjusted to have a CO:H<sub>2</sub> ratio of 2 in the syngas. The syngas is fed to the FT reactor operating at 220 °C and 25 bar. The wax produced by the FT reactor is sent to the HC reactor where it reacts with H<sub>2</sub> fed in stoichiometric amount at 350 °C and 25 bar. The downstream separation units are identical to the 1sFT, except for the pressure of the 3-phase separators set to 25 bar. The purge rate is set to 5% to avoid excessive accumulation of CO<sub>2</sub> in the FT section. The hydrocarbon mixture from the 3-phase separators is mixed with the HC reactor outlet stream before expanding to 1 atm and cooling to 35 °C, and feeding to a flash separator. The liquid fuel blend produced contains 25%<sub>wt</sub> gasoline, 40%<sub>wt</sub> SAF, 33%<sub>wt</sub> diesel, 1.4%<sub>wt</sub> light hydrocarbons, and traces (<1%<sub>wt</sub>) amount of wax.

**Economic analysis.** The RWGS reactor is modeled as an equilibrium reactor, while the FT and HC reactors are modeled as simple conversion reactors in Aspen HYSYS. In 2sFT, yields and selectivities of the FT and HC reactors as well as the cost correlations for RWGS, FT and HC reactors are obtained from Zang *et al.* (2021). In 1sFT, the reactor yields and selectivities are obtained from Zao *et al.* (2020), with correlations from Zang *et al.* (2021) used to estimate the cost. The levelized cost of production (LCP) is calculated assuming a 15% interest rate and 20-year lifetime. LCP is compared with the fossil fuel cost, which is assumed to be 14 \$/GJ<sub>fuel</sub> in the base case, and 23 \$/GJ<sub>fuel</sub> in the optimistic best-case scenario considering a carbon tax of 150\$/tCO<sub>2</sub> (IEA 2020).

## *2.2. Life cycle analysis*

The functional unit (FU) for the LCA analysis is chosen as “1 MJ of liquid fuel blend” and the assessment is done considering a Well-to-Tank (WtT) approach. GWP is also analyzed from a Well-to-Wake (WtW) perspective, assuming that all the carbon in the fuel blend is released as CO<sub>2</sub> during the use phase. Following the recommendation by von der Assen *et al.* (2013), system expansion via substitution is adopted to deal with multi-functionality herein.

**Data collection and life-cycle inventories.** The life-cycle inventories (LCIs) of 1sFT and 2sFT are computed from the simulated flowsheets described in Section 2.1 and are summarized in Table 1. The LCIs for DAC are taken from Keith *et al.* (2018) and those for H<sub>2</sub> are taken from Al-Qahtani, *et al.* (2021). The electricity source for H<sub>2</sub> production

is assumed to be onshore wind from the UK, and the credits given for the electricity sold as a byproduct are attributed based on the electricity production mix of the UK.

Table 1: life-cycle inventories of 1sFT and 2sFT processes. FH = Fired Heater, CW = Cooling water, WW = Wastewater. The FU is 1 MJ of liquid fuel blend.

	1sFT	2sFT			1sFT	2sFT	
	Inputs	Units			Outputs	Units	
CO <sub>2</sub>	$8.25 \cdot 10^{-2}$	$9.99 \cdot 10^{-2}$	kg	FU	$1.00 \cdot 10^0$	$1.00 \cdot 10^0$	MJ
H <sub>2</sub>	$1.14 \cdot 10^{-2}$	$1.23 \cdot 10^{-2}$	kg	Electricity	$6.70 \cdot 10^{-3}$	$6.00 \cdot 10^{-3}$	kWh
FH	-	$3.04 \cdot 10^{-1}$	MJ	CO <sub>2</sub>	$1.03 \cdot 10^{-2}$	$3.27 \cdot 10^{-2}$	kg
CW	$2.29 \cdot 10^{-4}$	$3.12 \cdot 10^{-4}$	m <sup>3</sup>	CO	$6.01 \cdot 10^{-4}$	$2.32 \cdot 10^{-4}$	kg
				WW	$6.41 \cdot 10^{-5}$	$6.95 \cdot 10^{-5}$	m <sup>3</sup>

**Environmental impact assessment.** The environmental assessment is conducted in SIMAPRO 9.3, using Ecoinvent 3.8 Cut-Off database for the background process inventories. The business-as-usual (BAU) fossil-based liquid fuel alternative is assumed to be “Petroleum {GLO} | market for”, a liquid fuel with a LHV of 43.2 MJ/kg. The environmental KPIs are GWP100 alongside the monetized endpoint impacts to human health, ecosystem quality and resource scarcity, all computed with the ReCiPe2016 impact assessment methodology (Huijbregts *et al.* 2017) and using the monetization factors from Dong *et al.* (2019) converted to \$<sub>2021</sub>.

### 3. Results and discussion

#### 3.1. Midpoint environmental impacts – global warming potential

Figures 2a and 2b compare the GWP of 1sFT and 2sFT against BAU, from a WtT (2a) and WtW (2b) perspective. Both 1sFT and 2sFT have negative GWP because of the credits from DAC, with 1sFT outperforming 2sFT by c. 30%.

The molar-based carbon efficiency<sup>1</sup> is c. 68% in 2sFT and 76% in 1sFT. Therefore, 2sFT has both a higher negative contribution from DAC ( $-8.5 \cdot 10^{-2}$  kg<sub>CO<sub>2</sub>-eq</sub>) and a higher positive contribution from direct emissions ( $3.3 \cdot 10^{-2}$  kg<sub>CO<sub>2</sub>-eq</sub>) compared to 1sFT. The positive contributions to the overall GWP are dominated by the direct emissions (65%), followed by H<sub>2</sub> production (19%) and heat generation (16%). In 1sFT credits from DAC are  $-7.0 \cdot 10^{-2}$  kg<sub>CO<sub>2</sub>-eq</sub>, while the total positive emissions ( $1.9 \cdot 10^{-2}$  kg<sub>CO<sub>2</sub>-eq</sub>) are determined by direct emissions (54 %) and H<sub>2</sub> production (46%)

Since the FU is a fuel blend, it is useful to assess the WtW GWP as well. We can observe from Figure 2b that c. 95% of the total GWP for BAU ( $7.6 \cdot 10^{-2}$  kg<sub>CO<sub>2</sub>-eq</sub>) is attributed to the use phase. Both 1sFT and 2sFT are significantly better than BAU, with 1sFT outperforming 2sFT, with a 75% and 57% GWP reduction, respectively.

#### 3.2. Endpoint analysis and total cost

Figure 2c compares the monetized values of all three endpoint environmental impacts. The total externalities cost of 1sFT and 2sFT is lower than BAU, but the reduction achieved by 1sFT is significantly larger (80% vs. 30%). For all the alternatives impact on resource scarcity (RS) represents the largest share of externalities cost. Compared to

<sup>1</sup> ratio between moles of carbon in the liquid fuel blend and total moles of CO<sub>2</sub> fed to the process

BAU, 1sFT shows 40% reduction and 2sFT a 15% reduction. In both 1sFT and 2sFT the DAC energy requirements are an environmental hotspot, being responsible for 93% and 80% of the total impact on RS, respectively. In terms of damage to ecosystem quality (EQ) both processes have a negative impact, while damage to human health (HH) is almost zero for 1sFT and slightly larger than BAU for 2sFT.

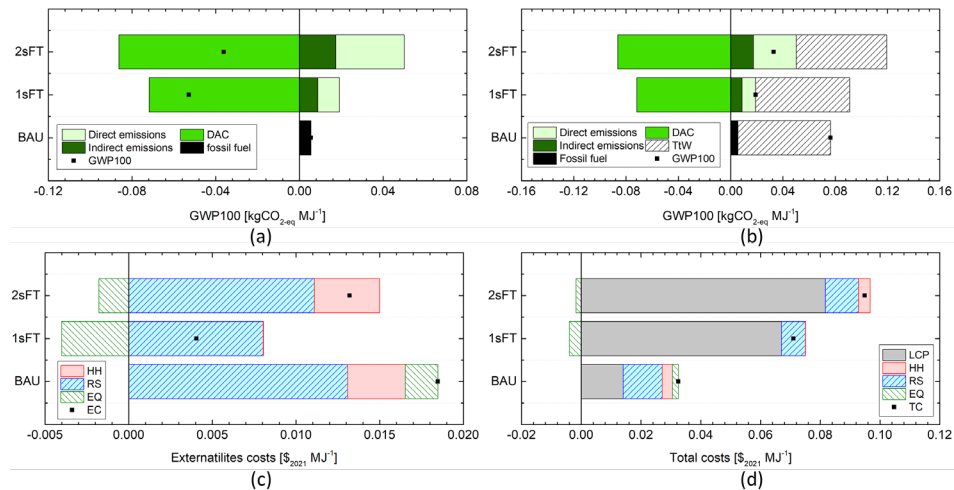

Figure 2: Results of the enviro-economic analysis for the 1sFT, 2sFT and BAU routes. (a) Well-to-Tank (WtT) global warming potential; (b) Well-to-Wake (WtW) global warming potential; (c) monetized externalities cost (EC); and (d) total cost (TC).

Turning to economic considerations, both options have a higher LCP compared to the fossil alternative, as expected. The LCP of 1sFT is 20% lower than that of 2sFT, but 5 times higher than the LCP of fossil fuel, nonetheless. In terms of total cost including externalities, 1sFT outperforms 2sFT by 25 % but has a total production cost 2 times higher than the BAU. It is worth noting that 1sFT has a 50% lower CAPEX than 2sFT, but the LCP is largely determined by the raw materials cost, where the difference between 1sFT and 2sFT per MJ<sub>fuel</sub> is only 10% (Table 1). In the base case, H<sub>2</sub> constitutes 75-78% of the raw material costs in 2sFT and 1sFT, respectively, with CO<sub>2</sub> accounting for the rest. However, in an optimistic scenario where prices drop to 1.5 \$/kg<sub>H<sub>2</sub></sub> and 50 \$/t<sub>CO<sub>2</sub></sub>, the LCP of 1sFT would decrease to 25 \$/GJ, only slightly higher than the cost of fossil fuels with a CO<sub>2</sub> tax of 150 \$/t (23 \$/GJ).

#### 4. Conclusions

This paper presented an enviro-economic assessment of two FT-based processes to produce liquid hydrocarbon fuels from CO<sub>2</sub> and H<sub>2</sub>, considering DAC and water electrolysis using wind energy as source of CO<sub>2</sub> and H<sub>2</sub> respectively. A one-step process using a novel catalyst was compared to a two-step process, assuming that the product blend is sent to an existing refinery to produce gasoline, SAF, and diesel. Our results show that the one-step process is superior both in economic and environmental terms to the two steps process, due to a lower capital cost, higher selectivity towards liquid hydrocarbons and lower energy requirements. Both processes have a negative GWP potential from a well-to-tank perspective, which compares favorably against fossil fuel production. The one-step process achieves a 75% reduction of well-to-wake GHG emissions, which is aligned with the reduction targets for SAF reported in the literature.

Our environmental assessment also considered an endpoint impacts analysis, confirming a better environmental performances of the synthetic fuels compared to fossil fuels, with an 80% reduction for the one-step process. The largest share of externalities cost in both the one-step and two-step processes is attributed to the energy requirements for DAC, and therefore alternative DAC processes should be considered to move further away from the fossil-dependency of the aviation sector. Nevertheless, the proposed low-carbon synthetic fuels are significantly more expensive than fossil fuels, and even if the prices of H<sub>2</sub> and CO<sub>2</sub> were to decrease, policy interventions such as carbon taxation, or reduced taxes on SAF would likely remain necessary for the low-carbon fuel to gain market shares. Future work will focus on adding more options for H<sub>2</sub> and CO<sub>2</sub>, including blue hydrogen, alternative DAC processes, biomass gasification and other biogenic carbon sources. On the methodological side, an uncertainty analysis will be carried out to confirm the environmental and economic results.

## Abstract

The aviation sector contributes 3% of global CO<sub>2</sub> emissions as it still relies heavily on fossil fuels. The use of low carbon hydrogen as a fuel, in both compressed or liquified forms, would drastically reduce its emissions. However, hydrogen has low volumetric energy density, and imposes a mass penalty due to storage tank requirements if used in compressed form. On the other hand, the liquefaction of hydrogen is energy-intensive and can consume ~40% of chemical energy stored in hydrogen. Ammonia, as a carbon-free hydrogen carrier, benefits from ease of storage and transport, and can be potentially used as an energy vector to enable advanced propulsion systems. Given the possibility of achieving zero-NO<sub>x</sub> in fuel cells, recent advances in fuel cell electric-powered aircraft, as well as fuel flexibility of Solid Oxide Fuel Cells (SOFCs), this work will explore the feasibility and challenges of direct ammonia-fed SOFCs as the power source for air aviation propulsion system. A model based on semi-empirical equations is developed for ammonia-powered fuel cells. A 130 kW general aviation case study is modelled and simulated in the paper to confirm the effectiveness and potential of the ammonia-powered fuel cell technology to be used as the next generation of propulsion systems in this size of aircraft. The comparative analyses demonstrated that the use of ammonia can decrease the mass of fuel consumed by 5.9% (in comparison with kerosene fueled aircraft) in a one-hour mission and allow achieving the emissions level targets set by Advisory Council for Aeronautics Research in Europe (ACARE) Flight Path 2050. Finally, the remaining practical challenges that need to be addressed to enable this important technology to be adopted by air vehicle manufacturers have been identified and discussed.

**Keywords:** Ammonia, Fuel cells, General aviation, Net zero targets, Flight Path 2050, Emission

## 1. Introduction

Anthropogenic greenhouse gas emissions from fossil fuel use are among the main contributors to climate change. It is estimated that the aviation sector, which is still highly dependent on petroleum-derived products, contributes to 3% of total carbon dioxide emissions [1], with an annual production of nearly 1000 million tons. Additional non-carbon pollutants are generated during the combustion process in gas turbines, such as nitrogen and sulfur oxides (NO<sub>x</sub> and SO<sub>x</sub>), which can contribute into contrail formation and global warming [2]. Not to mention the particulate matter (soot), known for its detrimental effects on human health, causing breathing issues, including asthma, bronchitis, coronary heart disease, and even cancer. Therefore, numerous efforts are being made to make the aviation sector more sustainable through its electrification. There are currently three main ways to obtain electrical energy on board. The first, represented by batteries, is currently limited by energy density. Bills *et al.* [3] estimated the distributions of specific energy required by different classes of aircraft. The mean requirements were determined as 600 (regional), 820 (narrow-body) and 1280 Wh/kg-pack (wide-body). However, despite the steady improvement over the last two decades, the specific energy of current generation Li-ion batteries is about 250 Wh/kg-cell [3]. Future developments are considering novel active materials and lithium metal anode, pushing the specific energy up to 400-500 Wh/kg-cell [4]. Post-lithium-ion technologies such as lithium/sulfur (Li/S) or lithium/oxygen (Li/O<sub>2</sub>) batteries might provide a further improvement up to 550 and 750 Wh/kg-cell [4]. Despite that, it is clear that batteries will not represent a viable solution for regional aircraft even in the short term and will require several decades to be deployed in long-range aircraft. Combustion engines (and in particular gas turbines), which are the second option, have low efficiencies in power production (around 45% [5]) and are currently relying on liquid fossil fuels. Despite the plans to develop hydrogen combustors, storage and safety are still concerning aspects. Sustainable aviation fuel (SAF) is the most promising solution in the short term. Despite recent tests by Airbus CITE [6] and Boeing CITE [7] proved its feasibility, limited availability and cost (two to eight times as much as kerosene) are currently hindering its massive deployment. Onboard fuel cells represent the last choice, which benefits from higher energy efficiency and enables fuel flexibility. The use of fuel cells such as solid oxide fuel cells (SOFC) in aviation is receiving much attention but is still in the early stages of development. Given the issues associated to hydrogen storage, aviation industries are considering the exploitation of ammonia, which offers no carbon content, slow reactivity and the possibility to liquify it below -33 °C at atmospheric pressure. This paper explores the feasibility of using onboard direct ammonia-fed SOFCs as one of the potential solutions for the next generation of disruptive propulsion technologies.

Currently, most studies of SOFCs to power air vehicles are based on the integration with a gas turbine. These simulations differ in architecture (new components can be implemented into the process), type of fuel used, and the type of system powered (all-electric aircraft or electric APU). Many of these studies concern large aircraft and consequently long-range missions that require fuel cells with the power higher than 400 kW. One of the main obstacles to the use of SOFC onboard is represented by the weight of the stack that causes an excessive fuel consumption. Many studies, in fact, in addition to analysing the performance, have focused on the power density of the system [8-12]. Tornabene *et al.* [8] delivered a preliminary estimation of the impact on the system's mass and volume of all the components required for an APU powered by a SOFC-GT. Whyatt and Chick [9] provided a similar analysis for a Boeing 787 and concluded that the system weighed 1500 kilograms beyond the break-even point. Steffen, Freeh and Larosiliere [10]

developed a model in which a SOFC-GT powered the APU of a 300-passenger aircraft. Their results, which showed an improved efficiency, but an insufficient energy density compared to combustion engines, are in line with other studies. Dollmayer et al.[11] analysed the performance of a two-engines all-electric aircraft powered by hydrogen for a 4000 nautical miles mission. They examined the mass penalties and fuel consumption, discussing strategies to lower fuel consumption such as cabin air for processing, a partial thrust recovery, or water re-utilisation. The influence of the exhaust temperature was also examined because it can enable considerable energy recovery. Their results also established that 4kg/kWh would be the starting mass-to-power ratio for achieving fuel consumption that would justify the presence of SOFC. Lim et al. [12] designed, built, and compared the performance of a SOFC as a stand-alone unit and a SOFC-GT. The study, which also included a comparison between hydrogen and methane, showed that high pressures have a positive effect on efficiency and power density. In a National Aeronautics and Space Administration (NASA) technical publication, Srinivasan et al. [13] replaced the APU of a Boeing 777-200ER with a SOFC-GT (450 kW) and explored different levels of integration with the electrical power supply (EPS), thermal management (TMS), and environmental control (ECS) systems. SOFC-GT integration reduced nitrogen oxides (NO<sub>x</sub>), carbon monoxide, and unburned hydrocarbons (UHC) emission by 15.45% (NO<sub>x</sub>), 3.25% (CO), and 4.72% (UHC) respectively for ground operations. In addition, the authors showed that higher integration increased fuel economy for long-range missions by up to 0.77%. However, the highest reduction in fuel consumption (3%) was obtained in another analysis that targeted short-range aircraft, supporting the hypothesis that SOFCs are currently best suited for small aircraft or Unmanned Air Vehicles (UAVs). In this regard, Ji et al. [14] modelled a UAV powered by a propane-fuelled SOFC hybrid engine, achieving a thermal efficiency of 57.6%. As discussed above, most of previous studies used the SOFC as an APU. This paper is now exploring the feasibility of applying this technology to primary propulsion. In other words, to bridge the above-mentioned research results and the stringent targets and limitations set in the ACARE's flight path 2050 for emissions level reduction, this study will explore the feasibility of using ammonia-powered SOFC as the main power source for General Aviation (GA) applications. For this purpose, an experimentally validated ammonia-fed SOFC model will be developed in section two. The developed model will be used as the main source of the power for propulsion system in section three where a small aircraft (Cessna 172 size) will be simulated as the case study. The simulation results are presented and discussed in this section followed by the identified remaining research challenges in the way of using onboard ammonia powered SOFCs as the propulsion systems for the future air vehicles. Conclusion remarks are summarized in section four. It should also be mentioned that although the GA contributions to the overall climate impact of aviation is not huge, it does not question the methodological approach presented in this paper.

## **2. Ammonia Powered SOFC Modelling**

This section describes the developed tool for performance simulation of the ammonia powered SOFC which could be used to generate the required power for future air vehicles. First, the mathematical modelling of the SOFC will be detailed through a semi-empirical physics-based approach. The developed process model in ASPEN Plus<sup>®</sup> software will then be explained, and the hierarchies of the calculation method are presented in a

flowchart format. Finally, the developed model will be validated against experimental data to confirm the validity and effectiveness of the proposed modelling approach.

### 2.1. Mathematical Model

The common technique for modelling SOFCs' performance in steady conditions starts from the Open Circuit Voltage (OCV) obtained from the Nernst equation as follow:

$$E_N = \frac{RT}{2F} * \ln\left(\frac{p_{H_2} * p_{O_2}^{0.5}}{p_{H_2O}}\right) \quad (2)$$

Where R is the gas constant, T is the temperature, F is Faraday's constant. The polarisation losses (so-called overpotentials) occurring within the FC (i.e., activation, ohmic and concentration losses) are then subtracted from the OCV to determine the actual voltage. The activation overpotential ( $\eta_{act}$ ) is due to the irreversibility of the charge transfer that take place at the electrodes. The ohmic overpotential ( $\eta_{ohm}$ ) is caused mainly by the electrolytic resistance to the ions flow. Finally, the concentration overpotential ( $\eta_{conc}$ ) depends on the mass transfer limitation to the kinetics of the electrochemical process.

$$V_{final} = E_N - (\eta_{act} + \eta_{ohm} + \eta_{conc}) \quad (3)$$

In addition to being influenced by the working conditions of the fuel cell, these potential variations are closely dependent on the geometric and chemical-physical characteristics of the fuel cell. Therefore, this modelling approach requires parameters that regard the activation energy, interaction factors, anodic and cathodic composition, and cell structure. The model adopted in this work is based on semi-empirical equations derived from interpolations of experimental data. Besides providing greater flexibility, this method excludes the need to determine the microscopic characteristics of the FC and the mentioned parameters. This study is based on a generator produced by Siemens-Westinghouse and composed of multiple tubular SOFCs with internal reforming connected in bundles. The single cell has an active area of 834 cm<sup>2</sup> and can produce about 130 kW at a temperature of 900-950 °C. YSZ was used as material for the electrolyte, while the anode is made of Ni-YSZ cermet [15].

For validation case, when natural gas is used, fuel is reformed with the steam coming from the anode exhaust gas recirculation. The products, mainly CO and H<sub>2</sub>, are sent to the anode and oxidised by oxygen coming from the cathode. The fraction of exhaust gas that is not recycled is sent to a combustion plenum (called afterburner), where the total oxidation of the remaining syngas or unburnt hydrocarbons takes place. Before being released into the atmosphere, the afterburner exhaust gases are used to pre-heat the incoming air. For ammonia, this compound, being carbon-less, is not subjected to SR but undergoes thermal cracking generating hydrogen and nitrogen ( $2NH_3 \rightarrow N_2 + 3H_2$ ). Since the process is carried out with Ni-based catalysts, it can occur directly at the FC inlet. For this reason, the temperature used to model the reforming is 950 °C, even though

previous studies have established that the decomposition of ammonia is already complete at 800 °C. The thermal cracking does not require steam; hence there is no need for recirculation. It should be noted that since the ammonia is thermochemically decomposed to hydrogen and nitrogen, and hydrogen undergoes electrochemical reaction, Eq. (2) is written based on hydrogen.

## 2.2. ASPEN Model

The described process has been reproduced in Aspen Plus using the model illustrated in figure 1. This section gives a detailed description of the technical specifications used to design the model. Aspen terminology is represented in italic>

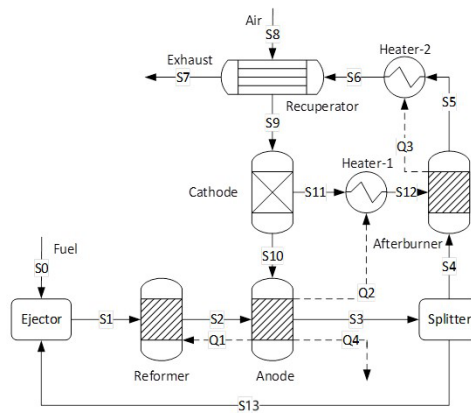

FIGURE 1 – ASPEN PLUS MODEL

The reforming and reactions occurring inside the anode were simulated using the *Rgibbs* block. This equilibrium reactor determines the final concentrations based on the chemical potential of the species involved. In other words, the Gibbs reactor predicts the product compositions by minimising the total Gibbs free energy ( $G_{total}$ ) (Equation 4)

$$G_{total} = \sum_{i=1}^N n_i \Delta G_{fi}^0 = \sum_{i=1}^N n_i RT \ln \frac{f_i}{f_i^0} \quad (4)$$

Where  $f_i^0$  and  $f_i$  represent the fugacity of the species  $i$  in the reactor and standard conditions, respectively. Two different algorithms have been developed for the model: the first (Figure 2a) allows the power produced by the fuel cell to be calculated from the amount of fuel consumed. The second (Figure 2b) determines the potential, current and fuel required starting from the expected power. These two algorithms are based on the same equations, which are rearranged to follow the structures described in Figure 1 (In a)  $V$ ,  $I$  and  $P$  are determined starting from the amount of fuel consumed. In b)  $V$ ,  $I$  and required fuel are obtained from a pre-set power [16]).

It should be mentioned that in case b), after an initial estimation of the voltage from the process parameters, the current is easily calculated using the relationship:

*Current = Power / Voltage*

(5) The next step is to calculate the amount of fuel required (mol/h) to generate that current. In the case of using hydrogen as the fuel, the required fuel could be calculated as follow:

$$H_{2,required} = \frac{Current}{2 * U_f * F} * (3600) = \frac{0.018655 * I}{U_f} \quad (6)$$

Where  $U_f$  is the utilisation factor determining the percentage of hydrogen consumed at the anode, and  $F$  is the Faraday constant. By calculating the amount of hydrogen required, the consumption of any suitable fuel can be determined just by knowing its composition. Finally, the efficiency can be obtained through the low calorific value ( $LHV_{fuel}$ ) of the used fuel and its molar flow ( $n_{fuel}$ ) (Equation 7)

$$Efficiency = \frac{Power}{(n_{fuel} * LHV_{fuel})} \quad (7)$$

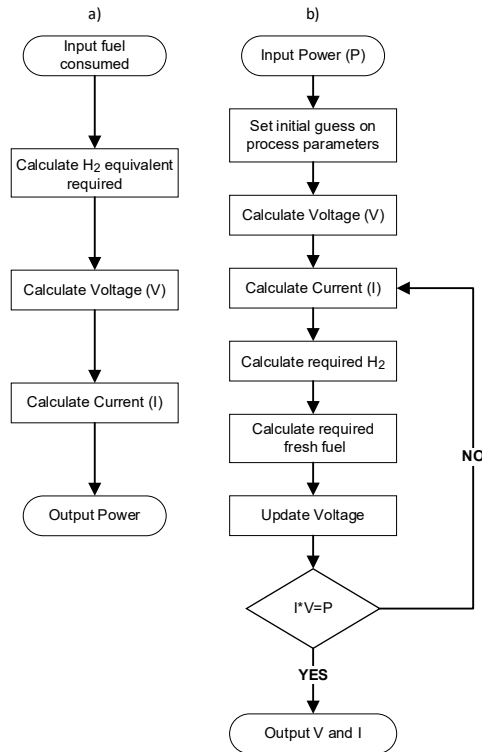

FIGURE 2 – HIERARCHIES OF CALCULATION USED IN THE MODEL

### 2.3. Validation of the Model

The developed model is validated with the experimental results of Zhu and Kee [17] SOFC fed with natural gas at a temperature of 910°C and pressure of 1 bar). The utilisation factor and steam to carbon ratio were set to 0.85 and 2.5, respectively. The natural gas used as fuel consists of the following components: methane 81.3%, ethane

2.9%, propane 0.4%, butane 0.2%, carbon monoxide 0.9% and nitrogen 14.3%. The proximity between experimental data and simulation results confirms the validity of the model (Table 1).

TABLE 1- VALIDATION OF THE DEVELOPED SOFC MODEL

	Literature data [17]	Simulation results
Power (kW)	120	120
Current density (mA/cm <sup>2</sup> )	180	175
Reforming temperature (°C)	550	537
<b>Anode outlet composition (mol%)</b>		
Water	48%	51.1%
Carbon dioxide	28%	25.1%
Hydrogen	14%	11.4%
Carbon monoxide	5%	7.3%
Nitrogen	5%	5.1%
<b>Exhaust stream composition (mol%)</b>		
Nitrogen	77%	77.3%
Oxygen	16%	16.1%
Water	5%	4.3%
Carbon dioxide	2%	2.2%

### 3. Results and Discussion

After having the validated SOFC model up-and-running, the next step is to assess the performance of the ammonia-powered SOFC to be used as the power source for general aviation. As a case study, a light aircraft with the take off power of 130 kW (Cessna 172 size aircraft) is used for simulation purpose. A short-range mission lasting a total of one hour is utilized in the simulations as shown in figure 3. The mission was simulated in all its phases, from take-off to landing, considering the different power requirements and duration of the phases. To calculate the required power for the propulsion system at each flight phase, the mission is simulated in Turbomatch (TM) - a Cranfield in-house developed software – for the Cessna 172 with Kerosene as the fuel. As a state-of-the-art gas turbine performance simulation and diagnostics code, TM is a key proprietary tool of the Propulsion Engineering Centre (PEC) at Cranfield University. This has been widely used in aircraft engine research projects and within the Cranfield postgraduate community [18]. The required power calculated by TM at Take-Off, Climb, Cruise, Descend, approach, and taxi phases are 130, 104, 83.2, 65, 52, and 19.5 kW respectively.

The mission with associated required power is then implemented in the developed SOFC model with ammonia as the fuel. Table 2 shows the results of the fuel consumption for different flight phases. The total fuel burn during the mission is 25.87 kg for ammonia powered SOFC. It is 5.9% less than the fuel consumption for the Kerosene powered aircraft with similar size (27.51 kg). The other advantages of using ammonia as the fuel is it does not generate any carbon dioxide. So, it is a high potential candidate for next generation of sustainable propulsion systems. However, the remained research challenges should be explored and addressed in order to enable this technology to be adopted by air vehicle manufacturers.

FIGURE 3 – DEFINED FLIGHT MISSION

TABLE 2 – SIMULATION RESULTS FOR 1-HOUR MISSION. FUEL: AMMONIA, T=950°C.

	Power (kW)	required	Duration (s)	Ammonia		
				kg/h	L/min	Fuel consumed (kg)
Take off	130		30	46.37	1.06	0.39
Climb	104		600	36.49	0.83	6.08
Cruise	83.2		1800	28.96	0.66	14.48
Descend	65		480	22.46	0.51	2.99
Approach	52		210	17.88	0.41	1.04
Taxi	19.5		480	6.62	0.15	0.88
<b>Total</b>						<b>25.87</b>

In summary, the feasibility and potential of using ammonia-fed SOFC as the propulsion system of future light air vehicles is studied and the simulation results reported in table 2. This technology is pretty aligned with Net Zero 2050 and Flight Path 2050 targets as it reduces the fuel consumption and does not produce carbon dioxide. However, it should be mentioned that this is just the first shot in this topic, and the study just took the power required of a kerosene-powered Cessna 172 and limited the comparison to the fuel used by a SOFC providing said power profile. In other words, different aspects of mass and aerodynamics considerations should be studied in future work to fully explore the pros and cons of using SOFC as the main source of power in propulsion systems. It may result in either increasing power required for a given performance or limiting performance when maintaining power levels. Other details like drag penalties and tank-system design and integration should also be discussed accordingly. Moreover, the following challenges are still remained:

- The first challenge is the thermal management system (TMS) architecture design and development. As the temperature of the ammonia powered SOFC is 950°C, an advanced and effective TMS should be designed and implemented to manage the thermal loads generated in the propulsion system during the mission.
- NO<sub>x</sub> can be generated, besides from ammonia oxidation, also by thermal processes that take place at temperatures above 1300°C and convert diatomic nitrogen. It is worth noting that, in some simulations, the exhaust gases leaving the afterburner contain nitrogen and oxygen at a temperature close to 1300°C. However, introducing a heat exchanger to slightly cool the gases entering the combustion chamber can solve the problem.
- Most of the global production of ammonia is based on steam methane reforming (SMR) to produce (grey) hydrogen, followed by Haber–Bosch synthesis. Although the state-of-the-art SMR technology offers the most economical approach, the process is associated with significant CO<sub>2</sub> emissions. So, potential solutions for green ammonia production are welcomed.
- The conventional SOFCs are developed mainly for stationary applications, in which the system weight may not be a key indicator. However, for air transportation, their energy-to-weight ratio is far below that of turboprops. Although the higher efficiency of SOFC may potentially compensate for this to some extent, for further deployment of SOFC-powered air vehicles, the energy-to-weight ratio should match or exceed that of turbines.
- Synchronization of the SOFC with other elements of the propulsion system should also be considered to address the implementation challenges like slow response time of SOFCs.

#### **4. Conclusion**

This research represents a first step in the feasibility study and conceptual design for introducing SOFCs with reforming onboard air vehicles. This technology makes it possible to overcome the obstacles posed by difficult hydrogen storage conditions. A physics-based model based on semi-empirical equations is developed for ammonia-powered SOFC and validated against experimental data. The performance of the developed model is assessed as the propulsion system for a light aircraft in Cessna 172

size with the Take-Off power of 130kW. Simulation results for a 1-hour mission confirm that using SOFC with ammonia fuel will reduce the mass of fuel consumed by the aircraft by 5.9% as well as omitting the carbon dioxide. So, the high potential of using ammonia powered SOFC as a disruptive propulsion technology for future aircraft is obvious. However, there are still remaining research challenges including thermal management system design, dealing with NO<sub>x</sub> production, and green ammonia production that need to be addressed in order to enable this important technology to be adopted by air vehicle manufactures in the future.

# Contents

- 375. Simulation-based design of regional biomass thermochemical conversion system for improved environmental and socio-economic performance**  
*Leonardo L. Corradini, Aya Heiho, Yuichiro Kanematsu, Ryoko Shimono, Satoshi Ohara, Yasunori Kikuchi* 2361
- 376. Conceptual Design of a Biorefinery to Use Brown Seaweed Sargassum**  
*Omar Flores-Mendoza, Teresa Lopez-Arenas* 2367
- 377. Design and Production of Biodiesel and Porous Filaments from Endemic Species of the Cienega de Chapala Region**  
*María Fernanda Torres-Magaña, José Luis Baltazar-Álvarez, Pascual Eduardo Murillo-Alvarado and Gabriela Guadalupe Esquivel-Barajas* 2373
- 378. Real-time control and scheduling decision making in fermentation-based food process operations**  
*Isuru A. Udugama, Keegan K. Hall, Christoph Bayer, Brent R. Young, Timothy G. Walmsley* 2379
- 379. Production of  $\text{Ca}(\text{HCO}_2)_2$  from formate solution through  $\text{CO}_2$  hydrogenation**  
*Taeksang Yoon, Hayoung Yoon, Sungho Yoon, Chul-Jin Lee* 2385
- 380. Techno-Economic Process Analysis of the Chemical Recycling of Nylon 6 Using Phosphoric Acid**  
*Ann-Joelle Minor, Ruben Goldhahn, Liisa Rihko-Struckmann<sup>a</sup>, Kai Sundmacher* 2391
- 381. Multiscale High-throughput Screening for Membrane-based Green Hydrogen Separation Process**  
*Nahyeon An, Seongbin Ga, Hyungtae Cho, Boram Gu, Junghwan Kim* 2397
- 382. Discrete Element Simulation and Economics of Mechanochemical Grinding of Plastic Waste at an Industrial Scale**  
*Elisavet Anglou, Yuchen Chang, Arvind Ganesan, Sankar Nair, Carsten Sievers, Fani Boukouvala* 2403
- 383. Multi-scale Modelling and Experimental Investigation of Hydrogen Sulphide Thermal Decomposition**  
*Anna Nova, Francesco Negri, Flavio Manenti* 2409

- 384. Reuse and recycling of waste material: design of a pyrolysis-based process**  
*Gabriel Rodríguez Garrido, Pablo Marinangeli, Jorge A. Ressia, Maria A. Volpe, Patricia M. Hoch* **2415**
- 385. Life Cycle Assessment of bio-oil produced through lignocellulosic biomass liquefaction**  
*Ana S. Augusto, Catarina G. Braz, Duarte M. Cecílio, Maria M. Mateus, Henrique A. Matos* **2421**
- 386. Impacts of defossilising downstream derivatives in petrochemical clusters – MTBE case study**  
*Inna Stepchuk, Mar Pérez-Fortes, Andrea Ramírez Ramírez* **2427**
- 387. Methane-to-X: an economic assessment of methane valorisation options to improve carbon circularity**  
*Ben Lyons, Andrea Bernardi, Nilay Shah, Benoît Chachuat* **2433**
- 388. Purification of Raw Bio-Methanol from Renewable Feedstocks: A Flexibility Assessment**  
*Matteo Fedeli, Alessandro di Pretoro, Ludovic Montastruc, Flavio Manenti* **2439**
- 389. Life cycle assessment of Pine needle-based electricity generation in India**  
*Pratham Khaitan, Ankush Halba, Pratham Arora* **2445**
- 390. Evaluation of alternative carbon based ethylene production in a petrochemical cluster: Technology screening & value chain impact assessment**  
*James Tonny Manalal, Mar Pérez-Fortes, Paola Ibarra Gonzalez and Andrea Ramirez Ramirez* **2451**
- 391. Syngas fermentation to ethanol: the effects of gas recycling on economics**  
*Haneef Shijaz, Fausto Gallucci, Adrie Straathof,<sup>a</sup> John Posada* **2457**
- 392. Modeling, simulation and techno-economic analysis of an integrated biorefinery based on halophytes**  
*Tutku Taşçı Çilak, Sanketkumar Raval, Sylvia Fasse, Mette H. Thomsen, Axel Gottschalk* **2463**
- 393. Optimal Control for Deriving Policies for Global Sustainability**  
*Urmila Diwekar, Apoorva Nisal, Yogendra Shastri, and Heriberto Cabezas* **2469**

- 394. Application of CAPE Tools into Prospective Life Cycle Assessment: A Case Study in Feedstock Recycling of Waste Plastics**  
*Yasunori Kikuchi, Yuki Nomura, Takuma Nakamura, Shoma Fujii, Aya Heiho, Yuichiro Kanematsu* **2475**
- 395. Designing roadmaps for transitioning to value chains with net-zero emissions: Case of the chemical industry**  
*Amrita Sen, Vyom Thakker, George Stephanopoulos, Bhavik R Bakshi* **2481**
- 396. Data Envelopment Analysis of Ammonia and Methanol as Sustainable Energy Storage Vectors**  
*Sebastiano C. D'Angelo, Michael Bregy, Philipp Steiner, Raul Calvo-Serrano, Gonzalo Guillén-Gosálbez* **2487**
- 397. Simulation of thermochemical recycling of waste plastic to produce dimethyl ether**  
*Mohammaed Awwad and Umer Zahid* **2493**
- 398. Sustainable recycling of refrigerants: Analysis of alternatives**  
*J. Moreno, I. Karpov, A. Ahmed, J. Foglia, H. Wu, A. Gadekar, P.L.J. Swinkels, R. Gani* **2499**
- 399. Thermodynamic study and simulation of the process of separation of the IPA+water mixture by heterogeneous azeotropic distillation**  
*Elvira Spatolisano, Camilla Barbieri, Laura A. Pellegrini, Stefania Moioli* **2507**
- 400. Sustainability assessment of poly(butylene succinate) production and End-of-Life options from wheat straw**  
*Sofia-Maria Ioannidou, Dimitrios Ladakis, Ricardo Rebolledo-Leiva, Maria Teresa Moreira, Ioannis K. Kookos, Apostolis Koutinas* **2513**
- 401. Computer simulation of a plastic waste gasification-solid oxide fuel cell power generation system using Aspen Plus**  
*Mahmudul Hassan Riyad, Sadman Fakid, Nahid Sanzida* **2519**
- 402. Enhancement of hydrochar from coal discards and sewage sludge (co)-HTC for transition to a low-carbon economy**  
*Gentil Kahilu Mwendu, Orevaoghene Eterigho-Ikelegbe, Jean Mulopo, Samson Bada* **2525**

<b>403. Fully Electrified Conversion of Low-Quality Plastic Waste to Polymer Precursors</b> <i>Kristiano Prifti, Andrea Galeazzi, Adrián Pacheco-López, Antonio Espuña, Flavio Manenti</i>	<b>2533</b>
<b>404. Deep neural network-based multi-objective optimization of NO<sub>x</sub> emission and profit by recovering lignocellulosic biomass</b> <i>Kim Y., Park J., Lim J., Joo C., Cho H., Kim J</i>	<b>2539</b>
<b>405. Decarbonization of gray ammonia production through the Allam power cycle: a techno-economic assessment and optimization</b> <i>Andrea Isella, Mattia Forina, Mario Spagna, Davide Manca</i>	<b>2547</b>
<b>406. Into the Valley of Death Rode the Green Transition</b> <i>Robert Pujan and Heinz A. Preisig</i>	<b>2555</b>
<b>407. A novel industrial biotechnology approach to valorize fatty acids to bioplastics: scope for scale-up and process efficiency using an integrated approach</b> <i>Pantelis Vasilakis, Kostas Pyrgakis, Melina Psycha, Antonino Biundo, Antonis Kokossis</i>	<b>2561</b>
<b>408. On the re-deployment of lignocellulosic biorefineries with solvent-free designs and process-to-process integration</b> <i>Iraklis Sarris, Kostas Pyrgakis, Antonis Kokossis</i>	<b>2567</b>
<b>T5: Systems methods in industrial biotechnology and biomedical applications</b>	
<b>409. Digital-twin development for a novel vibrating membrane aiming at fractionating fermentation broths</b> <i>Oscar A. Prado-Rubio, Wai Fung Hui, Mads Stevnsborg, Manuel Pinelo, Jakob Kjøbsted Huusom</i>	<b>2573</b>
<b>410. Post-Combustion Carbon Capture and Utilization by Sodium Hydroxide Aqueous Solution for Bicarbonate Microalgae Cultivation</b> <i>Jialin Liu, Yoong Kit Leong, Jo-Shu Chang</i>	<b>2579</b>
<b>411. Comparing different modelling approaches for metabolic network dynamic simulation under uncertainty</b> <i>Oliver Pennington, Dongda Zhang</i>	<b>2587</b>

- 412. Integrating hybrid modelling and transfer learning for new bioprocess predictive modelling**  
Sam Kay, Harry Kay, Alexander W. Rogers, Dongda Zhang **2593**
- 413. Machine learning-supported cybergenetic modeling, optimization and control for synthetic microbial communities**  
*Sebastián Espinel-Ríos, Katja Bettenbrock, Steffen Klamt, José L. Avalos, Rolf Findeisen* **2599**
- 414. Model-based optimization of a recombinant *E. coli* fed-batch process for best time-space yield and conversion efficiency**  
*Julian Kager, Nora Horst, Christoph Herwig and Ioannis V.Skiadas* **2605**
- 415. Closed-loop optimization of high-throughput robotic platforms for reproducible bioprocess development**  
*Federico M. Mione, Judit Aizpuru, Martin F. Luna, Pablo Rodriguez Bahamon, Jong Woo Kim, Ernesto C. Martinez, M. Nicolas Cruz B* **2611**
- 416. Dynamic microbial-community metabolic modeling for yogurt fermentation based on the metagenome of starter culture**  
*Sizhe Qiu, Zhijie Yang, Hong Zeng, Bei Wang, Aidong Yang* **2617**
- 417. Multilevel Discrete Modelling of Microbial Cell Cultures using Population Balances**  
*Menwer Attarakih, Hans-Jörg Bart, Khaled Rawajfeh* **2623**
- 418. Binary Classification of the Endocrine Disrupting Chemicals by Artificial Neural Networks**  
*Zahir Aghayev, George F. Walker, Funda Iseri, Moustafa Ali, Adam T. Szafran, Fabio Stossi, Michael A. Mancini, Efstratios N. Pistikopoulos, Burcu Beykal* **2629**
- 419. Digital Twins in Pilot Scale Fermentation: Non-Linear State Estimation for Improving Induction Timing**  
*Mads Stevnsborg, Kurt Selle, Ryan Barton, Oscar A. Prado-Rubio, Carina Gargalo, Krist V. Gernaey, Gary Gilleskie, Jakob K. Huusom* **2635**
- 420. Optimal dosing of thyroid hormones in hypothyroid patients with an individualized compartmental model**  
*Davide Manca, Federico Appiani, Giovanni Colombo* **2641**
- 421. Technoeconomic process modelling of waste remediation within a supply chain network**  
*Robert Milton, Jagroop Pandhal and Solomon F. Brown* **2647**

- 422. Spatio-temporal analysis of milk safety under climate change**  
*Lydia Katsini, Satyajeet S. Bhonsale, Styliani Roufou, Sholeem Griffin, Vasilis Valdramidis, Simen Akkermans, Monika Polanska, Jan F.M. Van Impe* **2653**
- 423. Ensemble Kalman Filter for estimation of intracellular nucleotide sugars from extracellular metabolites in monoclonal antibodies**  
*Luxi Yu, Ehecatl Antonio del Rio Chanona, Cleo Kontoravdi* **2659**
- 424. Towards a unified multi-scale strategy for bio-manufacturing process development**  
*Thomas Bisgaard, Nima Nazemzadah, Eduardo Krebs Kleingesinds, Negin Yousefi, Christian Beenfeldt, Seyed Soheil Mansouri* **2665**
- 425. Development of a framework for simulation of biotechnological processes**  
*Priscila Marques da Paz, Caroline Satye Martins Nakama and Galo Antonio Carrillo Le Roux* **2671**
- 426. Knowledge modelling framework for per-and poly-fluoroalkyl substances (PFAS) treatment solutions**  
*Madeleine Bussemaker, Nikos Trokanas, Ioannis Kavakiotis, Franjo Cecelja* **2677**
- 427. Combined metabolic modeling and experimental data for enhanced biotechnological production**  
*Anita L. Ziegler, Melanie Filbig, Johannes Parschau, Till Tiso, Lars M. Blank, Alexander Mitsos* **2683**
- 428. Machine learning models for predicting membranolytic anticancer peptides**  
*Fatemeh Alimirzaei, Chris A. Kieslich* **2689**
- 429. Data-driven prediction of peptide-MHC binding using oscillations of physicochemical properties**  
*Hyeju Song, Chris A. Kieslich* **2695**
- 430. A Computational Pipeline to Optimize 3D Scaffolds for Cancer Immunotherapy**  
*Lucy Todd, Matthew Chin, Marc-Olivier Coppens* **2703**
- 431. Developing Cole-Cole model for *Bacillus subtilis* fermentation**  
*Kumar Rajan Gopa, Tom Wenzel, Sankalp Jena, Supasuda Assawajaruwan, Valentin Khaydarov, Leon Urbas* **2709**

- 432. Improving accuracy scores of neural network driven QSAR models of mutagenicity**  
*Alexander D. Kalian, Emilio Benfenati, Olivia J. Osborne, Jean-Lou C.M. Dorne, David Gott, Claire Potter, Miao Guo, Christer Hogstrand* 2715
- 433. Investigating tunable experiment variable effects on hiPSC-CMs maturation via unsupervised learning**  
*Shenbageshwaran Rajendiran, Mohammadjafar Hashemi, Ferdous Frinklea, Nathan Young, Elizabeth Lipke, Selen Cremaschi* 2721
- 434. On the systematic development of large-scale kinetics using stability criteria and high-throughput analysis of curated dynamics from genome-scale models**  
*Konstantinos Mexis, Stefanos Xenios, and Antonis Kokosis* 2727
- T6: Multi scale energy systems engineering (organized by the EFCE energy section)**
- 435. Development and assessment of intensification alternatives on the lignocellulosic bioethanol production process**  
*Yulissa M. Espinoza-Vázquez, Fernando Israel Gómez-Castro, Eduardo Sánchez-Ramírez, Araceli G. Romero-Izquierdo* 2733
- 436. Optimal ship-based CO<sub>2</sub> transport chains from Mediterranean emission points to the North Sea**  
*Federico d'Amore, Matteo C. Romano* 2739
- 437. DynHeat: Heat Exchanger Network Design for Batch Processes via Dynamic Optimization**  
*Dörthe Franzisca Hagedorn, Sören Demandt, Florian Joseph Baader, Christiane Reinert, Niklas von der Aßen* 2745
- 438. Process Simulation Approaches to Reduce Commercial Risk of CCS Projects**  
*Ryan Muir, Ralph Cos, Chloe Smith, Stelios Papastratos* 2751
- 439. Incorporation of non-linear efficiency constraints in green ammonia production design for cost minimisation**  
*Nicholas Salmon,<sup>a</sup> René Bañares-Alcántara* 2757
- 440. Strategic participation of a gas-fired power plant in interdependent electricity and natural gas markets under carbon emission trading schemes**  
*Christos N. Dimitriadis, Evangelos G. Tsimopoulos, Michael C. Georgiadis* 2763

- 441. Modeling and optimization of hybrid P/VSA-membrane separation processes for CO<sub>2</sub> capture from post combustion flue gas**  
*Christos C. Chatziasteriou, Michael C. Georgiadis, Eustathios S. Kikkinides* 2769
- 442. Integration of renewable energy and CO<sub>2</sub> capture and utilization technologies for decarbonization of energy intensive process industries**  
*Calin-Cristian Cormos, Letitia Petrescu, Ana-Maria Cormos, Simion Dragan, Cristian Dinca, Marius Sandru* 2775
- 443. Simultaneous optimisation of energy recovery and water recirculation in a ceramic plant**  
*Miguel Castro Oliveira, Muriel Iten,<sup>a</sup> Henrique A. Matos* 2783
- 444. Embedding Flexibility to the Design of Pressure-Vacuum Swing Adsorption Processes for CO<sub>2</sub> Capture**  
*Steven Sachio, Adam Ward, Ronny Pini, Maria M. Papathanasiou* 2789
- 445. Multiple-Model Fault Detection of PEMFC**  
*A.Allam, M.Mangold, P.Zhang* 2795
- 446. Implications of Heat and Work Integration in Biomass to Fischer-Tropsch Fuels: A simulation Approach**  
*Samukeliso Dube, Baraka Celestin Sempuga, Xinying Liu* 2801
- 447. Modeling and Assessment of Electrochemical Reduction of CO<sub>2</sub> in Amine-based Capture Solvents**  
*Alexios-Spyridon Kyriakides, Panagiotis Kazepidis, Athanasios I. Papadopoulos, Panos Seferlis* 2807
- 448. Design of CO<sub>2</sub> Capture and Mineralization Systems: Integrated Process Optimization and Controllability Assessment in Parallel Infrastructures**  
*Thomas Prousalis, George Gkizas, Athanasios I. Papadopoulos, Panos Seferlis* 2813
- 449. Accurately Modeling Hydropower in the USA**  
*Amanda Farnsworth, Emre Gençer* 2819
- 450. Biogas valorisation to liquid fuels: modelling and setting up process targets**  
*Selusiwe Ncube, Baraka C Sempuga, Xinying Liu* 2825
- 451. Modeling Commercial Fleet Charging and Regulation Strategies via Data-driven Optimization**  
*James Owens, Emre Gençer* 2831

- 452. Economic Benefits from Planned Renewable Installations in the US using Hydrogen and Modular Ammonia Production Units**  
*Apoorv Lal, Fengqi You* 2837
- 453. Data-Driven Robust Model Predictive Control on Building Climate Control with Renewable Energy**  
*Wei-Han Chen, Fengqi You* 2845
- 454. Thermodynamic Modelling and Performance Analysis of Power Plant for Switching from Coal to Biomass**  
*Romuald Coupan, Ahmed Baccouche, Pierre Szymanski* 2851
- 455. Bottleneck-identification methodology and debottlenecking strategy for heat exchanger network with disturbance**  
*Liwon Zhao, Guilian Liu* 2859
- 456. A Power-to-Gas energy system: modeling and operational optimization for seasonal energy supply and storage**  
*Yifan Wang, Luka Bornemann, Christiane Reinert, Niklas von der Aßen* 2865
- 457. Liquid organic hydrogen carriers (LOHC) as a solution for the energy transition: a reactor design assessment**  
*Carlos Prieto, Antonio Sánchez, Mariano Martín* 2871
- 458. Powering Clean and Affordable Energy through Geothermal Integration: A Case Study on Dominica**  
*Keeara Bhagaloo, Rehannah Ali, Anastasia Baboolal and Keeran Ward* 2877
- 459. Optimal design of a water energy food nexus system through a multi-objective approach**  
*Daniel Peña-Torres, Marianne Boix, Ludovic Montastruc* 2883
- 460. Techno-economic comparison of peaking power plants: OCGT+CCS vs Lithium-ion batteries**  
*Mathew Dennis Wilkes, Diarmid Roberts, Solomon Brown* 2889
- 461. Bioenergy with carbon capture and storage (BECCS) – power generation coupled with hydrogen production**  
*Mathew Dennis Wilkes, Oludayo Asuni, Solomon Brown* 2895
- 462. Optimizing the Sustainable Energy Transition: A Case Study on Trinidad and Tobago**  
*Sherard Sadeek, Dhurjati Chakrabarti, Maria M. Papathanasiou, Keeran Ward* 2901

- 463. Optimal operation of a sustainable water desalination unit integrated a green energy system**  
*Ali Ahmadian, Ali Almansoori, Ali Elkamel* **2907**
- 464. Optimal production of green hydrogen with grid assistance for enhanced flexibility**  
*Christopher Varela, Mahmoud Mostafa, Edwin Zondervan* **2915**
- 465. Water sources evaluation for green hydrogen production: a case study in Brazil**  
*Leonardo O. S. Santana, Artur S. Bispo, Gustavo S. Santos, Chrislaine B. Marinho, Ewerton E. S. Calixto, José L. G. Almeida, Fernando L. P. Pessoa* **2921**
- 466. Sustainable Development Goals assessment of carbon capture on-board**  
*Valentina Negri, Margarita A. Charalambous, Juan D. Medrano-García, Gonzalo Guillén-Gosálbez* **2927**
- 467. Parametric study of the reactive absorption of CO<sub>2</sub> for soda ash production**  
*Maria F. Gutierrez, Peter Schulze, Andreas Seidel-Morgenstern, Heike Lorenz* **2933**
- 468. Machine learning enabled modelling and sensitivity analysis for the power generation from a 660 MW supercritical coal power plant**  
*Waqar Muhammad Ashraf, Vivek Dua* **2939**
- 469. Hydrogen production using renewable energy: solar PV and offshore wind power – An economic evaluation in Bahia**  
*Gustavo de S. dos Santos, Chrislaine do B. Marinho, Leonardo O. S. Santana, Artur S. Bispo, Fernando L. P. Pessoa, José L. G. Almeida, Ewerton E. S. Calixto* **2945**
- 470. Resilience-aware multi-scale integration of distributed energy systems**  
*Natasha J. Chrisandina, Shivam Vedant, Eleftherios Iakovou, Efstratios N. Pistikopoulos, Mahmoud M. El-Halwagi* **2951**
- 471. Techno-enviro-economic analysis of H<sub>2</sub> economy in China from H<sub>2</sub> production to utilization**  
*Xiaodong Hong, Zuwei Liao, Yao Yang, Jingdai Wang, Yongrong Yang* **2957**
- 472. Towards a novel concept for solid energy storage**  
*Adrian Straub, Bogdan Dorneanu, Harvey Arellano-Garcia* **2963**

- 473. Multiobjective optimization of distributed energy systems design through 3E (economic, environmental and exergy) analysis**  
*Bogdan Dorneanu, Sayeef Miah, Evgenia Mechleri, Harvey Arellano-Garcia* 2969
- 474. Calcium looping for CO<sub>2</sub> capture, H<sub>2</sub> and electricity coproduction in coal fired power plants**  
*B. Basant Kumar Pillai, Ramsagar Vooradi, Sarath Babu Anne* 2975
- 475. 3-E (Energy, Exergy & Ecological) analyses of Chemical Looping Air Separation integrated Oxy-Coal Combustion based Power plant**  
*Agarwal Shruti Sumankumar, Venkata Suresh Patnaikuni, Praveen Kumar Bommineni* 1981
- 476. Reliability analysis for robust power-to-X design and storage sizing under renewable uncertainty**  
*Jeongdong Kim, Meng Qi, Il Moon* 2987
- 477. Systematic Development of Strategies for the Decarbonization of Process Utility Systems**  
*Julia Jiménez-Romero, Adisa Azapagic, Robin Smith* 2993
- 478. Energy and Exergy analysis of Biomass Direct Chemical Looping Combustion for CO<sub>2</sub> capture and Utilization**  
*Shailesh Singh Sikarwar, Ramsagar Vooradi, Venkata Suresh Patnaikuni* 2999
- 479. End-effect mitigation in multi-period stochastic programming of energy storage operations**  
*Teemu J. Ikonen, Dongho Han, Jay H. Lee, Iiro Harjunkoski* 3005
- 480. How to accurately fast-track sorbent selection for post-combustion CO<sub>2</sub> capture? A comparative assessment of data-driven and simplified physical models for screening sorbents**  
*Sai Gokul Subraveti, Luca Riboldi, Hao Yang Xu, Yannick Jooss, Simon Roussanaly, Leif Erik Andersson, Rahul Anantharaman* 3011
- 481. A framework for decision-making to encourage utilization of residential distributed energy systems in Brazil**  
*Ana Paula Alves Amorim, Bogdan Dorneanu, Karen Valverde Pontes, Harvey Arellano-Garcia* 3017
- 482. Hydrogen infrastructure planning for heat decarbonisation in Great Britain**  
*Margarita E. Efthymiadou, Vassilis M. Charitopoulos and Lazaros G. Papageorgiou* 3023

- 483. Optimal Concentrated Solar Plant (CSP) location accounting for social and environmental impact: A three-location study in Spain**  
*José A. Luceño Sánchez, Mariano Martín, Sandro Macchietto* **3029**
- 484. Inventory data generation for prospective lifecycle design through process modeling of energy recovery from waste plastics**  
*Shoma Fujii, Yuichiro Kanematsu, Yasunori Kikuchi* **3035**
- 485. Process intensification in a fixed bed reactor for a small-scale process in the stranded assets**  
*Adrian R. Irhamna and George M. Bollas* **3041**
- 486. Optimal capacity planning integrating ammonia storage for power and heat decarbonisation**  
*Georgios L. Bounitsis, Vassilis M. Charitopoulos* **3047**
- 487. European Union's biomass availability for Sustainable Aviation Fuel production and potential GHG emissions reduction in the aviation sector: An analysis using GIS tools for 2030**  
*Sivaramakrishnan Chandrasekaran, Nora B. Salah, John A. Posada* **3053**
- 488. Statistical modeling of electrodes manufacture for CO<sub>2</sub> electroreduction to value-added products**  
*Jose Antonio Abarca, Guillermo Díaz-Sainz, Iván Merino-García, Jonathan Albo, Angel Irabien* **3059**
- 489. Comparative exergoeconomic analysis of two Organic Rankine Cycle (ORC) configurations**  
*Ladislao E. Méndez-Cruz, Miguel A. Gutiérrez-Limón, Raúl Lugo-Leyte, Mauricio Sales-Cruz* **3065**
- 490. Hybrid polymeric membrane – chemical absorption system for pre-combustion CO<sub>2</sub> capture**  
*Maytham Alabid, Nela Slavu, Marius Sandru, Cristian Dinca* **3071**
- 491. Electrification of ethylene production: exploring the potential of flexible operation**  
*Julia L. Tiggeloven, André P.C. Faaij, Gert Jan Kramer and Matteo Gazzani* **3077**
- 492. An MINLP model for the optimal design of CO<sub>2</sub> transportation infrastructure in industrial clusters**  
*Jude O. Ejeh, Sergey B. Martynov, and Solomon F. Brown* **3083**

- 493. Data Driven Leak Detection in a Real Heat Exchanger in an Oil Refinery**  
*Aslı Yasmal, Gizem Kuşoğlu Kaya, Emirhan Oktay,  
Ceylan Çölmekci, Erdal Uzunlar* **3089**
- 494. Optimization of flash-separation based CO<sub>2</sub> purification units**  
*Lorenzo Sala, Syed Ali Zaryab, Paolo Chiesa, Matteo Romano,  
Emanuele Martelli* **3095**
- 495. Big data analysis of solar energy fluctuation characteristics and integration of wind-photovoltaic to hydrogen system**  
*Yaoxi Chen, Siyu Yang, Yu Qian* **3101**
- 496. Dynamic Modeling and Control of CO<sub>2</sub> Capture Systems with a Biphasic Solvent**  
*Panagiotis Kazepidis, Athanasios I. Papadopoulos, Panos Seferlis* **3109**
- 497. Development of integrated liquid air energy storage systems based on air separation units using waste energy from power plant: A case study of South Korea**  
*Jaerak Ko, Seolji Nam, Soonho Hwangbo* **3115**
- 498. A systematic method for performing pinch analysis of the Liquid Air Energy Storage (LAES) process**  
*Vuppanapalli Chaitanya, S. Narasimhan, G. Venkatarathnam* **3121**
- 499. Climate-zone-based Techno-Economic Assessment of Different Carbon Capture Technologies for Coal-Fired Power Plants**  
*Mohammadamin Zarei, Ha-Jun Yoon, Chul-Jin Lee* **3127**
- 500. Numerical tool for dynamic simulation of anaerobic digesters including an air-inflated double membrane gasholder**  
*Giberto M. Yuki Junior, Sabine Sochard, Elio Dinuccio,  
Frédéric Marias* **3133**
- 501. An iterated double auction model for peer-to-peer electricity trading**  
*Timothy Huty, Prof Solomon Brown* **3139**
- 502. Comparing operational strategies for alkaline electrolysis systems considering a probabilistic wind power distribution**  
*Lucas Cammann, Johannes Jäschke* **3145**
- 503. Conceptual design of pre-treatment units for co-electrolysis of CO<sub>2</sub> and water**  
*Josephine Vos, Andrea Ramirez, Mar Pérez-Fortes* **3151**

<b>504. A Process Design, Intensification, and Modularization Approach for Membrane-Assisted Reaction Systems</b> <i>Yuhe Tian, Ayooluwa Akintola, Benjamin Akoh</i>	<b>3157</b>
<b>505. Multiscale design and analysis of templated zeolite for Li-O<sub>2</sub> battery with improved discharge capacity</b> <i>Khizar Hayat, Daniel Bahamon, Lourdes F. Vega, Ahmed AlHajaj</i>	<b>3163</b>
<b>506. Numerical Evaluation of Fuel Utilisation Enhancement Strategies in a Solid Oxide Fuel Cell System Fuelled by Hydrocarbons Mixtures</b> <i>Clyde-Theodore Nguimbous Batista, Amirpiran Amiri, Robert Steinberger-Wilckens</i>	<b>3169</b>
<b>507. Heat pumping and renewable energy integration for decarbonizing brewery industry and district heating</b> <i>Daniel Flórez-Orrego, Meire Ribeiro Domingos, François Maréchal</i>	<b>3175</b>

## Abstract

Utilizing regional biomass instead of imported fossil fuels can support sustainability; but the presence of multiple options for products and conversion methods creates a complex scenario. In this study, we are tackling the simulation-based design of a regional system utilizing local biomass by thermochemical conversion technologies. By choosing a remote island, Tanegashima, in Japan, as a case study, the availability of local biomass and the demand for its products was determined. A model on Aspen Plus<sup>TM</sup> was developed to examine the possible yield of biomass products in different scenarios. Life cycle assessment (LCA) and input-output analysis (IOA) were conducted to calculate environmental and socio-economic indicators. Almost all scenarios considered saw greenhouse gas emission reductions and improved economic circularity, with byproduct reutilization proving beneficial for improving resource self-sufficiency.

**Keywords:** Biofuels, process simulation, sugarcane bagasse, woody biomass

## 1. Introduction

Japan’s self-sufficiency ratio is only around 12.1% (IEA, 2020). In 2020, almost 90% of the country’s primary energy supply was fulfilled by fossil resources and only about 3.9% of Japan’s primary energy mix originated from biomass. Although local biomass use in Japan could make the country more self-sufficient and environmentally friendly (Goh et al., 2020), biomass must be converted into multiple different products of interest, like liquid fuels and chemicals. Hydrogen, ethanol, methanol, charcoal, and hydrocarbons usable as diesel are just a few examples of biomass-derived products (Kang et al., 2021). There are also various existing processes that can be utilized to perform this valorization; in some cases, the same end product can be created using different processes. In particular, thermochemical methods are the ones in which the biomass is decomposed by heat in addition to auxiliary chemicals such as gasification and pyrolysis (Wang et al., 2022). In addition to that, when designing a biomass valorization system, there is very likely to be a mismatch in the supply and demand quantities. For these reasons, if local governments and residents in a region make the decision to employ biomass as a fuel source due to the benefits outlined previously, a complex situation arises: a certain

biomass-derived product may have to be prioritized over the others and it is necessary to determine what final product and technology choice would maximize the potential benefits to the population (Sun and Fan, 2020). Previous works in the literature have explored the matching of supply and demand of biomass within regions (Ayoub and Yuji, 2012; Sun and Fan, 2020). To quantify such “potential benefits”, life cycle assessment (LCA) can be employed as a quantitative technology assessment tool (Kikuchi et al., 2010). Input-output analysis (IOA) (Leontief, 1936) could be applicable to illustrate how different sectors of a biomass-based economy interact with each other and to quantify the economic benefits of regional resource utilization (Kikuchi et al., 2020).

In this study, we are tackling the simulation-based design of a regional system utilizing local biomass by thermochemical conversion technologies. By choosing a remote island, Tanegashima, in Japan, as a case study, the availability of local biomass and the demand for its derived products was determined. A model on Aspen Plus™ was developed to examine the possible yield of biomass products in different scenarios. LCA and IOA were conducted to calculate environmental and socio-economic indicators.

## 2. Materials and methods

### 2.1. Tanegashima case study: biomass supply and fuel demand

In order to discuss the design of a biomass valorization system, the technologies and products considered in this study are applied to a case study in Tanegashima. The system boundary in this study is represented on Figure 1.

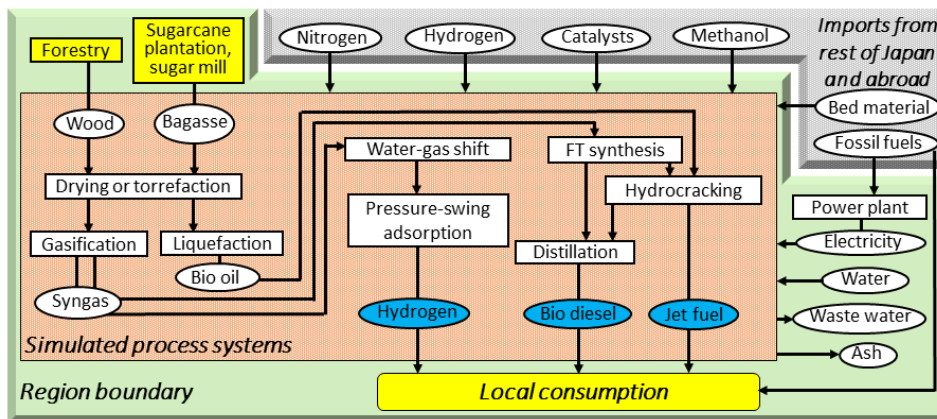

Figure 1: Biomass conversion system and its boundaries

Actual values were investigated and applied for estimating the supply of idle biomass from local forestry and sugarcane industries (Kikuchi et al. 2020; Kikuchi et al. 2016). As for the end product demand, hypotheses were made regarding the adoption of three biomass-derived fuels: hydrogen, jet fuel and biodiesel. Ten representative scenarios were generated to evaluate the effects of different technology and product choices, as listed in Table 1. In the first five, a single product is produced, and different technologies are used. In the other five scenarios, multiple products are manufactured. Scenarios Mix 1, 2 and 3 assume one third of the biomass is allotted to each product, altering the conversion technology between liquefaction, Fischer-Tropsch (FT) synthesis and liquefaction plus torrefaction pre-treatment, respectively. In Mix 4, 70% of the biomass is used for jet fuel production via liquefaction and 30% for hydrogen. In Mix 5, half of the raw materials are allocated for jet fuel production via liquefaction and the rest for diesel production via FT synthesis.

When possible, byproducts like char or flue gases are recycled into different unit operations, or combusted to generate steam and subsequently electricity. Thus, while electricity is always consumed to run some equipment, in some cases there is net generation of electricity.

Table 1: Scenarios of products and technologies applied for local biomass resources (Gas.: Gasification, FT: Fischer-Tropsch, Tor.: torrefaction, Liq.: liquefaction)

Allocation (wt%)	H <sub>2</sub>	Jet (FT)	Jet (Liq)	DL (FT)	DL (Liq)	Mix 1	Mix 2	Mix 3	Mix 4	Mix 5
H <sub>2</sub>	100					33	33	33	30	
Jet Fuel		100	100			33	33	33	70	50
Bio Diesel				100	100	33	33	33		50
Technology	Gas.	FT	Liq.	FT	Liq.	Liq.	FT	Liq. with Tor.	Liq.	Liq. And FT

## 2.2. Modeling of biomass conversion technologies in Aspen Plus<sup>TM</sup>

The process inventory data was extracted from the process simulation in Aspen Plus (Kikuchi et al., 2010). Biomass is initially described as a “non-conventional” component.

Figure 2: Gasification model scheme

As an example of biomass conversion modeling, the gasification model shown on Figure 2 is explained here. Dual fluidized bed gasification (Müller, 2013) was adopted in this study. The first stage, drying, was modeled with the RStoic reactor. (Patrocínio, 2017) The next block is the decomposition of biomass into conventional components modeled by an RYield reactor according to elemental balance (Abdelouahed et al., 2012). The pyrolysis occurs after decomposition process. The steam utilized as the gasifying agent is also an input in an RGibbs reactor at 400°C and atmospheric pressure. In this case, the final gasifier reactor is modeled as a CSTR in which reduction reactions occur in the gas phase. The combustion bed is also simulated on Aspen Plus by an RStoic reactor. Additionally, liquefaction is modeled with the RYield reactor taking data from previous studies (Wright et al., 2010). The torrefaction model developed by Peduzzi et al. was adopted (Peduzzi et al., 2014). Downstream processes were modeled by more conventional models (Saeidi et al., 2017).

## 2.3. Settings for LCA and IOA

The LCA boundary encompasses the conversion process itself, with biomass as the main input and the three potential products as the main outputs. Other auxiliary inputs necessary for operation such as electricity are also included. The inventory data was from IDEA v3.1 (AIST, 2022), a Japanese LCA database. The functional unit was defined as the utilization of local biomass for energy. The reference flow was set as unit mass of dry biomass input. IOA was performed based on the IO table for Tanegashima (Kikuchi et

al., 2020). IOA in this study was executed by adding a new sector(s) to expand the IO table representing the new products being generated in the island. This requires calculating all the monetary inputs to the new sector (money spent by the manufacturing units) and the outputs; product sales. This is done by estimating the fixed and operational costs (Turton, 2009). The costs of plant construction are divided evenly throughout the 20-year lifetime of the project. Selling price was calculated assuming internal return rate of 11%. The circularity of the economy before and after the changes is then determined.

### 3. Results and Discussion

#### 3.1. LCA results

The life cycle greenhouse gas (GHG) emissions are shown on Figure 3. The contribution of electricity represents a large share of the impact for the single product scenarios.

Figure 3: LCA results, life cycle

For FT processes, a relatively large amount of electricity is required in order to compress the syngas before it undergoes CO<sub>2</sub> removal and FT synthesis. Additionally, the operating temperature of gasification is high (>900°C). Therefore, all of the off gases released which could potentially produce electricity were re-directed into the gasifier to supply heat. On the other hand, for liquefaction, a smaller amount of the byproducts (char and flue gases) is required to heat up the pyrolyzer, since it operates at 480°C. Thus, net electricity generation is possible. Besides electricity, it can be seen that the liquefaction routes also stand out due to the large effects of hydrogen used in hydrocracking.

#### 3.2. Input-Output Analysis

The first step of the IOA was the calculation of the monetary flows due to raw materials and utilities induced by the technology implementation. These values are ascribed to pre-existing sectors in the Tanegashima IO table, and utilized to describe the monetary flows in the renewable fuel production sector. After calculating the final effects on the economy, the change in internal and external flows before and after the production of fuels from regional biomass resources are presented on Figure 4. The overall value of the imports into Tanegashima actually only decreases on scenarios H<sub>2</sub> and Mix 2. In all other scenarios, after establishing these new sectors, the monetary value of imports increases.

It can be seen that, if limited to fossil fuels, the values of the imports decrease in all scenarios, however there are increases in other sectors such as petrochemicals.

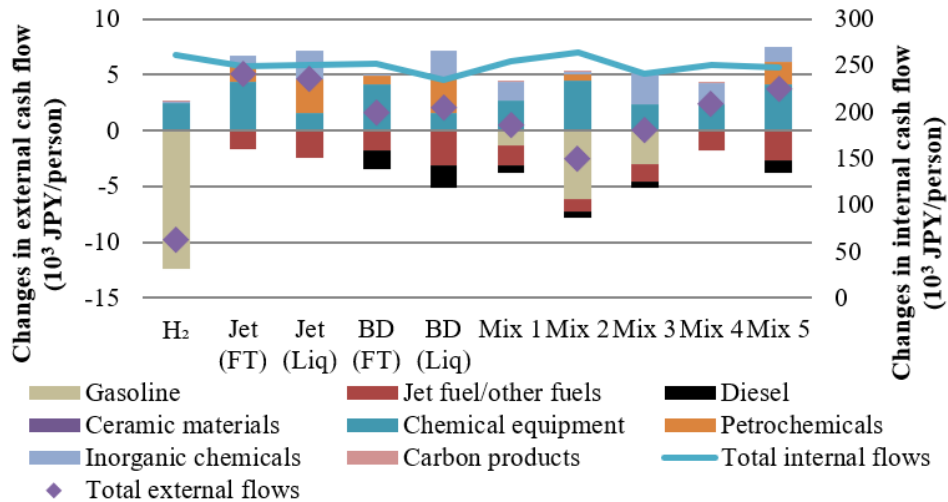

Figure 4: IOA results, where the bar and dots show the changes in external cash flows (left vertical axis) and the line shows those in internal cash flows (right axis).

One of the constants in all scenarios is the chemical equipment category. The capital costs for the plant, as would be expected, proved to be a significant factor in cash outflow. However, overall, the changes in internal flows were much larger, as the high added value of the fuels trickles down throughout many other sectors in the economy.

### 3.3. Interpretation of the multiple indexes for technology implementation

Using the results, three indexes were examined for interpretation: resource self-sufficiency (ratio of product demand fulfilled by the local biomass), GHG reduction potential and economic circularity improvement (increase in the ratio of internal monetary flows to total monetary flows).

Scenario H<sub>2</sub> was the optimal one in this study regarding resource self-sufficiency. This speaks to the efficiency of this conversion route itself and also to the lack of extra inputs required when compared to other scenarios. In fact, the Mix 4 scenario, in which mostly jet fuel is produced with the rest of the biomass generating hydrogen which fulfills the in-house demand for hydrogen in the hydrocracking process, performed better than the Jet (Liq) scenario, also due to the fact that demand for external auxiliary inputs was lower. As for the GHG reduction potential, the Jet (Liq) scenario stands out as the best performing one. This illustrates that, in addition to low GHG emission results from LCA, the process yield is also important as the amount of imported fuel substituted also plays a large role in the GHG emissions reduction. For circularity, scenarios with a reduction in export flows performed better but the difference between scenarios is not as large.

## 4. Conclusion

Production of multiple fuels in mixed scenarios was shown to be more efficient due to the synergy between the thermochemical conversion processes. In general, all cases, especially the ones more reliant on liquefaction, showed potential to cause significant reduction in the GHG emissions in the energy sector. Particularly, electricity was shown to be a significant factor in GHG emissions, thus integrating this sort of biomass valorization with other projects for a greener energy grid could also be beneficial.

# Conceptual Design of a Biorefinery to Use Brown Seaweed *Sargassum*

Omar Flores-Mendoza,<sup>a</sup> Teresa Lopez-Arenas<sup>a</sup>

<sup>a</sup>*Departamento de Procesos y Tecnología, Universidad Autónoma Metropolitana – Cuajimalpa, Vasco de Quiroga 4871, Mexico City 05348, Mexico*  
*mtlopez@cua.uam.mx*

## Abstract

The massive arrival of sargassum to the Caribbean beaches has generated a problem for its collection, treatment, disposal, and use. Therefore, the recovery of sargassum has become a topic of interest from the social, economic, and environmental point of view. The objective of this work is to propose a conceptual design of a sargassum biorefinery to produce three value-added products: alginate, a biopolymer and a biofertilizer. The methodology consisted mainly of the synthesis, design, and techno-economic evaluation of the biorefinery, using modeling and simulation tools. Comprehensive evaluation of the biorefinery design shows its feasibility (with moderate product yields) and profitability (with satisfactory return on investment and payback time) on an industrial scale.

**Keywords:** sargassum, biorefinery, circular economy, process simulation.

## 1. Introduction

Since 2011, the arrival of certain brown seaweed in the Caribbean, known as *Sargassum*, has been a problem not only for the tourism and fishing sectors, but also for the environment, given that the leachate produced by the seaweed saturates the habitat of nutrients and its presence in the sea prevents the photosynthesis of seagrasses. Moreover, the sargassum degradation by microorganisms in the open air generates greenhouse gases (GHG). Currently, the collected sargassum is stored in landfills and is used mainly as fertilizer. However, in some areas of the Caribbean, sargassum is also used to make bricks, cosmetics, and paper products; but they must be viewed with caution due to their ability to accumulate toxic metals. Thus, the implementation of the circular economy through sargassum biorefineries (Azcorra-May et al., 2022) can help cushion the secondary effects of its arrival, as well as obtain a benefit for society by transforming seaweed into useful bioproducts such as precursors for food, biofuels, enzymes, or biopolymers, generating a minimum of waste and emissions (Amador-Castro et al., 2021).

The species of *Sargassum natans* and *Sargassum fluitans* reproduce in the subtropical West Atlantic, which includes the Mexican Caribbean coasts, and in the North Equatorial Recirculation Region, which is located in the tropical area between Brazil and Africa (Wang, 2019). The main components of the cell wall of this brown seaweed are anionic polysaccharides, of which are alginates and sulfated polysaccharides that contain fucose; as well as cellulose, hemicellulose, lignin, arabinogalactan proteins and polyphenols (Kloareg, 2021). On the one hand, alginate is a compound widely used in various industries such as food (to maintain viscosity or retard crystallization), dental (as an impression material), paper (to provide smooth, continuous films with great ink and print

retention quality), and medical (for the creation of biomedical and clinical materials such as tissue engineering). While on the other hand, hemicellulose and cellulose are a source for the generation of sugars (pentoses and hexoses) that can be fermentable to produce biofuels, such as bioethanol, biogas, or biodiesel, as well as other bioproducts with high added value such as biopolymers, organic acids, amino acids, among others.

This work presents the design and evaluation of a sargassum biorefinery to produce alginate, PHB (polyhydroxybutyrate) and a biofertilizer, using process modeling and simulation tools. The case study considers the brown seaweed sargassum that arrives at one of the main beaches of the Riviera Maya, Mexico. First, a conceptual design of the biorefinery is proposed, then the process implementation and the technical evaluation are carried out in a modular process simulator, and then simulations are performed to determine the best process configuration, the equipment dimensions, the operating conditions, as well as the productivity and performance of the products. At this early stage of the process design, a non-cash flow economic evaluation is performed to determine the profitability of the process.

## 2. Simulation methodology

The methodology consisted mainly of the synthesis, design, and techno-economic evaluation of the biorefinery. To carry out the synthesis of the biorefinery, first a bibliographic review was carried out to determine the composition of the sargassum and the best processing alternatives, identifying the physical, chemical, and biological phenomena. So that the unitary operations, the reaction routes, physicochemical properties of the components, etc. were established. Subsequently, the design of the biorefinery was implemented in a process simulator, considering an industrial scale, and taking into account equipment sizing and design, operating conditions, production programming, cost information (raw materials, equipment, operation, investment), etc. And finally, the simulation of the process was carried out through material and energy balances to assess technical-economic aspects, such as: product yields, installed production capacity, utilities consumption and profitability.

### 2.1. Availability and composition of sargassum

Currently the sargassum is collected on the beaches, followed by a drying process for storage and use. In particular, the amount of sargassum on the beach of Tulum, in the Mexican Caribbean, in recent years has ranged between 4 500 and 9 000 tons per year. The changes in its composition of cellulose, calcium alginate, hemicellulose and lignin vary depending on the season in which the sargassum is harvested. For simulation purposes, an average of each of the compounds was obtained (Bertagnolli et al., 2014; Lopez et al., 2020), corresponding to a composition on a dry basis of: 23% calcium alginate, 11.15% cellulose, 9.6% lignin, 8.2% hemicellulose, and 48.05% other solids.

### 2.2. Selection and selling cost of products

Alginate has been selected as the main product due to its diversity of applications and its high selling cost, which was set in the simulation at 20 USD/kg (Galindo et al., 2007). The PHB was selected as the second product, since from the point of view of the circular economy, the reduction of plastic consumption and its replacement with biopolymers should be encouraged. The PHB income was established at 4 USD/kg (Lopez-Arenas et al., 2017). While organic solids, a by-product of the PHB fermentation process, can be recovered as a biofertilizer due to its nutrient content. The unit selling cost was set at 0.35 USD/kg (Praveen and Singh, 2019).

### 2.3. Synthesis and design of the biorefinery

As part of the synthesis of the conceptual design, five processing sections of the biorefinery were identified: raw material conditioning, alginate extraction, alginate purification, PHB production, and PHB and biofertilizer purification. The corresponding flowsheet diagram of the sargassum biorefinery is shown in Figure 1, and each section is briefly described below.

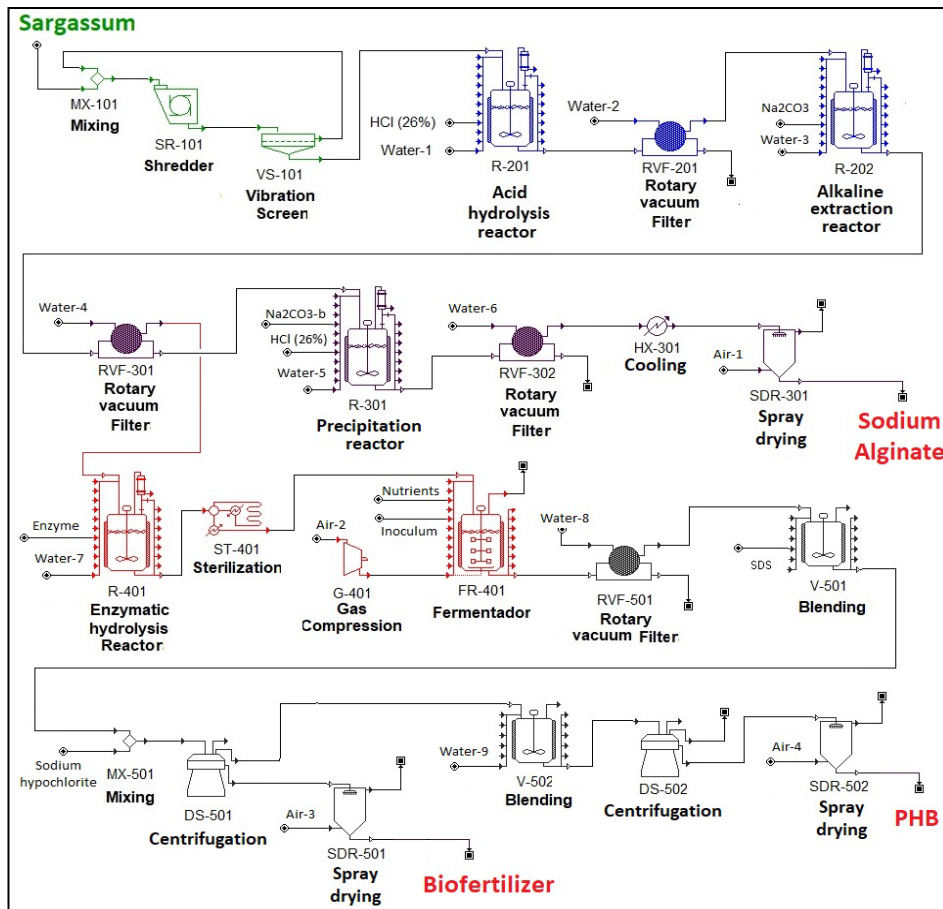

Figure 1. Process flowsheet diagram of the sargassum biorefinery.

#### 2.3.1. *Sargassum* conditioning

First, the size of the dried seaweed is reduced to increase the exposed area and therefore the mass transfer. This is done by shredding (SR-101) and subsequent screening (VS-101) to ensure maximum particle size.

#### 2.3.2. Alginate extraction

The crushed seaweed enters an acid hydrolysis reactor (R-201) to separate the cellulose and hemicellulose from the lignin, and to transform the calcium alginate into alginic acid. After removing the acidic liquid phase through a rotary filter (RVF-201), the alkaline extraction is carried out in the reactor R-202 with the addition of calcium carbonate, converting the alginic acid into sodium alginate. Subsequently, the liquid phase containing the soluble alginates is separated from the rest of the lignocellulosic biomass.

### 2.3.3. Alginate purification

The liquid phase rich in alginates is introduced into the reactor R-301, where hydrochloric acid and calcium carbonate are added to precipitate sodium alginate. Finally, the product is filtered (RVF-302) and dried (SDR-301).

### 2.3.4. PHB production

Lignocellulosic biomass is converted into glucose through an enzymatic hydrolysis reaction (R-401) using glucanases. Then, the hydrolyzed product is sterilized (ST-401) to avoid any contamination and production of unwanted compounds. The hydrolyzate passes to a fermenter (FR-401) for the intracellular production of PHB, using *Azohydromonas australica* as bacterial strain.

### 2.3.5. PHB and biofertilizer purification

Cell granules are recovered by filtration (RVF-501), and then PHB is extracted (V-501) by cell lysis by adding dodecyl sulfate surfactant. A sodium hypochlorite wash is then performed to achieve maximum cell disruption. Residual biomass and PHB are separated (DS-501). On the one hand, the residual biomass is dried for sale as a biofertilizer. And on the other hand, the stream with PHB is washed to remove the surfactant and sent for centrifugation (DS-502). Finally, the product is dried (SDR-502) to obtain the PHB in solid form.

## 2.4. Technoeconomic evaluation

Technoeconomic evaluation plays a crucial role in helping to select the best biorefinery conceptual design alternatives. From the technical point of view, product yields, processing times, installed capacity in terms of raw material and production rate are verified. In particular, the amount of required utilities is calculated, such as the consumption of heat transfer agents (cooling water and steam) and standard energy. While, to carry out the profitability analysis, an economic model without discounted cash flow was used to calculate the unit production cost, the rate of return on investment (ROI) and its payback time (PT). These cost effectiveness criteria provide a snapshot of the economics of the process and are often used to make preliminary estimates during the synthesis stage of process design. However, more rigorous profitability criteria could be used, in which cash flow is considered (such as the net present value method, NPV, or the internal rate of return, IRR) (Seider et al., 2009).

## 3. Simulation results

In this work, the biorefinery flowsheet diagram was implemented in *SuperPro Designer*, a commercial modular process simulator that allows the evaluation of material and energy balances, as well as the economic balance. This modular process simulator (like other commercial simulators such as *Aspen Plus*) includes databases of physicochemical properties of components, thermodynamic models, unit operations models, costs of raw materials and equipment, economic models, etc.

The biorefinery was simulated in batch mode and considering an annual operating time of 48 weeks. Each process equipment takes into account the times for material loading, process operation, material unloading and equipment cleaning, according to the case. The conceptual design proposal for the biorefinery considers a feed of 15 tons of sargassum per batch. Each process batch has a duration of 161.6 hours; however, each new production cycle can start after 37.3 hours of the previous cycle. Such that 212 batches are produced per year. A summary of the technical-economic evaluation is presented in Table 1.

Table 1. Technoeconomic report for the sargassum biorefinery.

<b>Technical assessment</b>			<b>Economical assessment</b>		
Concept	Value	Units	Concept	Value	Units
Sargassum consumption	3 180	t/yr	Direct fixed capital	32 822 000	USD
Sodium Alginate production	764.3	t/yr	Working capital	314 000	USD
PHB production	153.1	t/yr	Startup cost	1 641 000	USD
Biofertilizer production	0.472	t/yr	Total investment	34 777 000	USD
Sodium Alginate yield	0.2403	kg/kg S*	Operating cost	8 941 000	USD/yr
PHB yield	0.0485	kg/kg S*	ROI	19.98	%
Biofertilizer yield	0.0001	kg/kg S*	PT	5.0	yr
<b>Water and utilities consumption</b>					
Concept	Value	Units			
Process water	142.9	kg/kg SA*			
Steam	55.3	kg/kg SA*			
Cooling Water	5.5	t/kg SA*			
Standard Power	6.8	kW-h/kg SA			

\*S and SA to Sargassum and Sodium Alginate, respectively.

According to the technical results, it can be seen that the installed capacity of the plant in terms of annual sargassum consumption is within the availability of the Mexican beach of Tulum, as reported in the introduction section. The best product yield is obtained for sodium alginate, since it is the first product extracted; followed by the PHB yield, and finally, the yield of biofertilizer is quite low, which means that little residual biomass is recovered and its contribution to profitability is minimal.

Regarding the economic results, it can be observed that despite the estimated total investment being high, the biorefinery design shows positive and satisfactory profitability values for ROI and PT. According to Seider et al. (2009), an acceptable profit margin should be between 15-20% for ROI and 3 years for PT. It is worth mentioning that the operating cost considers various cost items, whose distribution is shown in Fig. 2(a). As can be seen, the utility cost is 15% of the annual operating cost, corresponding to the utility consumption reported in Table 1. The utility cost distribution is shown in Fig. 2(b), where the standard power (i.e., electricity) has the largest contribution. Therefore, alternatives to reduce energy consumption should be studied to reduce the cost and its environmental impact.

Figure 2. (a) Annual operating cost distribution and (b) utility cost distribution.

#### 4. Conclusions

The results showed that the implementation of a biorefinery from the perspective of the circular economy allows addressing the problem of sargassum, not only to mitigate the secondary effects of its arrival, but also that a benefit could be obtained by transforming this seaweed into useful bioproducts such as precursors for biomaterials and food, biopolymers, fuels, among others. In particular, the profitability of the proposed biorefinery is supported by the production of sodium alginate, which is a product with high added value and great potential for use in biomedical areas. Even though the conceptual design presented shows satisfactory profitability, several aspects can be improved and studied further, such as analyzing other process configurations, optimizing operating conditions, evaluating different installed capacities, and more.

# Design and Production of Biodiesel and Porous Filaments from Endemic Species of the Ciénega de Chapala Region

María Fernanda Torres-Magaña<sup>a</sup>, José Luis Baltazar-Álvarez<sup>a</sup>, Pascual Eduardo Murillo-Alvarado<sup>a</sup> and Gabriela Guadalupe Esquivel-Barajas<sup>a</sup>

<sup>a</sup>Universidad de La Ciénega del Estado de Michoacán de Ocampo. Av. Universidad Sur 3000, Lomas de Universidad, 59103 Sahuayo de Morelos, Michoacán México.

## Abstract

The production of biofuels has contributed to reducing the use of fossil fuels, however, in the means of obtaining biofuels, waste materials are generated, which must be given extra treatment for their storage. In such a way that the objective of the present investigation was to obtain biodiesel through the transesterification method, using the seeds of 3 plants (*Ricinus communis*, *Pithecellobium dulce* and *Prosopis laevigata*), which are endemic to the Ciénega Region of the State of Michoacán, Mexico. The generated residual biomass served as raw material for the synthesis of bioplastics. Both biodiesel and bioplastics were characterized by Fourier Transform Infrared Spectroscopy (FT-IR) and UV-VIS, thus it was possible to identify absorption bands, corresponding to the functional groups, which are similar to those of hydrocarbons. Thus, it is concluded that the remnants obtained during biodiesel production processes can be used for a second use as bioplastics.

**Keywords:** biodiesel, bioplastic, seeds.

## 1. Introduction

Due to anthropogenic actions, the planet has manifested various changes, due to the effect of greenhouse gases produced by the consumption of fossil fuels, which emit CO<sub>2</sub> and sulfur, for which reason it has ventured into the use of alternative fuels, such is the case of obtaining and applying biofuels.

Biofuels are fuels produced from raw materials of vegetable or animal origin. Another way of obtaining them is through the processing of agro-industrial products or organic waste. Arellano C. (2015), describes biofuels as an alternative of interest to reduce the accumulation of greenhouse gases and thus reduce dependence on the use of fossil fuels, in the same way in his manuscript he describes that when using biomass from In the food sector, an alternative is the production of lignocellulosic materials, since these do not compete directly with food intended for both human and animal consumption, which makes it possible to take advantage of biomass generated from agro-industrial processes.

Mentioned the above, the objective of the research has been based on the use of 3 endemic plants of the Ciénega region, which are: castor plant (*Ricinus communis*), mezquite (*Pithecellobium dulce*) and guamúchil (*Prosopis laevigata*), of which two processes are derive, the first is to obtain biodiesel from plants and the second is to take advantage of the lignocellulosic remnants so that they have become biofilms, which have properties similar to bioplastics.

## 2. Biopolymers

Biopolymers are macromolecular materials, which can be synthesized naturally or synthetically. The classification of biopolymers is based on three families, which are: proteins, polysaccharides and nucleic acids. Among the most abundant biopolymers are cellulose and starch, which are of interest for the present investigation.

### 2.1 Bioplastics

Bioplastics are materials that have an organic composition, the main polymers that characterize them being both starch and cellulose (Riera A., & Palma R., 2018). It is necessary to have chemical structures that allow the degradation of materials from native biota where they have been discarded (mainly they must be degraded by soil microorganisms).

### 2.2 Endemic plants and trees of the Ciénega de Michoacán Region

The use of the material that is used for the generation of a biofuel must be careful not to break the fine line of balance between the use of organic waste and the use of organic resources for human consumption (Merino P., & Nonay M., 2009) that is why for this project in the generation of two bioproducts. In biodiesel, the decision was made to use seeds of fruits that have been considered as plants of low nutritional value for humans such as Guamúchil and Mezquite which are characterized by be abundant trees in the Ciénega de Chapala region.

## 3. Methodology

For the development of the present investigation, it was divided into 5 stages which consist of: 1) sampling of endemic plant remnants, 2) extraction of essential oils and obtaining biodiesel, 4) characterization of oils and biodiesel 5) synthesis and characterization of thin films from residual biomass.

*Stage 1.* Identification of endemic plants. Castor weed plants were identified, in addition to mezquite and guamúchil trees, in the municipalities of Sahuayo-Jiquilpan, Michoacan, Mexico.

*Stage 2.* Castor berries were collected, in addition to sampling the remnants of guamúchil and mezquite berries, approximately 2 kg of each berry, which were stored in sterile plastic bags, later stored in a desiccator (Novatech), with the aim of facilitating the extraction of seeds.

*Stage 3.* Extractions of essential oils. For the development of this stage, an adaptation was made to the methodology proposed by Demirbas 2008, which consisted of: grinding the seeds and using the soxhlet method (KIMAX brand) in which 200ml of isopropyl alcohol (MEYER) were poured, subjecting at constant temperature and stirring at 200°C and 200 rpm. In order to extract the essential oil from the seeds, it was necessary to recirculate the alcohol in the extractor 15 times with a duration of approximately 45 minutes each. Upon completion of the 15 cycles, the sample was removed from the grill and placed in a desiccator for a period of 24 hours to remove as much water and alcohol as possible to subsequently obtain the pure essential oil from the seed. To obtain biodiesel, the essential oil was taken to the centrifuge (Hettich brand, EBA 20

model) for 30 minutes at 3,500 rpm and removing the degumming or residues to be able to be mixed with the 1% concentration of the potassium iodide solution (Reasol brand) with an addition of 3% (p/p) of distilled water and place on the grill to maintain agitation for 30 minutes at 60°C to finish it was placed in the centrifuge at 60 rpm for one hour.

*Stage 4.* Characterization of biodiesel. Biodiesel was characterized by Fourier transform infrared spectroscopy (FT-IR), Perkin Elmer Frontier model in the 4,500-400  $\text{cm}^{-1}$  region and by Perkin Elmer Lambda 25 model UV-VIS spectrophotometry, in the absorbance region of 300-800 nm.

*Stage 5.* Synthesis and characterization of biofilms. For the development of this stage, an adaptation was made to the methodology proposed by Salazar, 2013. To make use of the waste generated from obtaining biodiesel, a bioproduct has been generated that is formed from the remains of seeds that passed by the transesterification method with an adaptation to the methodology carried out by Salazar M., & Valderrama A. (2013) in which the previous conditioning was carried out in an extraction hood (Tecnolab brand) with a grill that preheats a Porcelain evaporation dish (Duve brand) at 75°C in which 30 ml of distilled water (Golden Bell) and 3 ml of natural glycerin are added, shake for 5 minutes; add 0.9 ml of a 1 molar solution of glacial acetic acid (Golden Bell brand) keep stirring for 10 minutes and then pour it into a glass petri dish to take it to the preheated desiccator at 75 °C for 8 hrs. And finally they were characterized by UV-VIS and FT-IR.

#### 4. Results and discussions

Seeds and berries were collected in the municipalities of Sahuayo and Jiquilpan Michoacan Mexico (Fig.1), later the essential oils were obtained from each of the samples, which were characterized by UV-VIS, to identify the band of greater absorption, which oscillated for the 3 samples in the interval of 700-800 nm (Fig. 2).

Fig.1. Seeds and berries of endemic plants of Sahuayo-Jiquilpan, Mich. a) *Prosopis laevigata*, b) *Ricinus communis* and c) *Pithecellobium dulce*.

Fig.2. UV-VIS characterization of endemic plants from Sahuayo-Jiquilpan, Mich. a) *Prosopis laevigata*, b) *Ricinus communis* and c) *Pithecellobium dulce*.

Biodiesel was synthesized through the transesterification method, which was characterized by FT-IR, with the aim of identifying its functional groups (Fig. 3). Where it can be seen that both in *Ricinus communis* and in *Pithecellobium dulce* there is a greater predominance by the OH group, since their absorption bands are greater compared to that of *Prosopis laevigata*.

Fig.3. FT-IR characterization of endemic plants from Sahuayo-Jiquilpan, Mich. a) *Prosopis laevigata*, b) *Ricinus communis* and c) *Pithecellobium dulce*.

However, during the synthesis of biodiesel, remnants are generated during its elaboration, in such a way that it was decided to give this residual material a conversion, for which bioplastics were synthesized from it (Fig. 4).

Fig. 4. Bioplastics obtained from biodiesel remnants. a) *Prosopis laevigata*, b) *Ricinus communis* and c) *Pithecellobium dulce*.

The bioplastics were characterized by FT-IR (Fig. 5), where it can be observed that there is a decrease, compared to the characterization of biodiesel, in the absorption bands belonging to the esters and amides groups.

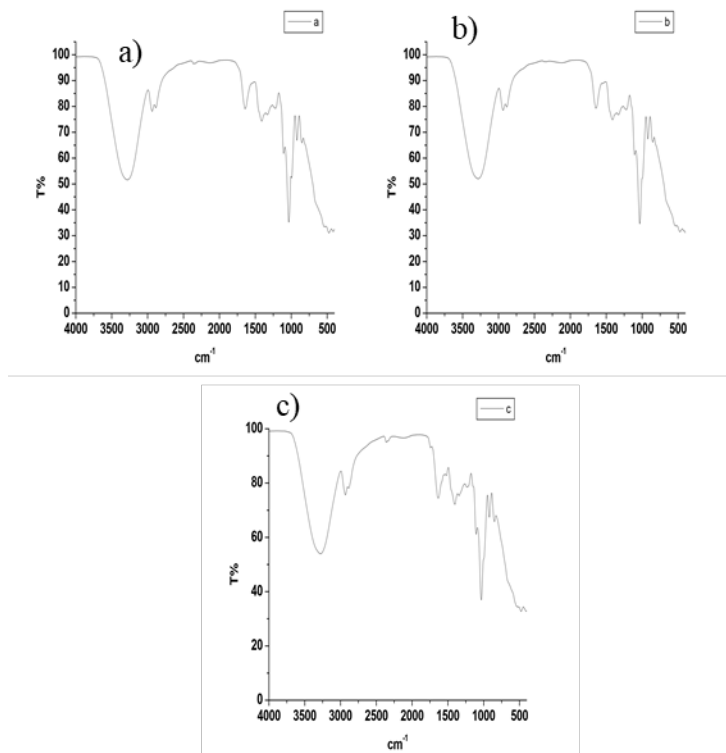

Fig. 5. FT-IR characterization of bioplastics, Mich. a) *Prosopis laevigata*, b) *Ricinus communis* and c) *Pithecellobium dulce*.

In the same way, a proposal was developed where this technology can be migrated on an industrial scale, for which the design at the industry level is proposed (Fig. 6).

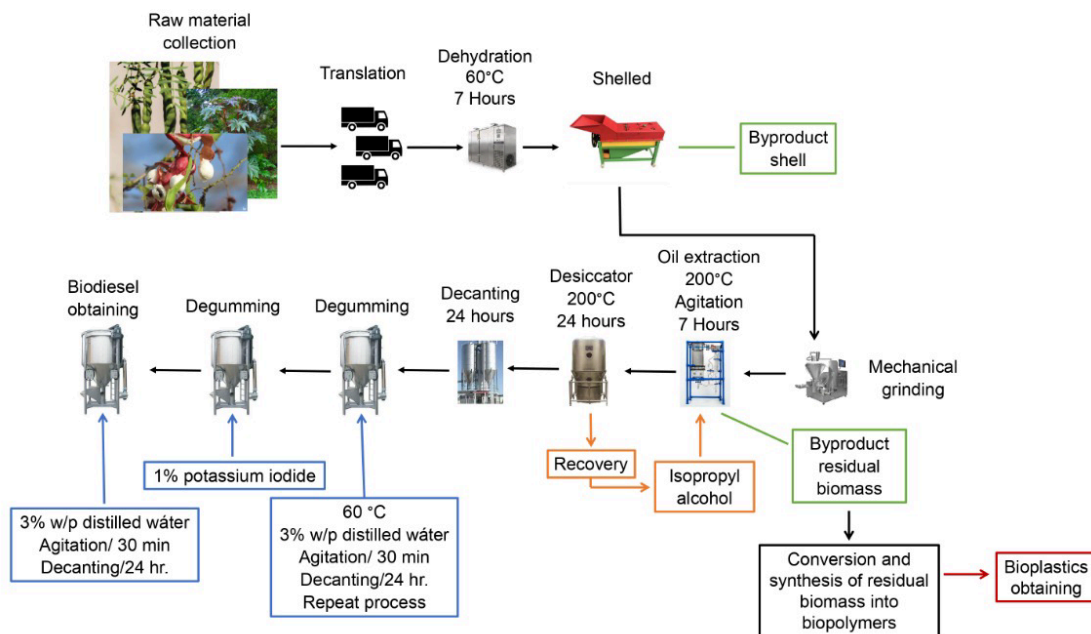

Fig. 6. Biodiesel and bioplastics industrial production scheme.

## 5. Conclusions

The transesterification method is suitable for obtaining biofuels, in particular it is the case of biodiesel. However, the synthesis process involves various reagents, which in turn produce materials of waste, for which it is considered viable to use them to obtain bioplastics, which can serve as environmentally friendly materials.

## Abstract

With government policy encouraging decarbonisation, the New Zealand food processing industry is rethinking its process operations and their improvement. This work focuses on identifying opportunities to decarbonise industrial sites using simultaneous multi-process control and scheduling optimisation methods. A common issue for multi-process sites is the disconnection between the unit operation level process controls that operate under closed loop regulatory, or advanced regulatory, principles and the scheduling layer that ideally operates under real-time optimisation principles. As the first step towards solving this issue, an illustrative case of a cream cheese production process consisting of a pasteurisation unit, two fermentation units and a separation unit are studied by constructing a plant wide scheduling model in Python, integrated with a fermentation model, to explicitly model the interactions between two layers. Compared to typical plant operation, controlling the dosing of substrate in the fermenter allows for more uniform fermenter end times leading to improved scheduling of successive batches which results in less discarding of batches due to poor quality. Future work will embed the trade-off between overall energy usage, product quality and product throughput constraints (supply chain) within a holistic objective function centred on carbon footprint.

**Keywords:** process control, fermentation modelling, real-time decision making

## 1. Introduction

Food and dairy production processes account for over 40% of New Zealand export revenue but represent a significant proportion of New Zealand's natural gas and coal consumption [1]. Like many other countries [2], the New Zealand government has implemented the Emission Trading Scheme to encourage the process industries to decarbonise while supporting them to maintain their competitive edge through co-investment in low-emission technology. From an engineering perspective, tackling the decarbonisation challenge requires a mix of capital investments into new technologies, e.g., integrating heat pump technologies in supplying process heat for milk spray dryers [3], and real-time control optimisation of industrial site operations.

Food production processes are often operated batch-wise where a given batch is fed through multiple unit operations over time. As such, the control of these food production

processes requires both process control (carried out at the unit operation level) and scheduling of unit operation utilisation throughout multiple batches. However, the simultaneous multi-process control and scheduling optimisation methods are not an established practice in the process systems engineering domain. At present, a hierarchical process control approach is taken where plant-wide scheduling and unit operation level control are executed at different layers, i.e., sequentially. In this approach, instructions are passed down the process control hierarchy from the plant-wide scheduling layer to advance process control layer and onwards to regulator controls. The idea being that the process control layer will focus on ensuring aspects such as product quality while the scheduling layer focuses on process optimisation [4].

However, food processing has large inherent production variations due to availability of the natural raw materials (e.g., milking seasons for dairy processes) and changes in consumer demands. As a result the schedules need to be constantly updated, for example, using short term and continuously updating schedules [5]. Another option of tackling these variations is to change set-points in the underlying supervisory and regulatory level control structure in “real-time”. This entails speeding up or slowing down the unit operations such that the overall production schedule is not influenced. In practice, a combination of both “real-time” control actions and timely re-scheduling will be needed to ensure a production process maintain quality, production targets while actively ensuring decarbonisation goals are met.

The aim of this study is to investigate the decarbonisation potential of simultaneous optimisation of process control and multi-plant scheduling actions in the food industry. Figure 1 expresses the current industry practice in contrast to the proposed approach.

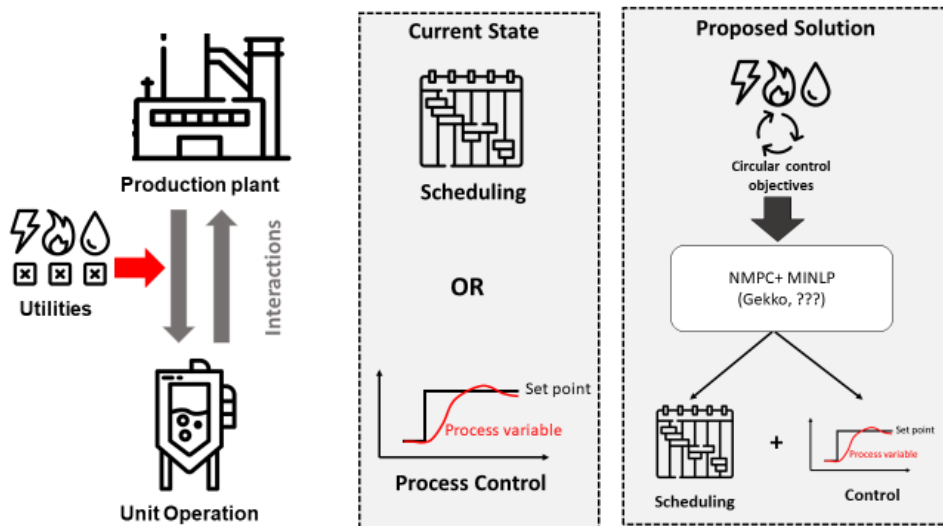

Figure 1: Visualisation of the challenge, current state and the proposed solution

Solvers such as active-set based APOPT have the potential to be a useful tool in bridging the gap between sequential and simultaneous methods for scheduling and control optimisation. For example, by translating advanced process control concepts such as model predictive control from differential algebraic equations to algebraic form allows

the simultaneous solution of the scheduling and the control problem as a mixed-integer non-linear optimisation problem [6]. As a realistic test case, this paper presents a fermentation-based process to illustrate the potential of simultaneous decision-making.

## **2. Model Development**

This section details the current state of the test case model of a simple cream cheese production process with a pasteurisation, fermentation and downstream processing unit operations. The test model is implemented in Python and solved using the GEKKO library with its APOPT solver.

### *2.1. Plant level model*

A sequential scheduling model is used to represent the dynamic dependency of unit operations at the plant level. The scheduling model consists of three-unit operations; pasteurisation, fermentation and separation. Two fermenters are used in parallel while only a single pasteuriser and separation unit are present. This resembles industrial plant design since the fermentation time is longer than the processing times of the other two units. The pasteurisation and separation processing times are assumed to be static while the fermentation processing time varies between batches. A fermentation model is used to determine fermentation time where model parameters are randomly varied to simulate variation within a real process. More detail on the model is provided in Section 3.2. The model also considers cleaning in place (CIP) procedures as well as transfers between unit operations. These procedures are also assumed to have static times.

The model is initially setup to replicate reality where the fermentation end time is not known at the beginning, which means successive operations can only be scheduled when the fermentation ends. This can then be compared with a scenario where the fermentation is perfectly controlled to finish within a target time, and the next batch can begin preparation in advance allowing for maximum production. The time series data was stored in data frames from the Pandas package which is then visualised in a Gantt chart using the Plotly package in Python.

### *2.2. Fermentation model*

The mechanistic fermentation model reported in [7] is used as the basis of modelling the fermentation process. The model tracks substrate (lactose), biomass (*Lactococcus lactis*) and product (lactic acid) evolution over time. The model utilises a Monod type biomass growth kinetics with substrate and product inhibition thus production rates are dependent on substrate concentration and availability. To represent inherent variabilities that are present in fermentation processes, the model parameters are randomly sampled from a uniform distribution within the reported upper and lower parameter bounds in [7]. The initial concentration of substrate, product and biomass were assumed constant throughout batches to represent feedstock standardisation. To this end, all variation in fermentation concentration profiles between batches is due to random variations in model parameters.

The fermentation model is implemented into Python as a series of ordinary differential equations (ODE) representing time dependent evolution of substrate (S), biomass (B) and product (P). In the case of no fermentation control the model is solved simultaneously with the Scipy numerical integration package across a series of discretised time points. Integration is performed until the product concentration reaches 5 g/L which represents experimental observations in [7] that ensures the target product quality is achieved.

To allow for fermentation end time control the model must be formulated as a dynamic non-linear programming (NLP) that is solved in Python GEKKO using the IPOPT solver [6]. The time dependent concentration growth rates of the species are governed by Equations 1-3 where the substrate dosing flowrate,  $m_s$ , has been included in Equation 2 as a manipulated variable. However, the flowrate must be divided by the fermenter volume to convert mass flow to change in concentration per unit time. A terminal constraint is applied in Equation 4 which enforces that the product concentration at the target final time,  $t_f$ , is equal to the target concentration,  $P_{target}$ . The model is solved across a consecutive series of time points ranging from 0 to  $t_f$ . Lastly the objective function is applied to maximize the final product concentration pursuant to the terminal constraint.

$$\frac{dX}{dt} = \mu_{max} \left( \frac{S}{K_{sx} + S} \right) \left( 1 - \frac{P - P_{ix}}{P_{mx} - P_{ix}} \right) \left( \frac{K_{ix}}{K_{ix} + S} \right) X \quad 1$$

$$\frac{dS}{dt} = -q_{s,max} \left( \frac{S}{K_{ss} + S} \right) \left( 1 - \frac{P - P_{is}}{P_{ms} - P_{is}} \right) \left( \frac{K_{is}}{K_{is} + S} \right) + \frac{m_s}{V} \quad 2$$

$$\frac{dP}{dt} = \alpha \frac{dX}{dt} + q_{p,max} \left( \frac{S}{K_{sp} + S} \right) \left( 1 - \frac{P - P_{ip}}{P_{mp} - P_{ip}} \right) \left( \frac{K_{ip}}{K_{ip} + S} \right) \quad 3$$

$$P \times t_{final} - P_{target} = 0 \quad 4$$

$$t = [0, t_{final}] \quad 5$$

$$\max\{P \times t_{final}\} \quad 6$$

### 2.3. Model integration and decarbonisation

The scheduling and fermentation model are integrated such that simultaneous decisions can be performed between changing manipulated variables in the fermentation process, and schedule changes at the plant wide level. More specifically, the fermentation end time applied to the scheduling model is dynamically updated from the fermentation model which is influenced by control actions. Regarding decarbonisation, the combined modelling of the schedule and fermentation enables the calculation of energy intensive actions such as CIP and material flows in unit operations. In future work, further investigation of explicit minimization of CO<sub>2</sub>-e will be investigated. Explicitly considering decarbonisation allows identification of effective actions both in the scheduling layer and unit operation layer (e.g., mitigating scheduling actions that may require batch disposal or situations where CIP must be redone).

## 3. Model output

Figure 2 illustrates the process schedule for the two use cases and Figure 3 shows the concentrations of species within each fermenter batch. In both use cases 10 fermentation batches are processed. Figure 2a illustrates the progression of production batches through the cream cheese production process with no fermentation control and Figure 3a shows the corresponding fermentation concentrations.

Each batch is first heat treated in the pasteuriser prior to transfer to one of the two fermenters, then the batch is sent for separation. The inherent variations in the fermentation time clearly influence the schedule as the next batch cannot be pasteurised until a fermenter is available, nor separated until the separator is available. For example, in batch number 3 (second batch on fermenter 1), the fermentation process has finished

early but cannot be transferred out for another two hours until the separator is available. This can result in product quality degradation leading to batch disposal. In contrast, Figure 2b shows the production schedule where the fermentation end time is perfectly controlled by substrate dosing to finish (i.e. reach the target lactic acid concentration) at 6 hours. The concentration profile in each batch is shown in Figure 3b where the substrate concentration changes considerably between batches due to control induced dosing.

Figure 2: a) Current schedule of cream cheese process where fermentation end times are not controlled b) Improved schedule where the fermentation is controlled to finish at a specified end time.

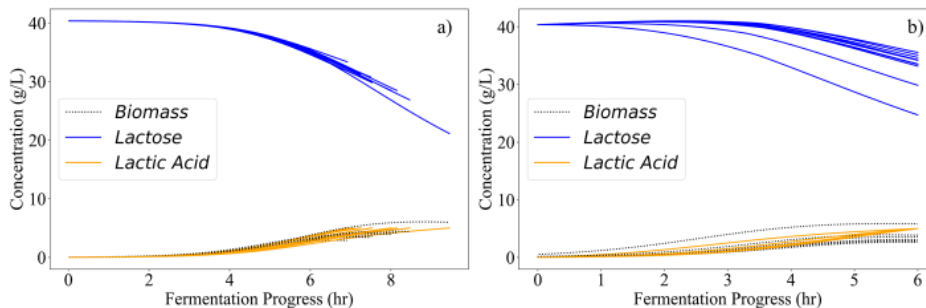

Figure 3: a) Concentration profiles in a cream cheese fermenter with random variation and no control b) Concentration profiles in a fermenter with random variation but controlled to achieve the target lactic acid concentration at 6 hours.

Fermentation control leads to improved scheduling since fermentation end times are known so successive batches can be scheduled so that fermentation ends as soon as a separator is available. As such, batches can immediately be transferred for separation resulting in no potential loss of product. It should be noted that in the improved case, the fermentation operation is changed from a batch to fed-batch.

Despite likely improvements in the form of reductions in batch disposal, the optimized schedule finishes the 10 batches the same time as the un-optimized schedule due to the separator unit availability. However, tightly controlling the fermentation end time means extra substrate dosing is needed. From a decarbonisation perspective, this optimisation

does not consider the carbon trade-off from substrate dosing (which increases the CO<sub>2</sub>-e of a given batch) that may be needed to save the batch, and the cost of losing the batch which has implications on successive batch scheduling. As an immediate future step, the simultaneous optimization of batch scheduling and fermentation substrate dosing must be considered. For example, re-looking at batch number 3 in Figure 2a (un-optimized case), a fed-batch fermentation could reduce the initial dosage of substrate thereby reducing the biomass growth rate and lactic acid production rate. As such, the end time of the fermentation will be prolonged which reduces the waiting time for separation without product degradation. In this example, the reduced substrate dosing will not only improve the overall CO<sub>2</sub>-e of the specific batch, but also reduce the overall CO<sub>2</sub>-e of a unit of finished product.

#### 4. Conclusions and Future work

This work presented a cream cheese fermentation process where a plant wide scheduling model was integrated with a fermentation model to illustrate the propagation of variations in fermentation times at unit operation level and scheduling level. This work is the first step towards solving the key issue involving the disconnection between the operation level process controls to maintain product quality and the scheduling layer that attempts to maximise product throughput. It was seen that unit operation level decisions such as dynamic dosing of substrate can reduce the variation experienced at the scheduling layer thereby allowing for improved scheduling of successive operations. In future work, the test case will be used to develop a simultaneous multi-process control and scheduling optimisation methods that explicitly consider the CO<sub>2</sub>-e trade-off for all decisions.

## Abstract

With growing levels of  $\text{CO}_2$  emission and severity of global warming, interest in carbon capture and utilization (CCU) has increased. However, the amount of  $\text{CO}_2$  reduction that can be realized is lower than that of  $\text{CO}_2$  emissions, and most of the existing CCU technologies cannot be commercialized owing to their limited economic feasibility. Therefore, it is necessary to identify new chemicals as CCU products. When  $\text{CaO}$  is added to a formate aqueous solution, it reacts with the formate to produce calcium formate ( $\text{Ca}(\text{HCO}_2)_2$ ). In this study,  $\text{Ca}(\text{HCO}_2)_2$  was synthesized using dolomite and  $\text{CaO}$  ash, an industrial waste. Process design and evaluation were performed based on the experimental data. When  $\text{CaO}$  ash and dolomite were used as the raw material, the production costs were 16% lower and 8% higher than those of the conventional process, respectively. Moreover, for both materials, the  $\text{CO}_2$  emissions were 20% lower than those of the conventional processes.

**Keywords:**  $\text{CO}_2$  hydrogenation, Calcium formate, Carbon capture and utilization

## 1. Introduction

Carbon capture and utilization (CCU) technologies, which convert  $\text{CO}_2$  to value-added chemicals, have emerged as promising solutions to address the growing severity of global warming related issues (Aresta and Dibenedetto 2007; Peters et al. 2011). However, most of the existing CCU processes have not been commercialized because of their low economic feasibility compared with the conventional process (Chauvy et al. 2019; Lindsey and Jeskey 1957). Furthermore, the amount of  $\text{CO}_2$  that can be eliminated through CCU is lower than that of the  $\text{CO}_2$  emissions. Therefore, novel CCU chemical products must be identified (Rafiee et al. 2018).

Recently, Park et al. (2020) developed a method for producing formic acid by hydrogenating  $\text{CO}_2$  through a heterogeneous Ru catalyst and an aqueous amine solution. This method can overcome the disadvantage of heterogeneous catalysts, i.e., a low conversion rate. However, the process involves multiple distillation processes in separation (Figure 1(a)).

Calcium formate,  $\text{Ca}(\text{HCO}_2)_2$ , is used in various applications such as animal feed, cement production, and leather tanning as an additive (EFSA 2015).  $\text{Ca}(\text{HCO}_2)_2$  is typically produced by the carbonylation of calcium hydroxide with carbon monoxide (Ma et al.

2016). Recently, Yoon et al. (2022) reported the production of  $\text{Ca}(\text{HCO}_2)_2$  using  $\text{CaO}$  ash (waste from a desulfurization process) and  $\text{CO}_2$  through hydrogenation. This method can instantaneously convert  $\text{CaO}$  ash, an industrial waste, to  $\text{Ca}(\text{HCO}_2)_2$  and separate products through simple evaporation in mild conditions. Moreover, the main raw material,  $\text{CaO}$ , is readily produced through the calcination of dolomite, an abundant natural resource.

In this study,  $\text{Ca}(\text{HCO}_2)_2$  was synthesized through  $\text{CO}_2$  hydrogenation, with process design performed based on experimental data (Figure 1(b)). The feasibility of the process was confirmed through a techno-economic analysis (TEA) and lifecycle assessment (LCA), in comparison with the conventional process (Ma et al. 2016).

Figure 1 Schematic of (a) existing and (b) proposed (Yoon et al. 2022) processes for  $\text{HCO}_2\text{H}$  and  $\text{Ca}(\text{HCO}_2)_2$  production

## 2. Experimental

### 2.1. Hydrogenation of $\text{CO}_2$ to $[\text{Et}_3\text{NH}][\text{HCO}_2]$

$\text{CO}_2$  hydrogenation was performed in a stainless-steel tubular reactor packed with 1.5 g of Ru/bpyTN-30-CTF catalyst. The reactor was pressurized to 120 bar and heated to 120 °C before the reaction.  $\text{H}_2\text{O}$  and  $\text{Et}_3\text{N}$  were supplied to the reactor, and an  $\text{Et}_3\text{N}$  concentration of 3 M was maintained using a high-pressure liquid pump. The liquid product was analyzed to determine the formate concentration. The results indicated that the solution contained 2.03 M  $[\text{Et}_3\text{NH}][\text{HCO}_2]$  and 0.73 M  $[\text{Et}_3\text{NH}][\text{HCO}_3]$  (Equation (1)). The solution was heated at 90 °C and ambient pressure for 2 h to remove  $\text{CO}_2$  that remained as the  $\text{HCO}_3$  adduct and could react with  $\text{CaO}$  to produce  $\text{CaCO}_3$ .

## 2.2. Synthesis of $\text{Ca}(\text{HCO}_2)_2$ using CaO ash

Flue gas desulfurization ash (CaO/CaSO<sub>4</sub> ash) can be generated as a product of the desulfurization process using CaO. Because the solubility of CaSO<sub>4</sub> (0.2 g per 100 mL H<sub>2</sub>O at 20 °C) is considerably lower than that of Ca(HCO<sub>2</sub>)<sub>2</sub> (16.6 g per 100 mL H<sub>2</sub>O at 20 °C), CaO and CaSO<sub>4</sub> are expected to be separated in a facile manner. When CaO/CaSO<sub>4</sub> ash was added to the [Et<sub>3</sub>NH][HCO<sub>2</sub>] solution at 90 °C for 5 min, a clear solution with a white precipitate, CaSO<sub>4</sub> (Equation (2)), was obtained. CaSO<sub>4</sub> and Ca(HCO<sub>2</sub>)<sub>2</sub> were separated from the solution through filtration and evaporation, respectively.

## 2.3. Synthesis of $\text{Ca}(\text{HCO}_2)_2$ using dolomite

First, dolomite was calcined in a furnace at 950 °C and ambient pressure for decomposition to CaMgO<sub>2</sub> (Equation (3)). Results of an X-ray diffraction analysis indicated that all of the dolomite was completely decomposed to CaO and MgO. Allen et al (2009) highlighted that reaction kinetics between Ca and Mg ions are considerably different. Therefore, when calcined dolomite was added to the [Et<sub>3</sub>NH][HCO<sub>2</sub>] solution at 90 °C, and a reaction was allowed to occur for 5 min, only CaO was expected to react with formate and produce Ca(HCO<sub>2</sub>)<sub>2</sub> while MgO remained as the oxide (Equation (4)). Because MgO is sparingly soluble in water, it remained as a precipitate in the solution, which could be filtered to yield a high purity product. This filtrate could be separated into Ca(HCO<sub>2</sub>)<sub>2</sub> and solvents by simple evaporation, as described in Section 2.2.

# 3. Process design and analysis

## 3.1. Process design

Based on the experimental results, two Ca(HCO<sub>2</sub>)<sub>2</sub> processes were designed using CaO ash and dolomite. Figure 2 illustrates the process flow. Gaseous CO<sub>2</sub> and H<sub>2</sub> were compressed and heated to 120 °C at 120 bar before being supplied to the hydrogenation reactor. The unreacted gases were separated through degassing and recycled. The degassed solution was introduced to the reactor with a CaO mixture, thereby synthesizing Ca(HCO<sub>2</sub>)<sub>2</sub>. Because the reaction kinetics and solubility of CaO and MgO were considerably different, only CaO transformed to Ca(HCO<sub>2</sub>)<sub>2</sub>, and MgO remained as solid in the solution. The solid component, as a byproduct with high purity, was separated by filtering. The remaining solution was separated into the solvent and Ca(HCO<sub>2</sub>)<sub>2</sub> through evaporation.

## 3.2. TEA

The economic feasibility of the process was evaluated in terms of the production cost. Table 1 lists the prices of the raw materials and utilities, and Table 2 summarizes the results of the economic analysis. When dolomite and CaO ash were used as the raw materials, the production cost was approximately 8% higher and 16% lower than that of the conventional process, respectively. Figure 3(a) shows the breakdown of the production cost for each process component: raw material, utility, pretreating and reaction, and separation. The cost components are defined in the following text.

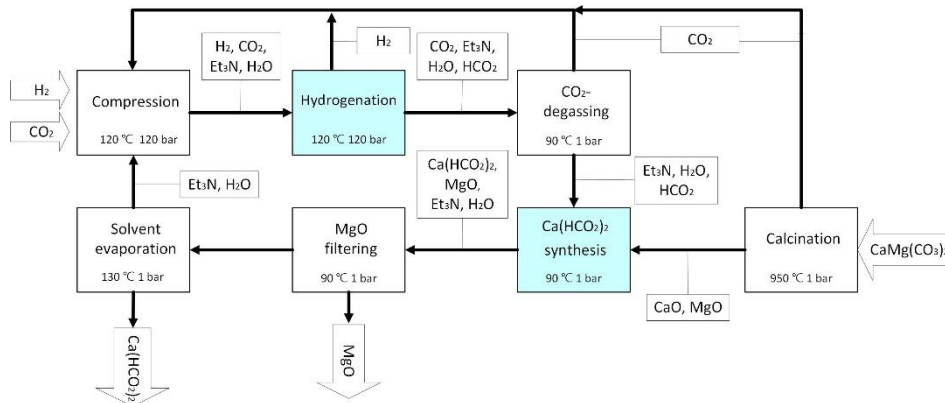

Figure 2 Block flow diagram of  $\text{Ca}(\text{HCO}_2)_2$  production using dolomite.

- Raw material: Summation of all costs associated with the raw materials.
- Utility costs: Summation of all costs for utilities.
- Pretreating and reaction: Summation of capital expenditures (CAPEX) and fixed operational expenditure (fixed OPEX) for the pretreatment of material (e.g., compression and heating) and reaction.
- Separation: Summation of CAPEX and fixed OPEX for separation equipment/processes such as a column.

The ratio of utility costs was higher than that of the raw material costs, which indicated that  $\text{Ca}(\text{HCO}_2)_2$  production is energy-intensive. The high energy consumption is attributable to the evaporation of water (Yoon et al. 2022).

Table 1 Material and utility costs for the economic analysis

Component	Price (unit)	Reference
$\text{CO}_2$	35 (USD/tonne)	(Kim et al. 2011)
$\text{H}_2$	1630 (USD/tonne)	(Lee et al. 2018)
LP steam	13.28 (USD/GJ)	(Turton and Bailie 2012)
Electricity	0.066 (USD/kWh)	(Turton and Bailie 2012)
Cooling water	0.354 (USD/GJ)	(Turton and Bailie 2012)
Natural gas	11.34 (USD/GJ)	(Turton and Bailie 2012)

### 3.3. LCA

LCA was performed to evaluate the  $\text{CO}_2$  emissions resulting from the processes. The Intergovernmental Panel on Climate Change 2013 GWP 100a method was applied for the analysis. Data from Ecoinvent 3.8 database and the literature were used to calculate the influence of the product and  $\text{CO}_2$  emission factors (Lee et al. 2018; Wernet et al. 2016). The functional unit of analysis was 1 kg of  $\text{Ca}(\text{HCO}_2)_2$ . Because the processes associated with CCU are multi-functional and yield more than one product, the  $\text{CO}_2$  emission of the byproduct was excluded from the total  $\text{CO}_2$  emission. Table 2 summarizes the LCA results. The  $\text{CO}_2$  emissions associated with both the proposed processes were 20% lower than those of the conventional process. Figure 3(b) shows the breakdown of the cost and  $\text{CO}_2$  emissions. Similar to the cost, the  $\text{CO}_2$  emissions corresponded to the following four components:

- Raw material: Summation of  $\text{CO}_2$  emissions from raw materials.
- Utility: Summation of  $\text{CO}_2$  emissions for utilities consumed in the process.

- Purge: Summation of  $\text{CO}_2$  emission from the purge gas.
- Byproduct: Summation of  $\text{CO}_2$  emissions from the byproducts, excluded from the total  $\text{CO}_2$  emission.

For all processes, the contribution of the utility to the total  $\text{CO}_2$  emission was the most notable (~50% of the total value), and it accounted for more than 80% of the total  $\text{CO}_2$  emissions in the CCU processes.

Table 2 Results of economic and lifecycle analysis of each process.

	Conventional	Proposed (dolomite)	Proposed (CaO ash)
Production cost (USD/tonne)	678	729	567
$\text{CO}_2$ emission ( $\text{kgCO}_{2\text{eq}}/\text{kgCa}(\text{HCO}_2)_2$ )	3.97	3.18	3.19

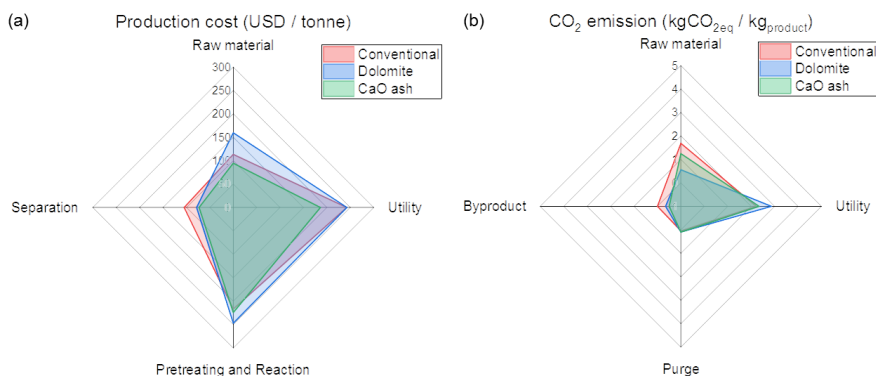

Figure 3 Breakdown of (a) production cost and (b)  $\text{CO}_2$  emission for  $\text{Ca}(\text{HCO}_2)_2$  production.

#### 4. Conclusions

This paper proposes two processes for  $\text{Ca}(\text{HCO}_2)_2$  production based on CCU, using CaO and formate adduct. The novel processes were compared with the conventional process. The proposed processes could selectively produce  $\text{Ca}(\text{HCO}_2)_2$  and byproducts with high purity while utilizing  $\text{CO}_2$  as a value-added chemical. Although the production cost of the CCU process using dolomite was 8% higher than that of the conventional process, it emitted 20% lower  $\text{CO}_2$ , demonstrating environmental feasibility. When CaO ash was used as the CaO source, the economic and environmental feasibility were comparable to those of the conventional approach. The results highlight the potential of  $\text{Ca}(\text{HCO}_2)_2$  production based on CCU method as a replacement for conventional processes. The energy consumption can be reduced to enhance the economic feasibility of the CCU-based processes.

## Abstract

Chemical recycling has increasingly gained attention in order to counteract environmental pollution and support the transition to a circular economy. Today, only around two percent of polyamides are chemically recycled each year. This is mainly due to the economic performance of the process. The conventional depolymerisation process of polyamide 6 using phosphoric acid was simulated to analyse the techno-economic potential and identify its existing constraints. A conceptual process design was carried out using Aspen Plus and Python. The results show that the process becomes profitable at 4600 t/year of caprolactam. Assuming a reasonable plant capacity of 12.6 kt/year, the payback time would be between three and seven years in the best- and worst-case scenarios. The disposal of the waste stream containing unreacted polyamide 6, oligomers and phosphoric acid, as well as phosphoric acid raw material costs together contribute 47% of the total production cost. Accordingly, a sensitivity analysis showed that the total annualised costs depend significantly on the amount of phosphoric acid raw material used. Overall, the results indicate great industrial potential for the depolymerisation of polyamide 6. Still, the focus of further research on this conventional process should rely on phosphoric acid and its efficient recovery along with the treatment of the waste stream.

**Keywords:** chemical recycling, circular economy, Nylon 6, process simulation, techno-economic analysis.

## 1. Introduction

The massive production of plastics caused undeniable issues such as environmental pollution and depletion of petroleum-based resources. To meet the recycling target of 50% set by the European Commission for 2025, chemical recycling has increasingly gained attention (Pohjakallio et al., 2020). As opposed to the most popular mechanical recycling strategy, chemical recycling avoids quality loss of the polymer (also called downcycling), thereby acting in favour of a circular economy with multiple polymerisation–depolymerisation cycles. Chemical recycling involves breaking down the polymer chain into monomers through a high-temperature and solvolytic environment (Coates and Getzler, 2020).

According to a recent review, polyamide 6 (PA6), also known as Nylon 6, is an ideal candidate for chemical recycling as it is not thermodynamically and kinetically limited (Coates and Getzler, 2020). Despite having been investigated since the early

1960s, still today, only a minor fraction of the annual PA6 production is recycled each year (Coates and Getzler, 2020). Reportedly, the reasons for this are the low profitability and economic competitiveness of depolymerisation processes (Kamimura et al., 2014). Several companies have been employing the chemical recycling of PA6. The acid-catalysed hydrolysis of PA6 to its respective monomer caprolactam (CL) using phosphoric acid ( $\text{H}_3\text{PO}_4$ ) and steam can be considered as a conventional process which is covered by several patents, e.g. of BASF (Corbin et al., 1999). Furthermore, acid-catalysed hydrolysis of polyamides has been investigated experimentally (Chen et al., 2010). However, the cost contributions, bottlenecks, most sensitive parameters, and the reason for lacking economic performance of the process have not been identified yet. In order to improve the understanding and find possible opportunities for optimisation of the process, the chemical recycling process of PA6 using  $\text{H}_3\text{PO}_4$  was simulated, and a techno-economic analysis was performed, both of which have never been published in the literature. Subsequent to the next chapter giving the background information and methods, in the results section, the scale for profitability, the payback period, as well as the leading fixed and variable cost contributions are estimated. Additionally, the effect of the most influential parameters is studied within a sensitivity analysis and case study.

## 2. Background and Methodology

In the following, the continuous conventional process described by BASF will be referred to as the “representative process” (Corbin et al., 1999). This representative process was simulated and analysed with a model connecting Aspen Plus and Python. To study it in the most realistic manner, the changes to this process were kept at a minimum.

### 2.1. Polyamides and Depolymerisation Background Knowledge

PA6 is most commonly synthesised through hydrolytic ring-opening polymerization, involving reversible reactions, e.g. the hydrolysis of CL to aminocaproic acid (ACA) and polycondensation and addition reactions (Penczek et al., 1985). However, due to dipole-dipole and hydrogen bonding interactions of the amide groups, required depolymerisation temperatures are really high. The ceiling temperature of 277 °C can be lowered by adding a solvent such as  $\text{H}_3\text{PO}_4$  in the conventional process (Coates and Getzler, 2020).

### 2.2. Thermodynamics and Kinetics

Vapour-liquid equilibrium (VLE) data of water and CL are retrieved from the NIST database by AspenPlus, and the NRTL model was used to describe the VLE behaviour.  $\text{H}_3\text{PO}_4$  and PA6 were assumed to be non-volatile.

Owing to the excess of water and catalyst, the literature approximates the hydrolytic depolymerisation of PA6 to CL by a pseudo-first-order reaction in PA6 (Chen et al., 2010). This is displayed in Eq. 1, where  $[\text{PA6}]$ ,  $k'$  and  $X$  are the PA6 concentration, the rate constant and conversion, respectively.

$$-\frac{d[\text{PA6}]}{dt} = k' \cdot [\text{PA6}] \Leftrightarrow dt = \frac{dx}{k' \cdot (1-X)} \quad \text{with } [\text{PA6}] = [\text{PA6}]_0 \cdot (1-X) \quad (1)$$

The reaction kinetics for chemical recycling using  $\text{H}_3\text{PO}_4$  are not available. Therefore, the required kinetic parameter is derived from Eq. 1 using the batch data point with the final time and conversion given by the representative process (Eq. 2).

$$k' = \frac{1}{t_f} \cdot \ln\left(\frac{1}{1-X_f}\right) \quad (2)$$

### 2.3. Data Base for Component Input Into Aspen Plus

A database needed to be established for the component input of PA6. Scalar properties, such as heat of formation and degree of polymerisation, as well as temperature-dependent

properties, such as solid and liquid heat capacity values, were taken from the Polymer Handbook, and parameters were regressed when necessary (Brandrup et al., 2003). As reaction enthalpy, the negative of the standard polymerisation enthalpy (-12.5 kJ/mol) was assumed (Brandrup et al., 2003).

#### 2.4. Process and Equipment Design

The process is designed to be as similar as possible to the representative process. The rate-based continuous stirred tank reactor (CSTR) model was chosen because of the liquid-phase reaction and slow reaction kinetics. The type of pumps, heat exchangers, vacuum equipment, columns or vessels was determined by heuristics. For the economic evaluation, equipment dimensions such as the vessel height, diameter, wall thickness or weight need to be known. The equipment design was done by a combination of empirical equations, e.g. the determination of heat exchanger areas or column diameters, and heuristics such as tray sizing or the choice of the heat exchanger tube length (Seider et al., 2009).

#### 2.5. Utilities

Cooling water (CW), low-pressure steam (LP), medium-pressure steam (MP), high-pressure steam (HP) and No. 2 fuel oil (OIL) were chosen as utilities. The temperature (T), enthalpy of evaporation ( $h_e$ ), or higher heating value (HHV) of those are displayed in Table 1.

Table 1: Details of the chosen utilities.

CW	LP	MP	HP	OIL
$T_{in} : 30^{\circ}\text{C}$	$T : 139.9^{\circ}\text{C}$	$T : 186^{\circ}\text{C}$	$T : 250^{\circ}\text{C}$	HHV :
$T_{out} : 45^{\circ}\text{C}$	$h_e : 2144 \text{ kJ/kg}$	$h_e : 1991 \text{ kJ/kg}$	$h_e : 1715.2 \text{ kJ/kg}$	43046.4 kJ/kg

Near-optimal approach temperatures were defined according to temperature levels, e.g. 5 °C for ambient temperature levels. The pipeline and valve pressure drop was neglected, and the heat exchanger pressure drop was set dependent on the phase of the stream.

#### 2.6. Economics

The capital investment expenditures (CAPEX), total operational expenditures (OPEX) and cash flow were calculated in U.S. dollars. The CAPEX was computed using the Lang factor method with an accuracy of 35%. The Lang factor  $F_L$  is multiplied by the sum of the free onboard (f.o.b.) equipment purchase costs  $C_{pi}$  and accounts for all other direct and indirect investment costs (Eq. 3).

$$\text{CAPEX} = 1.05 \cdot F_L \cdot \sum_i \frac{I_i}{I_{bi}} \cdot C_{pi} \quad (3)$$

The purchase costs were calculated using regressed correlations as a function of equipment size factors and updated to the current year by applying the chemical engineering plant cost index I (Seider et al., 2009).

The OPEX comprise variable costs, manufacturing costs, and general and administrative (G&A) costs. The variable costs, such as raw materials, utility and waste treatment costs, were determined using current industrial market prices and a plant operating factor of 0.9 was assumed. Direct wages and benefits were calculated by accounting for the typical labour requirements dependent on the type of equipment and assuming five shifts (J. Harmsen et al., 2018). The other manufacturing costs, such as maintenance, overall plant overhead and fixed costs, as well as the G&A costs, are typical fractions of the labour costs, capital investment expenses or sales (Seider et al., 2009).

For the cash flow analysis, net earnings have been calculated with the sales (S) and the income tax rate according to the U.S. federal income tax rate schedule for corporations. Subsequently, the annual cash flow was calculated by incorporating the depreciation (D) and assuming one year for the plant construction (Eq. 4 and 5) (Seider et al., 2009).

$$\text{Net earnings} = (S - \text{OPEX}) \cdot (1 - \text{income tax rate}) \quad (4)$$

$$\text{Annual Cash Flow} = (\text{Net earnings} + D) - \text{CAPEX} \quad (5)$$

The total annualised costs (TAC) are shown in Eq. 6 and include a reasonable return in investment  $i_{\min}$  of 0.2 (Seider et al., 2009).

$$\text{TAC} = \text{OPEX} + i_{\min} \cdot \text{CAPEX} \quad (6)$$

### 3. Results and Discussion

#### 3.1. Choice of Separation System and Process Flowsheet

In contrast to the representative process, pure PA6 enters the depolymerisation reactor. Hence, the required separation steps after depolymerisation to purify CL from water need to be adapted to this simplification. It was investigated whether a flash evaporator would be sufficient to achieve the patents' CL recovery constraints (see Figure 1).

Figure 1: CL recovery (left) and purity (right) versus temperature at different flash unit pressures.

The graphs show that within the pressure range, the recovery and purity constraints cannot be met at the same time. Hence, a distillation column was chosen with an operating pressure of 16 kPa, which allows the use of a single liquid ring pump as well as CW as a cold utility. The process flowsheet for a reasonable CL production capacity of 14.0 kt/year, including the equipment and utility choices, is shown in Figure 2.

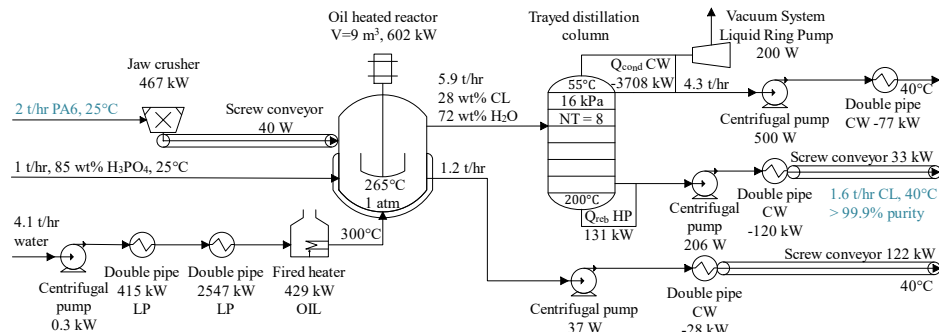

Figure 2: Schematic representation of process flowsheet and choice of equipment and utility.

As can be seen, crushed PA6 reacts to CL using  $\text{H}_3\text{PO}_4$  and superheated steam in a jacketed and agitated reactor with a conversion of 80%. The formed CL is obtained at the top as a vapour stream along with steam. Superheated steam functions in several ways, as it shifts the reaction equilibrium by carrying CL, supports mixing and supplies heat. As described in chapter 2.1,  $\text{H}_3\text{PO}_4$  acts as a catalyst by activating the carbonyl group and facilitating the attack of water. However, it is also consumed in the simultaneous protonation of ACA and salt formation (Češarek et al., 2020). Those products are discharged at the bottom of the reactor and have to be treated as hazardous waste.

The product stream is obtained at the bottom of the vacuum distillation column with a recovery of 99.9% and a CL purity of over 99.9 wt%. Subsequently, the product stream is cooled and solidified to 40 °C by a heat exchanger and screw conveyor.

### 3.2. Economic Analysis

It was found that the described process is profitable, as the break-even point is already reached at a CL production of 4.6 kt/year.

#### 3.2.1. Cost Contributions

To identify the most cost-intensive process units, the OPEX and CAPEX structure was investigated (Figure 3).

Figure 3: Costs of the process units in \$MM (left bar chart) and OPEX (right pie chart).

Despite the fact that the CAPEX of \$5.5M is rather small compared to the OPEX of \$26.3M per year, none of these process units stands out regarding their capital expenditures. On the other hand, the graphs reveal that variable costs are dominant. Even more interesting is that H<sub>3</sub>PO<sub>4</sub> raw material costs and its waste treatment as reactor discharge make up 47% of the overall OPEX. The cost contribution of H<sub>3</sub>PO<sub>4</sub> is, therefore, further investigated through a sensitivity analysis.

#### 3.2.2. Sensitivity Analysis and Case Studies

Next to the amount of H<sub>3</sub>PO<sub>4</sub>, possible effects of electricity price volatilities were analysed. Additionally, the kinetic pre-exponential factor was varied to study the consequences of potential inaccuracies on the results, which are displayed in Figure 4.

Figure 4: Sensitivity analysis where TAC is displayed over the percentual change of certain variables.

The change of the H<sub>3</sub>PO<sub>4</sub> amount has notably the most significant impact on the TAC, which aligns with the results of the previous chapter. This is because increasing the amount of H<sub>3</sub>PO<sub>4</sub> does not only result in high raw material costs but also in huge waste treatment costs. This further proves that H<sub>3</sub>PO<sub>4</sub> is the main bottleneck of the process. On the other hand, the electricity and OIL price variations barely have any impact on the TAC. Similarly, in a range of 30%, any inaccuracy of the pre-exponential factor would have minor effects. However, the profitability of the process heavily depends on the PA6 waste raw material purchase cost, with an upper profitability boundary of \$650 per tonne.

### 3.2.3. Cash Flow Analysis in Best and Worst Case

To account for inaccuracies and model errors, a best and worst-case scenario was established for the profitability and cash flow analysis (see Figure 5). Utility prices and the pre-exponential factor were all altered by 20%. Additionally, the Lang-Factor method for calculating CAPEX has an accuracy of  $\pm 35\%$ , which was incorporated as well.

Figure 5: Cumulative cash flow in \$MM for 19 years in the best, standard, and worst-case scenarios.

It can be predicted that the process becomes profitable within a minimum of three to a maximum of seven years, and cumulative cash flow stays within certain boundaries. This proves that the established model and process analysis are solid.

## 4. Conclusions

In this work, a techno-economic analysis of the conventional chemical recycling route of PA6 was performed. It showed that the process stays profitable even after the incorporation of realistic parameter inaccuracies and worst-case assumptions. The results indicate that neither the reaction nor the purification part of the process has a significant impact on the TAC. Instead, the amount of  $H_3PO_4$  and the waste stream containing unreacted PA6, oligomers and  $H_3PO_4$  are the critical variables. Eventually, it can be concluded that depolymerisation processes of PA6 can be very promising and have a great potential for optimisation, especially regarding the catalyst and solvent amount.

## Abstract

Hydrogen purification is essential to use ammonia as a carrier of green hydrogen since the green hydrogen produced from the transported ammonia inevitably results in nitrogen as a byproduct. The membrane-based separation process has been considered an option for green hydrogen purification because of its various advantages. The selection of proper membrane materials is an important task to efficiently separate gas mixtures. Because it is difficult to compare numerous membranes through experiments, the membrane has been selected using the molecular simulation-based high-throughput screening (HTS) method. However, in the previous studies, the physical properties used to evaluate the membrane materials were not directly related to the separation process performances. To address this limitation, this study entailed the use of multiscale HTS to select the covalent organic frameworks (COFs) best performing in the membrane-based green hydrogen separation process. The proposed method combines the process and molecular simulations to evaluate the performances of COF membranes. The proposed multiscale HTS method was applied to a COF database, and the 648 COFs in the database were explored to select the COFs with the highest performance in hydrogen separation.

**Keywords:** green hydrogen, membrane separation process, covalent organic framework, high-throughput screening

## 1. Introduction

The recent enthusiasm for green technology has put green NH<sub>3</sub> as a hydrogen transportation medium in the spotlight. Separation of N<sub>2</sub> and H<sub>2</sub> is a critical step in converting NH<sub>3</sub> transported from another location into hydrogen for use (Morlanés et al., 2021). Among the various hydrogen purification methods, the membrane-based hydrogen separation process is an active topic of research owing to its ease of use and low energy cost (Ahmad et al., 2012). Various polymer membranes have been designed for efficient gas separation, but the trade-off between selectivity and permeability remains challenging. To address this issue, new nanoporous materials, such as metal organic frameworks and covalent organic frameworks (COFs), have been actively developed. Due to their chemical diversity and structural tunability, COFs have the highest potential for use as

membranes (Aydin et al., 2022).

Selecting an appropriate material among the many porous materials developed to date is one of the most important tasks in the design of a membrane-based separation process because membranes significantly impact the membrane separation process performance. Previous studies on molecular simulation-based high-throughput screening (HTS) have evaluated various materials (Gulbalkan et al., 2022). However, the inability to evaluate the performance in the actual membrane process is a limitation in the previous HTS studies because the computational cost was too high and because only molecular simulation was used.

Therefore, to provide a practical evaluation of the membranes, this study proposes a multiscale evaluation framework. Using the multiscale evaluation framework, this study aimed to select high-performing COF membranes for the membrane-based green hydrogen separation process. In this multiscale evaluation framework, molecular and process simulations were performed to evaluate each COF with process performance. The 20 COFs with the highest  $H_2$  recovery were selected based on the evaluation results. Finally, by examining the  $H_2$  recovery and purity of the membrane process for various process conditions, the performances of the selected COFs were presented for different situations.

## 2. System description

The concept of ammonia as hydrogen transportation media is a future technology for transporting green hydrogen from renewable resource-rich countries to other countries. Green hydrogen is produced in areas with abundant renewable energy resources, and green hydrogen is transported to other areas in the form of ammonia. In the destination, the ammonia is decomposed into hydrogen. The hydrogen should be purified to high purity since its applications as an energy source or as a chemical stock require high purity of hydrogen.

To produce high purity of hydrogen from the transported green ammonia,  $NH_3$  decomposition,  $NH_3$  separator, and  $H_2$  purification processes are required (Figure 1). First, the  $NH_3$  decomposition reactor decomposes  $NH_3$  into  $N_2$  and  $H_2$ . The trace amount of unreacted  $NH_3$  is assumed to be completely removed in the  $NH_3$  separator. The mixture of  $N_2$  and  $H_2$  gases is used as the feed into the membrane separation process. The process conditions are set at a temperature of 313.15 K and a pressure of 8 bar. The ratio of hydrogen to nitrogen ( $H_2:N_2$ ) in the composition was assumed to be 3:1, as in  $NH_3$ . In this study, a co-current membrane separator is used, assuming the same flow directions in the feed and permeate sides. Other required parameters are listed in Table 1.

Figure 1. The schematic of integrated  $NH_3$  decomposition and  $H_2$  purification

Table 1. Model parameters and simulation conditions

Definition	Symbol	Value (unit)
Feed flowrate	$F_{f,0}$	3.02 mol/s
Feed composition, H <sub>2</sub> :N <sub>2</sub>	$x_{H_2,0}, x_{N_2,0}$	0.75: 0.25
Membrane inner diameter	$D_i$	$2 \times 10^{-3}$ m
Membrane outer diameter	$D_o$	$2.5 \times 10^{-3}$ m
Membrane module diameter	$D_m$	0.1 m
Number of fibers	$N$	600
Fiber length	$L$	0.6 m
Mass transfer coefficient	$k$	$1 \times 10^{-4}$ m/s

### 3. Multiscale membrane screening method

Figure 2 illustrates the steps involved in the screening method used in this study to discover the membranes with the highest process performances. The proposed multiscale HTS method consists of structural analysis, molecular simulation, process simulation, and results analysis under a wide range of operating conditions (i.e., assess the H<sub>2</sub> recovery and purity of each component and compare the different membranes). To select the best-performing COF membranes, the proposed methodology is applied to the CURATED COF database. Each step of the methodology is explained in the following section.

#### 3.1. Structural properties analysis

This step involves screening work based on the structural property. For gas molecules to permeate, the pore limiting diameter (PLD), which is the smallest pore in the nanoporous material, must be greater than the gas molecule diameter. The COFs with a PLD larger than 3.31 Å, the diameter of the N atom, were chosen because this study requires that H<sub>2</sub> and N<sub>2</sub> be permeable. The PLDs were calculated using the Zeo++ software (ver. 0.3).

#### 3.2. Molecular simulation

In this step, the Grand Canonical Monte Carlo (GCMC) and molecular dynamic (MD) simulations were performed to acquire the parameters for membrane permeance calculations. Permeance, defined by the ratio of membrane permeability ( $P$ ) to thickness ( $d$ ), is an essential parameter to evaluate the process performance. Permeance is obtained using the following equation:

$$a_i = \frac{P}{d} = \frac{q_i \cdot \mathcal{D}_i}{p_i \cdot \rho \cdot d} \quad (1)$$

where  $q$ ,  $\mathcal{D}$ ,  $p$ , and  $\rho$  denote gas uptake, self-diffusion coefficient, partial pressure, and density of COF, respectively. The subscript  $i$  denotes each gas component. Parameters  $q$  and  $\mathcal{D}$  are calculated from the GCMC and MD simulations, respectively. The simulations were conducted using the RASPA 2.0 package.

The N<sub>2</sub> and H<sub>2</sub> partial pressures were set to 2 and 6 bar, respectively, and the temperature at 313.15 K for the GCMC simulations. The GCMC simulation used 10,000 and 20,000 cycles for equilibration and ensemble averages, respectively. The van der Waals (vdW) interaction, which was modeled using the Lennard–Jones (LJ) 12-6 type equation, was used to approximate the interaction between atoms in the systems (Altintas and Keskin, 2019). The LJ parameters for N<sub>2</sub> and H<sub>2</sub> molecules were obtained from the transferable potential for the phase equilibria (TraPPE) force field. A vdW cutoff distance of 12.8 Å was used to truncate the vdW interactions between atoms.

MD simulations were performed to calculate  $\mathcal{D}$  for both H<sub>2</sub> and N<sub>2</sub> (Azar et al., 2019). Thirty molecules for each gas component were simulated in infinite dilution. The number of initialization, production, and total cycles was set to 1000, 10,000, and 1,000,000,

Figure 2. The multiscale high-throughput screening method

respectively. MD simulations were performed in the NVT ensemble with a time step of 0.5 fs. The mean square displacement of gas molecules was used to calculate  $D_i$ .

### 3.3. Process simulation

Figure 3. An illustration of a hollow fiber membrane separation module

Using the permeance obtained in the previous section, the  $H_2$  recovery was calculated through process simulation in this step to evaluate each COF membrane. To simulate the membrane separation process, the system is configured as shown in Figure 3.  $P$ ,  $F$ , and  $y$  represent pressure, flowrate, and mole fraction, respectively. The subscripts  $f$ ,  $p$ , and  $i$  represent the feed, permeate side, and gas component, respectively. The partial pressure difference between the feed and permeate sides, which is calculated using Eq. (2), determines the flux of gas passing through the membrane.

$$J_i = a_i(P_{f,i} - P_{p,i}) \quad (2) \quad P_{j,i} = x_{j,i}P_j \quad \text{for } j = f \text{ or } p \quad (3)$$

where  $J$  denotes the permeate flux in  $\text{mol}/(\text{m}^2 \cdot \text{s})$ ,  $a$  denotes the membrane permeance in  $\text{mol}/(\text{Pa} \cdot \text{m}^2 \cdot \text{s})$  derived from the molecular simulations, and  $P$  denotes the partial pressure in Pa. Partial pressure is calculated using the total pressure and molar fraction of each component, as shown in Eq. (3), where  $x_{j,i}$  denotes molar fraction of component  $i$  in  $j$  stream. The component balances for each feed and permeate side are expressed as follows:

$$\frac{dF_{f,i}}{dz} = -J_i W_{int} \quad (4) \quad \frac{dF_{p,i}}{dz} = J_i W_{int} \quad (5)$$

where  $W_{int}$  denotes the interfacial membrane width in m, calculated using  $W_{int} = \pi D_o N$ . The detailed calculation method is described in the literature (Gu, 2022). The flowrate and pressure for each side and component are derived from solving the above ordinary differential equation along with  $z$ -axis. Then, the  $H_2$  purity and recovery are defined as follows:

$$\text{Purity} = \frac{F_{p,H_2}}{\sum F_{p,i}} \times 100 (\%) \quad (6) \quad \text{Recovery} = \frac{F_{p,H_2}}{F_{f,H_2}} \times 100 (\%) \quad (7)$$

The  $H_2$  product must be at least 97% pure to be used as an energy source; the higher the recovery, the better. A parametric study with varied operating conditions was carried out to identify the optimal conditions for maximized  $H_2$  recovery while satisfying the purity standard.

## 4. Results and discussion

### 4.1. Multiscale high-throughput COF screening results

In this section, the results of each screening step are reported. Figure 4(a) presents the PLD distribution of the 648 COFs in the CURATED COF database, where the PLD threshold of 3.31 Å is indicated by a red dashed line. Among the target COFs, 16 COFs were identified to have PLD values below the threshold. GCMC, MD, and process simulations were performed for the remaining 632 COFs.

The process simulation results are displayed in Figure 4(b). While most COF membranes can produce H<sub>2</sub> with a high purity greater than or equal to 80%, the H<sub>2</sub> recovery varies widely. The red dots in the graph represent the top 20 COFs that achieved the highest recovery with H<sub>2</sub> purity above the 97% threshold.

Figure 4. Pore limiting diameter distribution of CURATED COFs database (a), and H<sub>2</sub> purity and recovery results from process simulation (b).

### 4.2. Analysis of membrane module performance

This section analyzes the influence of feed flow rate on the membrane process performances, which reveals the correlation between H<sub>2</sub> recovery and H<sub>2</sub> purity of the 20 selected COFs. Figure 5(a) displays the variations in H<sub>2</sub> purity and H<sub>2</sub> recovery for varied feed flowrates into each fiber. It is shown that the recovery decreases with increasing feed flowrate, while the purity is higher at a higher flowrate. In other words, by increasing the feed flowrate, the purity constraint can be met at the expense of recovery. When each COF was set to have an H<sub>2</sub> purity of 97% by adjusting the feed flowrate individually, Tp-DBD turned out to achieve the highest H<sub>2</sub> recovery (synthesized by 2,5-diamino-1,4-

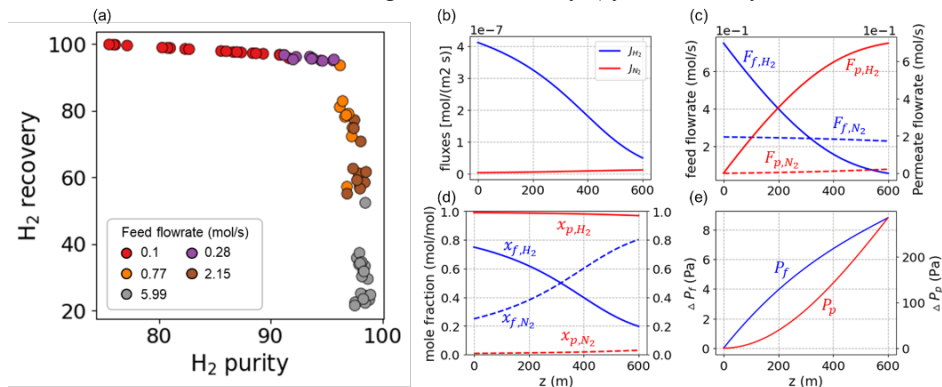

Figure 5. Process simulation results with different feed flowrate and (a) the spatial profiles of fluxes, (b) flowrates, (c) mole fractions (d) pressure drop, and (e) in the feed and permeate sides in the module

benzenediol dihydrochloride and 4,6-triformylphloroglucinol) (Cui et al., 2021). The spatial profiles of the state variables are provided in Figure 5(b)–5(e). Therefore, Tp-DBD COF, which demonstrated an increase in H<sub>2</sub> recovery (46.54% to 92.11%) with a change in feed flowrate (3.02 mol/s to 1.00 mol/s), is the highest-performing COF.

## 5. Conclusion

This study demonstrated the use of the multiscale HTS method to select the best membrane material for the membrane separation process for green hydrogen purification. The proposed multiscale HTS method, consisting of structural analysis, GCMC simulation, MD simulation, and process scale simulation, is used to evaluate the process performance of each membrane. The method was applied to the CURATED COF database to identify the top 20 COFs. By analyzing the H<sub>2</sub> purity and H<sub>2</sub> recovery for different feed flowrates, the COF membrane with the highest recovery was determined. The parametric study with varied feed flowrate demonstrated the trade-off relation between H<sub>2</sub> recovery and purity. The feed flowrate was reduced from 3.02 mol/s to 1.00 mol/s, yielding the highest performance (H<sub>2</sub> recovery of 92.11%).

## Abstract

Efficient and sustainable chemical recycling pathways for plastics are vital for addressing the negative environmental impacts associated with their end-of-life management. Mechanochemical depolymerization in ball mill reactors is a new promising route to achieve solid-state conversion of polymers to monomers, without the need for additional solvents. Physics-based models that accurately describe the reactor system are necessary for process design, scaling up, and reducing energy consumption. Motivated by this, a Discrete Element Method (DEM) model is developed to investigate the ball milling process at laboratory and industrial scales. The lab-scale model is calibrated and validated with data extracted from videos using computer vision tools. Finally, scaled-up ball mill designs capable of depolymerizing varying feeds of PET waste were simulated, and their capital and operating costs are estimated to assess the economic potential of this route.

**Keywords:** ball milling, plastic recycling, discrete-element-method, technoeconomics

## 1. Motivation and background

Traditional economies rely on linear production processes in which raw materials are manufactured into useful products and later discarded as waste. However, this economic model places a significant strain on natural resources and the environment, particularly in the case of single-use plastics. In 2018, 360 million tons of plastics were produced globally, with 80% ending in landfills or in the sea, whereas only 10% were recycled (Tricker et al., 2022). To alleviate the environmental stress on natural resource degradation, there is increasing interest in transitioning to a circular economic model in which waste materials, such as plastics, will be recycled back into the economy.

Plastic recycling methods can be categorized into mechanical and chemical pathways. Most recycling infrastructures currently focus on mechanical processes in which waste is physically reshaped into new products from a melt. However, mechanical and thermal stresses acting on the polymer melt during processing degrade the integrity of the plastic product; therefore, each plastic product can only be recycled a limited number of times, and only if mixed with large quantities of virgin polymers (Tricker et al., 2022). A promising alternative is the chemical recycling of polymers, which bypasses the limitation of material degradation entirely, by converting polymers directly to monomeric molecules through depolymerization. Common chemical recycling pathways such as pyrolysis and solvolysis involve high energy consumption or the use of solvents, therefore hindering their economic viability. The development of alternative depolymerization

processes for plastic waste is crucial for implementing sustainable practices and reducing negative environmental effects. In a previous study (Tricker et al., 2022), it was shown that mechanochemical depolymerization in ball mill reactors is a promising route for converting solid polymers into monomers without the need for additional solvents. Mechanochemical depolymerization pathways utilize the mechanical energy supplied by collisions between grinding bodies (balls and walls) of a ball mill to drive the reaction between solid reactant particles. Thus, accurately simulating the movement and interactions between these entities can provide crucial information for explaining mechanisms of mechanochemical depolymerization and for optimizing process design. Two modeling frameworks have predominantly been used to simulate ball mill systems: semi-empirical population balance and mechanistic Discrete Element Method (DEM) models. DEM models for ball milling have received increasing attention owing to their ability to describe the kinematics of moving entities and the corresponding energy involved in their collisions during ball milling. Additionally, ball milling operations at the industrial scale can be energy-intensive; hence, even a marginal improvement in efficiency can lead to a significant reduction in expenses. For instance, approximately 110 kWh of electric energy is consumed during the production of 1 ton of cement, of which 70% is required for comminution, whereas only 1-5% is explicitly used for particle breakage; the remaining energy is wasted (Boemer & Ponthot, 2017; Tavares, 2017).

Figure 1: The main components of this study include: (a) experimental design and machine learning computer vision tools for the calibration of a lab-scale DEM model, and (b) DEM simulations of scaled-up ball mill configurations for various operating settings to estimate capital and operating costs

In this work, a DEM model was developed to investigate the depolymerization of poly(ethylene terephthalate) (PET) powder. First, high-speed video recordings of a lab-scale ball mill were obtained at operating conditions that allowed for quantitative PET depolymerization in corresponding experimental studies in the same mill (Tricker et al., 2022), and a computer vision algorithm was used to track the moving balls in the reactor. The extracted data were used to parameterize the DEM model and predict the kinematic interactions of moving entities in the mill. Once the mechanistic model parameters were optimized, the geometry of an industrial-scale ball mill reactor was created, and various operating settings were simulated. The resulting DEM simulation was used to investigate the tradeoffs between achieved PET yields and energy requirements at the industrial scale. Finally, capital, and operating costs of the process were calculated for various scenarios of waste feeds, using data obtained from US state levels of plastic waste collection.

## 2. Methods

### 2.1. High-fidelity model for the laboratory ball mill reactor

PET depolymerization experiments were performed in a Retch MM400 vibratory ball mill with stainless steel grinding bodies. PET in powder form was milled with a stoichiometric amount of sodium hydroxide (NaOH) to form ethylene glycol (EG) and disodium terephthalate salt ( $\text{Na}_2\text{TPA}$ ). Details regarding experimental conditions and results have been reported in (Tricker et al., 2022). A transparent PMMA milling vessel

identical to that used in the depolymerization experiments was manufactured and used in motion-tracking experiments, but without reactants (PET + NaOH) present. The mill's operation at various conditions (ball numbers and sizes, milling frequencies) was filmed using a high-speed camera (2134 fps) to study the collision kinematics between balls and the vessel wall. A Python script based on the OpenCV computer vision library was used to analyze the video frames and track the position of the ball(s). The coordinates of the ball(s) in space and time were identified and used to calculate their velocity, which is defined as the change in position between two consecutive frames.

Figure 2: (a) Experimental setup including a vibratory 25mL reactor and stainless-steel balls (b) Replication of the experimental setup in DEM simulation with one and two balls (c) The geometry of the industrial-scale reactor as simulated in the DEM software

Next, the geometry of the laboratory setup was developed in Solidworks while the DEM model was developed in EDEM. The Hertz-Mindlin contact model was applied, as it is most appropriate for non-cohesive spherical shapes (Metta, Ierapetritou, & Ramachandran, 2018). Typical steel properties were used as inputs to the DEM model (density 7900 kg/m<sup>3</sup>, Poisson's ratio 0.3, coefficient of restitution 0.5, shear modulus 77 GPa). The coefficient of static and rolling friction are taken as 0.5 and 0.01 respectively based on (Metta et al., 2018). For PMMA-steel interactions, a grid search of the coefficient of restitution and the friction parameters was performed, and optimal values that match the velocity and the number of collisions between the simulation and the motion-tracking experiments were identified. The laboratory ball milling simulation was validated based on the recorded experiments under different operating conditions. Once the lab-scale simulation is validated by experiments, the identified parameters that govern ball-to-ball and ball-to-wall interactions can be used to simulate a scaled-up geometry.

### 2.2. Scaling up and technoeconomic analysis of ball mill reactor

A typical industrial ball milling setup comprises a rotating cylindrical vessel filled with balls and PET particles. Electric energy is used to satisfy the energy requirements necessary to drive the electric motor that rotates the mill and grinding media. To establish the operating costs, a new geometry and scale of DEM simulations was developed. A rotating cylindrical vessel was designed, and the simulation was developed (Figure 2c) using the validated material and contact parameters. The resulting torque requirements loads were extracted from the DEM simulation, and the operating costs were evaluated based on Equation (1) for 7920 hours of operation annually.

$$\text{Electricity Cost} = \text{Price} \times \text{Power} = \text{Price} \times (T_M \times \omega_M) \quad \text{Equation (1)}$$

$$C_{\text{Ball Mill}} = 64640 \times W^{0.64} \quad \text{Equation (2)}$$

$$Y_{\text{PET}}(\%) = 6.38 \text{ BPR} - 46.35 \text{ for } 10 \leq \text{BPR} \leq 23 \quad \text{Equation (3)}$$

Here,  $T_M$  is the torque associated with the rotation of the reactor vessel while  $\omega_M$  is the mill's angular velocity, which in this work is equals to 15 rpm. The angular velocity was chosen such that it lies between 60-80% of the critical speed depending on the reactor

volume (Wang, Yang, & Yu, 2012). The fill level of the ball mill was kept constant at 30 %, and the radius of the balls was set to 80 mm for all cases. An electricity cost of \$0.07/kW-h was used while the purchase cost of the ball mill equipment was estimated based on the feed flowrate ( $W$  [ton/hr]) according to Equation (2) (Seider, Seader, Lewin, & Widagdo, 2004), and then adjusted to the 2022 dollar value via the CEPCI Index. According to our previous kinetics study on the PET depolymerization reaction (Tricker et al., 2022) for the lab-scale ball milling system, monomer yield follows a linear relationship (Equation (3)) with the ball-to-powder mass ratio (BPR) parameter, that is, the ratio of the ball mass to the mass of the reactants. Assuming that the same BPR values can be maintained at the industrial scale, the corresponding conversion, and costs can be calculated. Higher BPR ratios results in higher PET monomer yields, and full conversion is achieved when  $BPR = 23$  with a 20 min reaction time (Tricker et al., 2022). The BPR parameter was used to scale-up the reactor and to evaluate the corresponding conversion, number of balls, and reactor volume for a certain PET waste feed.

### 3. Results and Discussion

#### 3.1. Laboratory-scale model validation

The average ball velocity is compared in Figure 3a, which reveals that the values are in near-perfect agreement for the different operating conditions (vibration frequencies, diameters) tested and can thus validate the lab-scale model. Stainless-steel balls with diameters equal to 17.6 mm and 20.6 mm were used for the model validation while the milling frequency ranged from 22.5 to 30 Hz. Once the DEM parameters were estimated, the simulation can be executed for different conditions and reactor sizes, and the results can be used to further analyze the ball milling system.

#### 3.2. Simulations at the industrial scale

DEM simulations were used to define the scaling-up procedure for PET waste depolymerization in ball mills and to evaluate the associated energy requirements. To illustrate the resulting capital and operating costs of plastic waste depolymerization at the industrial scale, two separate cases were considered.

##### 3.2.1. Case-study 1: Influence of BPR to the operating costs

The BPR ratio significantly influenced the extent of PET depolymerization. To this end, the first case study depicts how the operating costs change with respect to the BPR value for the same feed of 1000 kg/hr PET waste (+400 kg/hr NaOH). The reactor volume and number of balls required to depolymerize the PET waste were calculated based on the BPR parameter.

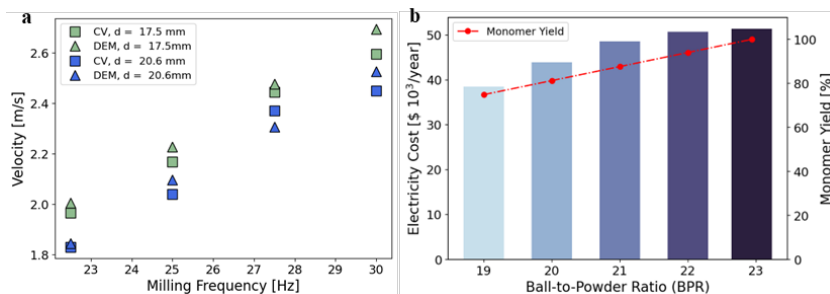

Figure 3: (a) Comparison of the average velocities of the stainless-steel ball at different vibration frequencies (22.5 – 30 Hz) extracted from the DEM simulations (triangles) and the recorded ball mill experiments (squares), (b) Comparison of annual electricity cost and achieved monomer yield for reactors processing 1000 kg/hr of PET (+400 kg/hr NaOH) at different BPR ratios.

The results of this analysis are shown in Figure 3b, which illustrates how the electricity cost changes with different BPR values. For higher BPRs, more balls are added inside the mill to grind the same amount of waste, resulting in increased power requirements for the mill rotation. More specifically, to achieve a 75% monomer ( $\text{Na}_2\text{TPA}$ ) yield (BPR=19), \$1.62/tonne<sub>PET</sub> are spent on electricity, whereas for full depolymerization (BPR=22.9) the cost is increased to \$2.16/tonne<sub>PET</sub> for 20 min milling time (Tricker et al., 2022). The purchase cost of the ball mill vessel was estimated to be \$119,719 and was constant for all BPR combinations (assuming a negligible cost for the additional grinding balls). However, as PET conversion is reduced, subsequent unit operations will be necessary to separate and recycle unreacted PET waste which will increase capital and operating expenditures.

### 3.2.2. Case study 2: Influence of PET waste feedstock flowrate

The second case study illustrates the dependence of the total cost of ball milling to the mass flow rate of PET waste. Different PET waste recycling feed flow rates were evaluated, and the corresponding costs were estimated for a BPR value of 20 resulting in 81.2 % of PET converted to monomers. The PET waste for different US states were used as input to the DEM simulation based on recycling quantities for 2018 as described in the report of the National Association for PET Container Resources (*NAPCOR 2018*). The study region encompasses the South Atlantic region of the US, which in turn comprises nine states (Florida, Georgia, North Carolina, Virginia, Maryland, South Carolina, West Virginia, and District of Columbia). It is assumed that the PET recycling quantities are equally distributed to each state in the region based on the corresponding population for the same year. The resulting PET waste flowrates for each state are used as inputs to the DEM simulation using stoichiometric NaOH feed.

Figure 4: PET waste collected at each state in 2018 scaled based on population, and the resulting capital and operating costs. The graph illustrates the capital and operating costs per kg of PET waste fed in the ball mill reactor. The bars denote the capital cost per feed flow rate in \$ kg<sub>PET</sub><sup>-1</sup>hr, whereas the electricity cost per tonne is shown on the secondary axis for 20 min operation (red dotted line).

The results of this analysis are shown in Figure 4, which illustrates how the required expenditure per unit feed changes for different PET waste feeds. As expected, both capital and operating costs increased with feed flow rate, because maintaining the same BPR value requires larger numbers of balls and a larger reactor volume, which would require greater motor power to achieve depolymerization conditions for that entire mass of grinding bodies. In contrast, per unit costs decreases as the feed rate increases highlighting the benefits of economy of scale.

The economic potential of the mechanochemical route based solely on raw material (PET bale: \$150/tonne, NaOH: \$608/tonne, H<sub>2</sub>SO<sub>4</sub>: \$96/tonne) and product (vTPA: \$1143/tonne, EG: \$961/tonne) prices (Singh et al., 2021) was evaluated at \$978/tonne of

TPA, which is an indication of the upper bound of the potential profits. This value, in combination with the low electricity costs that were estimated in both case studies at \$2-3/tonne<sub>PET</sub>, reveals that there is still a significant profit margin to account for mechanical pretreatment, required to grind PET waste to micro sizes, as well as downstream processes to recover the products of mechanochemical hydrolysis of PET waste that can be capital- or energy-intensive, i.e., rTPA crystallization, EG distillation, salt recovery (Singh et al., 2021).

#### 4. Conclusions

In this work, we built a DEM simulation required to design and cost PET depolymerization via ball milling for a variety of feedstock flow rates and operating settings. Two case studies demonstrate the dependence of the operating and capital costs on the achieved PET conversion and feed flow rates. The results indicate that this can be viable process economically, especially for states that recycle more PET where there would be a benefit from economy of scale. Also, there are economic trade-offs to be considered in the future with respect to more costly depolymerization at high conversions, versus partial depolymerization and design of subsequent separation/purification steps and recycling streams. In future work, a more detailed technoeconomic analysis of plastic waste depolymerization via mechanochemical reactions will be performed to account for pre-treatment costs to shred plastic waste into powder form, as well as downstream treatment to purify the mechanocatalysis products. This analysis will be critical for comparing this technology with alternative recycling routes and aid policymakers and industry stakeholders in making informed decisions regarding its overall potential.

## Abstract

The splitting of hydrogen sulphide into hydrogen and elemental sulphur results to be a promising route for the treatment of this dangerous waste gas and, at the same time, for the sustainable production of hydrogen. To reach relevant production rates a comprehensive approach should be applied to the modelling of the process. This work investigates how the thermal decomposition of hydrogen sulphide can be described at different scales: the kinetic scale, the reactor scale, and the chemical process scale. In particular, a detailed kinetics is implemented into DSmoke, a reactor simulation suite for complex kinetics and non-ideal reactive systems. The obtained reactor model is validated through an experimental lab campaign. At the process scale, the splitting step is integrated into a complete plant design (considering a 10 t/h H<sub>2</sub>S feed, the mass flow of H<sub>2</sub> produced from the simulated plant is equal to 543.8 kg/h, with a production cost of 2.39 \$/kg).

**Keywords:** hydrogen sulphide, H<sub>2</sub>S decomposition, multi-scale model, orange hydrogen.

## 1. Introduction

Hydrogen sulphide (H<sub>2</sub>S) is a compound that is naturally present in many resources (both fossil and renewable) and is also artificially produced in some industrial processes. The main source are the processes for the treatment and desulphurization of oil and gas. Since hydrogen sulphide is pollutant, corrosive and flammable, it cannot be released in the environment, and it must be conveniently processed.

At present, H<sub>2</sub>S is usually sent to sulphur recovery units (e.g., Claus process), which perform a partial oxidative conversion able to transform H<sub>2</sub>S into sulphur and water via sulphur dioxide (SO<sub>2</sub>) as intermediate and, at the same time, to recover thermal energy. The process leads to the production of elemental sulphur, a more environmentally friendly and less hazardous compound than H<sub>2</sub>S. In this case hydrogen is not recovered and is completely wasted in the form of water. An interesting alternative could be its conversion into sulphur and hydrogen (Burra et al., 2018), according to the overall splitting reaction ( $\Delta H_r^0 = 84.9$  kJ/mol):

The production of hydrogen results in great interest since this compound is a highly valuable product with a wide range of applications, especially in the energy and chemicals industry. Hydrogen is usually identified through different colours, according to the

production process. Black refers to coal gasification, grey to natural gas reforming, turquoise to natural gas pyrolysis, blue to reforming/gasification + CCUS, green to electrolysis of water with renewable electricity, purple to electrolysis of water with electricity from nuclear plants and yellow to electrolysis of water with mixed-origin grid energy). H<sub>2</sub>S thermal splitting represents a promising path to produce relevant amounts of hydrogen. This H<sub>2</sub> has not been yet classified in the chromatic scale, therefore, it will be named “orange hydrogen”. Obtaining this product from the H<sub>2</sub>S generated in hydrotreating processes may enable the recovery and recycling of H<sub>2</sub>, significantly reducing the need to acquire new H<sub>2</sub> sources and, in general, reducing costs and environmental impacts. In addition, H<sub>2</sub> has the potential to be integrated into the fuel cycle for energy storage carriers, leading to the complete suppression of air pollutants emissions.

A variety of splitting techniques aimed at producing hydrogen and sulphur from H<sub>2</sub>S, have been studied. To date, the developed H<sub>2</sub>S splitting methodologies include thermal (catalytic/membrane-assisted), photocatalytic, non-thermal plasma, thermochemical, electrolysis and biological processes (De Crisci et al., 2019). At 1200 °C, 1 atm and with a steady gas flow rate of 50 mL/min, H<sub>2</sub>S conversion was 35.6 % (97.5 % of its thermodynamic limit). To decrease the high-temperature requirements, catalytic processes have been investigated. Low-temperature processes have been performed with the use of MoS<sub>2</sub>-based catalysts, resulting in 95 % conversion to H<sub>2</sub> at 500 °C. Other materials have also been studied, including, for example, perovskites (Burra et al., 2018), alumina oxides (Cha et al., 2022) and vanadium-decorated titanium carbides (Zhou et al., 2021). Photocatalytic reactions have also been considered. TiO<sub>2</sub> is the most studied semiconductor because of its nontoxicity, low cost, and high stability (Uesugi et al., 2022).

Nevertheless, H<sub>2</sub> generation from H<sub>2</sub>S has not yet been scaled up to bulk production due to economic and technical reasons (Gupta et al., 2016). Some of the open issues are related to the complete capture of pure H<sub>2</sub>S, its energy-intensive regeneration step, the management of sulphur vapours, and the H<sub>2</sub>S effective conversion into hydrogen and elemental sulphur. The problem requires a multi-scale approach, able to model the process from the kinetic scale, to the reactor scale, to the complete process scale. In this work, the hydrogen sulphide thermal splitting is analysed at different scale levels, proposing in this way a comprehensive approach to the study of a process.

## 2. Materials and methods

### 2.1. Experimental set up

The study of H<sub>2</sub>S splitting is first approached by conducting an experimental campaign. An ex-novo laboratory apparatus has been set up. It consists of an open circuit system fed by a gaseous H<sub>2</sub>S/N<sub>2</sub> mixture with a H<sub>2</sub>S concentration up to 8 vol%. The reactor is made of quartz and is designed according to the ideal Plug Flow Reactor (PFR) model. To ensure the adequate thermal conditions required by the process, the reactor is placed inside a tubular oven. Upon exiting the reactor, the sulphur is condensed thanks to the bubbling of the reaction gases into a flask containing distilled water. The gaseous stream is then sent to a stilling chamber to remove all the entrained droplets. A filter ensures then the complete removal of any solid particle from the stream. The gases are finally analysed with a Micro GC (Micro Gas Chromatograph).

### 2.2. DSmoke simulation

DSmoke is a reactor network simulation suite for complex kinetics and non-ideal reactive systems, developed by the research group at Politecnico di Milano. The software allows

the modelling of sequences of reactors (in series or in parallel), possibly coupled with mixers and/or splitters. It is composed by a chemical interpreter, that processes the kinetic mechanism and the thermodynamic properties of the species, and by a reactor model developer.

The lab reactor employed in the experimental campaign has been modelled in DS<sub>Smoke</sub> with a network of three reactors in series. This sequence is composed by a first isothermal plug flow reactor, corresponding to the homogeneously heated length of the quartz tube inside the oven, a second plug flow reactor, displaying a linear temperature profile (going from the temperature value inside the oven to room temperature) and corresponding to the part of the tube at the exit of the oven, where the temperature drops rapidly, and finally a third isothermal plug flow reactor, simply corresponding to the remaining length of the tube. Table 1 shows the details of the three reactors composing the series.

Table 1 - Details of the three reactors composing the DS<sub>Smoke</sub> model sequence.

	Length [mm]	Diameter [mm]	Volume [mm <sup>3</sup> ]
Reactor 1	180	22	68389.2
Reactor 2	5	22	1899.7
Reactor 3	355	22	134878.7

The kinetic scheme introduced in the program for the thermal splitting of hydrogen sulphide has been developed by the group in the past years (Manenti et al., 2013). It is a revised model, introducing some modifications on H<sub>2</sub>S pyrolysis literature schemes (Binoist et al., 2003). The complete mechanism, validated on literature and industrial data, is presented in Table 2.

Table 2 - Kinetic parameters for H<sub>2</sub>S pyrolysis. Rate eq.:  $k=A \cdot T^{\beta} \cdot \exp(-E_a/RT)$  [m-kmol-s-K] (Manenti et al., 2013).

### 2.3. Process simulation

The detailed process simulation has been developed using Aspen HYSYS V11 suite. As a thermodynamic model, the SRK (Soave-Redlich-Kwong) equation of state has been chosen for the reactive section of the process, while the Aspen HYSYS amine package has been chosen for the separation section. The reactors present in the process are modelled as Gibbs Reactors.

The reaction is highly endothermic and takes place with an increase in the number of moles. So, it is favoured at high temperatures and low pressure. An H<sub>2</sub>S mass flow of 10 t/h enters the splitting reactor at 1000 °C and 180 kPa. Sulphur is removed by condensation. Residual sulphur vapours are then hydrogenated to produce H<sub>2</sub>S. The obtained gas stream (containing hydrogen in an amount equal to 83 mol% and unreacted H<sub>2</sub>S and H<sub>2</sub>S produced by the hydrogenation of sulphur vapours in an amount equal to 17

mol%) is treated in an amine scrubbing process employing  $2 \times 10^6$  kg/h of a DEA (25 wt%) water solution (Jamekhorshid et al., 2021). After a water removal step, the sweet stream contains pure  $H_2$  and can be sent to the compression train to reach the market pressure of 200 bar.  $H_2S$  is instead recirculated to the splitting reactor. The detailed process flow diagram is reported in Figure 1.

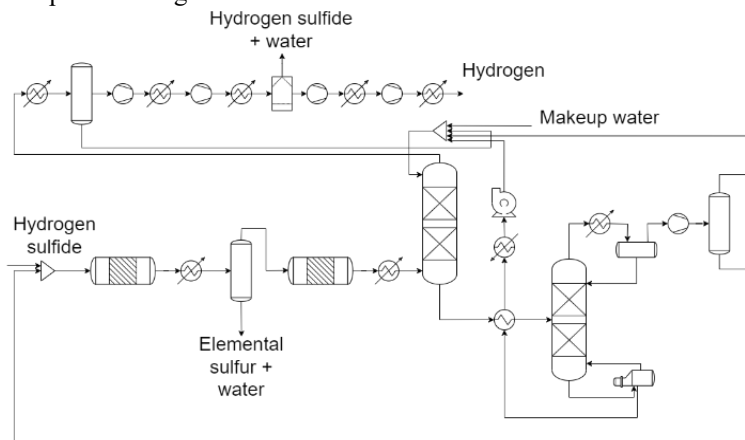

Figure 1 - Process flow diagram for  $H_2S$  conversion.

### 3. Results and discussion

#### 3.1. Experimental results

The reaction has been performed at 1 bar and with a stream of 2 L/h  $H_2S$  (1.5 wt%) in  $N_2$  as feed (to ensure a long residence time and therefore a thermodynamic regime of reaction). Tests at different temperatures has been carried out, obtaining the results summarized in Table 3. The conversions achieved are quite in line with the expected thermodynamic conversions (Kaloidas & Papayannakos, 1987). The error is due to the recombination that takes place at the exit of the reactor: above  $800^\circ C$   $H_2$  reacts with sulphur to give back  $H_2S$ .

Table 3 - Experimental  $H_2$  concentrations and conversions.

Temperature [ $^\circ C$ ]	$H_2$ concentration [mol%]	Experimental conversion [%]	Conversion at thermodynamic equilibrium [%] (Kaloidas & Papayannakos, 1987)
640	0.06	5	6
740	0.18	14	18
831	0.35	28	31
929	0.54	43	47
1016	0.71	56	61
1107	0.81	64	73

#### 3.2. DSmoke lab reactor simulation

The models realized are simulations of the  $H_2S$  splitting reaction performed in the lab reactor. Two temperatures have been considered: 1016 and  $1107^\circ C$ . The results reported in the previous section, 3.1, are an experimental validation of the models obtained with the software.

In Figure 2 and 3 it is possible to notice that along the length of the reactor the concentration of  $H_2$  increases and reaches a plateau, corresponding to the thermodynamical equilibrium. This condition is reached at a short length of the reactor (equal to 12 mm at  $1016^\circ C$  and 4 mm at  $1107^\circ C$ ), suggesting that, in the considered operative regime, a more compact reactor could be a convenient design choice. At the

point of temperature drop (after a residence time inside the reactor of 30 s), the concentration of  $H_2$  starts to decrease, due to the recombination reaction. The temperature drop takes place in a 5 mm length; therefore, the quench is rapid, and the recombination reaction interrupts, fixing a final value for the  $H_2$  concentration.

Figure 2 - Molar concentrations of  $H_2S$ ,  $S_2$ ,  $H_2$  at 1016 °C.

Figure 3 - Molar concentrations of  $H_2S$ ,  $S_2$ ,  $H_2$  at 1107 °C.

### 3.3. Process design

Considering the process scale, a conceptual design for a plant integrating a  $H_2S$  splitting step results to be significantly different from that of classical  $H_2S$  sequestration and conversion processes. This is due to the high concentration of  $H_2S$  that characterises the process streams. In particular,  $H_2S$  is present as a pure component in the feed. This results in a difficult separation of the unreacted  $H_2S$  and in an extremely energy-intensive regeneration step.

In a simulation with the characteristics described in section 2.3, the production is equal to 8666 kg/h of elemental sulphur and 543.8 kg/h of hydrogen. The process is characterized by a considerable  $H_2S$  recycle, consisting of 48340 kg/h. This aspect has a

huge impact on the operative costs of the plant, but at the same time makes the complete conversion of  $\text{H}_2\text{S}$  into  $\text{H}_2$  and  $\text{S}_2$  possible. Water as well can be recirculated inside the plant, exploiting the streams coming from the condensation steps. This allows to reduce the needed amount of makeup water to 110.5 kg/h. The steam consumption, particularly the one related to the regeneration column reboiler, is high, equal to  $1.843 \times 10^5$  kg/h. A possible point of improvement could be represented by an optimisation able to reduce the energy consumption at the regeneration step.

An economic analysis has also been performed, by calculating the cost of the utilities associated with the treatment of  $\text{H}_2\text{S}$  in the simulated plant. The total OPEX are 1301.18 \$/h. Considering the obtained  $\text{H}_2$  productivity of 543.8 kg/h,  $\text{H}_2$  production cost is 2.39 \$/kg. In Europe, this price is lower than the average price of  $\text{H}_2$  produced through electrolysis (3.6 \$/kg) and is almost equal to the price of  $\text{H}_2$  produced from natural gas (EIA, 2019).

#### 4. Conclusions

In this work a multi-scale approach has been applied to the development of a process layout for  $\text{H}_2\text{S}$  thermal splitting, including the kinetics, the reactor modeling and the plant design. As future development, DSmoke will be integrated into Aspen Hysys as CAPE-OPEN tool, in order to better combine the different scales and to optimize the process.  $\text{H}_2\text{S}$  splitting could really contribute to improving the performances of refineries, biorefineries and other industrial plants, since it changes the role of  $\text{H}_2\text{S}$  from waste to commodity.

## Abstract

This paper addresses the use of pyrolysis to reduce carbon footprint of several waste material as agricultural waste plastic (AWP). The destination of such residues was usually landfills, but there is a high potential for the obtention of high added value products after the pyrolysis process is completed, with the added benefit of reducing the carbon footprint and then accomplishing objectives of circular economy. Argentina's energetic matrix relies on the use of natural gas, which is abundant, so there is no compromise with the energy demand, however, the production of fuels from waste brings financial and environmental benefits, thus being highly attractive. Pyrolysis is a multifunctional process, and the indirect "avoided" impacts associated with the production of energy that substitute primary one can be considered (Giugliano et al., 2011).

Different paths for the treatment of the pyrolyzed material can be taken, as well as different pretreatment paths. Also, the possibility of mixing the feedstocks is considered, being the composition one of the key variables for the economics of the process. The objective function for the optimization considers environmental aspects as the reduction of CO<sub>2</sub> emissions. The potential carbon footprint emissions of pyrolysis process are calculated and compared to incineration and recycling processes. Results show that pyrolysis rises as the best alternative for reducing the carbon footprint, not only because CO<sub>2</sub> emissions are highly reduced, but also because the products are a fossil fuel replacement when the appropriate paths for pre and post treatment are used. Limitations are related to the composition of the residue to be treated.

**Keywords:** Pyrolysis, GHG emissions, circular economy

## 1. Introduction

The management and disposal of agricultural waste plastic (AWP) in the southwest region of Buenos Aires, Argentina, has become an environmental challenge. This waste is mainly composed of empty agrochemical containers and silo bags. As it is relatively easy to separate both sources of residues, silo bags can be physically recycled as they are made of polyethylene, and they do not contain any toxic component. Agrochemical containers, however, cannot be recycled with ease because they are contaminated with the pesticides or fertilizers used and no real solution has been found for the end of life of this waste. Recently, industry was interested in chemical recycling of waste plastic, mainly to decrease the carbon footprint and to be in line with circular economy (Kruger, 2020).

According to ISO 15270 (2008), pyrolysis is one of the four methods of chemical recycling, which transforms plastics back into basic chemicals by thermal decomposition at elevated temperatures, where usually all the plastic additives and contaminants are also converted back into basic chemicals. The pyrolysis products, liquid and gas, could be used as feedstock in chemical industry substituting conventional fossil-based energy or product, but technologies are still in early stages for industrial scale use. The advantages are the potential to improve the recycling rate of plastics, as well as reducing fossil fuels demand for energy and GHG emissions. All of these is aligned with circular economy principles.

The goal of this study is to analyze pyrolysis of AWP as an end-of-life treatment, comparing it with other popular options, i.e. incineration. The carbon footprint of each option will also be calculated, depending mainly on the temperature of the thermal process if applicable (Gasification, incineration, pyrolysis) but the carbon footprint for disposing the AWP in landfills will also be calculated. For the pyrolysis process the optimal process temperature, the amount of utilities used for heating (e.g. natural gas for the pyrolysis reactor, if the pyrolysis gas results insufficient as fuel for this heating requirement) and for the condensing units will be found solving a nonlinear programming problem. Being the feedstock a residual material from other economic activities the price is very low or can be neglected in some cases. A comparison between two other different treatments for the residues (incineration and mechanical recycling) is presented. Between the main objectives, the calculation of CO<sub>2</sub> emissions and carbon footprint together with energy production and economic aspects was considered. Calculations of emissions were made using the 2006 Intergovernmental Panel on Climate Change (IPCC) guide, published data and data obtained in the context of the present study. Manfredi et al (2011) show that GHG emissions are lowered using pyrolysis opposite to other thermal treatments.

## 2. Materials and methods

Experimental data are required to adjust parameters of the models used for the simulation and optimization of the process. Pyrolysis of AWP is carried out in a bench scale reactor, at 500°C, under 5cc/min of N<sub>2</sub> flow (Figure 1).

Figure 1: Pyrolysis bench scale reactor.

The products are a liquid, a gas, and a carbonaceous co-product. The products are characterized in the *context* of their use for generating thermal and electrical energy. The solid co-product was studied in order to determine the possible presence of toxics (metals, Polyunsaturated Aromatic Hydrocarbons, Polycyclic Aromatic Hydrocarbons PHAs) The characterization tools are thermal analysis (DSC/TGA), elemental analysis, lower heating value (LHV) and viscosity measurements and gas chromatographic associated to mass spectroscopy detection

(GC/Mass) analysis. CO<sub>2</sub> equivalent emissions are calculated using these results. Pyrolysis technology is compared to both mechanical recycling and incineration of plastic, considering CO<sub>2</sub> emissions. In addition, the energetic efficiency of the pyrolysis

process of AWP is calculated, considering the liquid and gas products as alternatives to fuel- oil and natural gas respectively.

The liquid and the char were analyzed to find their composition. The carbonaceous solid was practically free from transition metals, with only 120 ppm of iron. The presence of PAHs was not detected.

Liquid and gas are rich in saturated and non-saturated hydrocarbons, showing only trace amounts of oxygenated compounds. While gas is postulated to be a thermal source for the pyrolysis endothermic process, liquid is envisaged as a substitute of heavy fuel-oil, or at least for the formulation of blends with liquid fossil-based fuels.

From experimental values a simulation model is built for the pyrolysis reactor together with the mill used to chip the containers and the separation sector to obtain char, liquor and gas. Mass and energy balances are posed for all the equipment. This model is used for the optimization of the process. To model the process, yields of liquid, gas and char were correlated vs. temperature of reaction, so this temperature could be used as optimization variable.

The yields % as a function of the temperature are then used to find the flowrates of char, liquid and gas products. Those are found from the experimental values as functions of temperature  $T[^\circ\text{C}]$  as:

$$\text{Liquid yield \%: } y_{LIQ} = -1.50\text{E-}03 T^2 + 1.47 T - 2.99\text{E+}02 \quad (1)$$

$$\text{Char yield \%: } y_{CHAR} = -1.00\text{E-}05 T^3 + 1.63\text{E-}02 T^2 - 8.85 T + 1.60\text{E+}03 \quad (2)$$

$$\text{Gas yield \%: } y_{GAS} = 1.65\text{E-}03 T^2 - 1.61 T + 4.29\text{E+}02 \quad (3)$$

Char yield has been approximated with a cubic function as it presents a plateau between 500-550 °C, to represent with fidelity the experimental behavior. A process schematic is shown in Figure 2. For illustrative purposes only one condenser is shown, but due to the high temperatures of the gas three units are used, with different cooling media (Dowtherm© for the first heat exchanger, where the gas is cooled with no phase change, Dowtherm© to condense up to 100°C, and cooling water for the subsequent unit. Final temperature of the process streams leaving the condenser is approximately 80°C).

Global mass balances for the pyrolysis products:

$$M_j = M_{feed} y_j / 100; j = LIQ, GAS, CHAR \quad (4)$$

being  $M_j$  the amount of liquid, gas or char obtained from the pyrolysis reactor after the condensation step takes place.

Energy balances for the process are also posed, together with the equations that allow calculating the energy requirements of the rest of the equipment.

### 3. Results

The analysis of the scenario corresponding to the accumulation and location of AWP in the region under study indicates that a plant for processing 4t per day is feasible, so this will be used as a calculation basis ( $M_{feed} = 4$  t/day).

Equipment dimensions were calculated for the requirements of the process. The condensing unit is composed of several heat exchangers as the gas leaves the pyrolysis unit at the pyrolysis temperature (between 450-650 °C) as different refrigeration utilities will be used in each step. This total cost of the process can be calculated using this information.

Figure 2: Process schematic for a standard pyrolysis process.

Figure 3: Yield of products from pyrolysis

Figure 3 shows the global liquid, gas and char yields for different pyrolysis temperatures as presented in Eqs. 1 to 3. The liquid product is maximized for a temperature around 500°C. It will be assumed for the purpose of obtaining the process model that the yields for a pilot scale reactor will be like the experimental ones. For approximately 500 °C, which resulted to be the optimum temperature for maximizing the liquid production, it was obtained experimentally that LHV was 49,6 MJ/kg for the liquid and 46,9 MJ/Kg for gas. It was found that those values do not change significantly between process temperatures ranging from 450 to 600°C as the amount of products change with temperature, but not the composition. Gas LHV is used to calculate the heat generated for the pyrolysis process. This could replace partially the equivalent of fossil-based fuel-oil traditionally used for energy production in thermoelectric plants in the region, with a consequent decrease in CO<sub>2</sub> eq. emissions (7.74 t of CO<sub>2</sub> avoided per day).

Figure 4: Energy obtained from the products

Table 1: Products distribution for the whole process

T (°C)	Liquid [kg/day]	Gas [kg/day]	Char [kg/day]
450	2000	1520	480
500	2400	1400	200
550	2200	1620	180
600	1680	2200	120

The incineration of AWP, without energy recovery produces 4,61 [t CO<sub>2</sub>/t of plastic]. (O. Eriksson and G. Finnveden, 2009). Thus, the pyrolysis gas, used as the energy source of the recycling process originates 3.76 t CO<sub>2</sub> / t AWP per day, being the net CO<sub>2</sub> emission -4.0 t CO<sub>2</sub> per day.

For our process it is found that 4 t CO<sub>2</sub>/day are avoided compared to incineration.

Regarding the use of the products as energy source, from Figure 4 it is shown the compromise between the production of liquid (which can be further used to produce higher added value products or can be injected in oil ducts as its characteristics are similar to light crude) and the production of gas that can be used as a fuel substitute to process the AWP. In any case, it must be noticed that producing plastics requires less energy than disposing them. Regarding the Sustainable Development Goals, it is tempting to conclude that the solution for the problem of pollution due to plastics should be banning them. But this will collapse with another objective of Zero hunger, as the petrochemical industry is tightly linked to the food related industry, apart from being counterproductive (Creadore and Castaldi, 2022)

#### 4. Alternatives for processing

The study has been conducted using chipped agrochemical containers, made from polyethylene. Alternative sources for the feedstock can be considered:

1. Gas can be used to generate energy for the reactor instead of using fossil-based fuel, as shown in this paper
2. Liquid can be used as a fuel for the reactor, in which case there will be a remnant of gas.
3. As the amount of energy required for the pyrolysis process can be between 4 and 10 MJ/t, an analysis can be made of the external requirements as the energy required increases (for example when more gas is produced to decrease or even eliminate the need of an external source for fuel).
4. If there is biomass present in the residue (sometimes the containers are labeled and the paper is not separated beforehand, so it is chipped together with the plastic giving a mixed residue) LHV decreases. For example, for 10% biomass, LHV decreases 5%.

Several scenarios can be included within the model to compare the emissions and the cost of the process. If the objective is to decrease emissions, the objective function is to minimize t CO<sub>2</sub>/t AWP as shown in this work.

## 5. Conclusions

Chemical recycling by pyrolysis represents a solution to the environmental problem associated with the end of life of AWP.

The impacts on environment are positive since liquid and gas products generate energy with a negative CO<sub>2</sub> emission balance.

Emissions due to incineration are avoided and at the same time, replacement of fossil-based fuel by pyrolysis liquid originates a significant decrease in CO<sub>2</sub> emissions.

Apart from the numerical results, from the experiments the carbonaceous co-product has no toxic components, thus it could be disposed in soils without producing negative impacts. These results can be compared to the other possible processes to dispose AWP,

- Landfills: 0,25 kg CO<sub>2</sub>/kg plastic,
- Waste-to-energy processes 2,20 kg CO<sub>2</sub>/kg plastic.
- Mechanical recycling emissions are alike to those of landfills, 0,2 kg CO<sub>2</sub>/kg plastic.

If the pyrolysis gas is used to generate electricity, emissions are neglected as it is used to replace a fossil fuel.

Studies are being conducted to analyze the impact of this solid product from pyrolysis on the crops when used to improve soil which are beyond the scope of this work. Future work is also related to the development of processes for adding value to the liquor. Also, studies for scaling up the process are being conducted, because of the availability of data.

## Abstract

The objective of the present work was to assess the impact on the environment of a biofuel produced through lignocellulosic biomass liquefaction through a Life Cycle Assessment (LCA). Using *SimaPro* software, the Product Environmental Footprint (PEF) methodology was used to calculate the global environmental impact. The system was expanded to consider the credits of petroleum coke replacement. The effect of the type of solvent used in the liquefaction process was studied, as well as the possibility of operating the pilot plant in continuous mode.

**Keywords:** Biomass liquefaction, biofuels, environmental impact, Life Cycle Assessment, *SimaPro*.

## 1. Introduction

In response to the challenges of climate change, the European Green Deal (2019) set the goal of transforming the European Union (EU) into a resource-efficient and carbon-neutral economy, mobilising the industry for a clean and circular economy. In this context, the EnerGreen project, developed by Cimentos Maceira e Pataias, S.A., built a pilot plant to produce advanced biofuels from biomass-derived waste to replace the usage of petroleum coke in a clinker's kiln.

The main objective of this work was to carry out an LCA study that analysed the environmental impact of bio-oil production through the liquefaction of lignocellulosic biomass using the *SimaPro* software. The effect of the life cycle stages of the bio-oil was studied and evaluated to define which steps of the process are the main contributors to the environmental impact and which impact categories are the most affected. Two different biomass sources were compared, eucalyptus and sludges from the paper industry, at BATCH and later at continuous operating conditions.

The LCA method used for this purpose was the Product Environmental Footprint (PEF), available in *SimaPro* software. This methodology is the most suitable to use in this study since its results consider the European citizens' average impact as a reference.

## 2. Methods

### 2.1. Goal and Scope

The LCA study presented in this work has been conducted according to the ISO 14040/44 guidelines (2006a, 2006b), following an attributional approach. The study was conducted in a cradle-to-gate scope, considering the operation of the units (material and electric and thermal energy usage). On the other hand, energy and materials related to the construction of the processing units are not included in data inventories.

The inventory data was obtained from the biomass liquefaction pilot plant installed at Secil – Maceira e Pataias to produce 1GJ of energy. The Ecoinvent 3.6 database is used for the background data assuming the Portuguese context.

### 2.2. Life Cycle Inventory

In the liquefaction process (Figure 1), the biomass is fed to an endless screw, undertaking a pre-treatment process. Here, the biomass is pre-heated and sprayed with the solvent, 2-ethyl hexanol (2EH), undergoing a process of swelling, where the volume of the cells increases, breaking the cellulosic and lignocellulosic membranes, facilitating the access of the catalyst to all components of the residue. The liquefaction process takes place inside the stirring reactor at a temperature between 130 and 250 °C in the presence of an acid catalyst, p-toluene sulfonic acid.

The reactor is equipped with an external jacket, where the gases from liquefaction (mainly steam) circulate. The gases also go through a hollow conveyor outside the endless screw to pre-heat the feed and are condensed afterwards.

Figure 1 – Biomass liquefaction facility installed in Secil – Maceira e Pataias.

The lower calorific value (LCV) of the liquefied biomass was calculated as the pondered average of the components' LCV present in the reactive mixture and used to assess the amount of bio-oil equivalent to 1 GJ of energy. The results are presented in Table 1, together with the values for petroleum coke.

Table 1 - Mass of fuel to obtain 1 GJ of energy.

	LCV (GJ/ton)	Mass (kg) to 1 GJ
Bio-oil from Eucalyptus	21.1	47.5
Bio-oil from Paper Sludges	15.7	63.7
Petcoke	31.3	32.0

Table 2 presents the data inventory introduced in *SimaPro* to produce bio-oil from eucalyptus and paper sludges in BATCH and continuous operating conditions. Since biomass sources are residues, they were considered to have zero impact and weren't introduced in *SimaPro*.

Table 2 – Data introduced in *SimaPro* for the liquefied biomass from eucalyptus and paper sludges for BATCH and continuous mode.

Inputs and outputs	Eucalyptus		Paper Sludges	
	BATCH	Continuous	BATCH	Continuous
<i>Inputs</i>				
Solvent (kg)	29.8	3.7	208.7	3.9
Catalyst (kg)	1.1	0.5	4.0	0.4
Fuel (kg)	0.8	6.8	1.2	0.8
Transport (tkm)	5.3	43.3	15.9	10.1
Electricity (kWh)	2.0	16.3	3.0	1.9
<i>Outputs</i>				
Bio-oil (kg)	47.5	47.5	63.7	63.7
Condensed water (l)	19.9	210.3	139.1	132.8
<i>Avoided products</i>				
Petroleum coke				32.0

### 2.2.1. Introduction of p-toluene sulfonic acid and 2-ethyl hexanol in *SimaPro*

As p-toluene sulfonic acid and 2EH are not available in the Ecoinvent database, these two components' environmental impact must be estimated. To create this molecule, the RREM method was used (Huber et al., 2022), which consists of four steps: general research on the chemical process, setting up the reaction equation, researching the required thermal energy, and modelling the dataset. Toluene sulfonic acid, the catalyst, is synthesised from a reaction between toluene and sulfuric acid with a molar ratio of 1:1.

The values introduced in *SimaPro* (Table 3) correspond to their respective molar masses, considering a yield of the reaction of 100 %. As the energy for this reaction was not found in the literature, it was assumed that 1 kg of product needed 1.8 MJ to be created (Huber et al., 2022).

Based on the synthesis of 2EH via butanol (BuOH), the same procedure applied to the catalyst was used. The synthesis of 2EH via butanol through the Guerbet reaction starts with a dehydrogenation of butanol followed by aldol condensation and hydrogenation of the unsaturated condensation product. A bifunctional catalyst, characterised by a dehydrogenating/hydrogenating metal species and a basic component, is required for this reaction to occur. Homogeneous catalysts at 120°C based on phosphine complexes of different transition metals (Rh, Ru, Ir, Pt, Pd, and Au) are used in the Guerbet self-condensation of BuOH.

Based on stoichiometric production reactions of p-toluene sulfonic acid and 2EH and molar masses, the following inputs in Table 3 were inserted in *SimaPro*.

Table 3 – Inputs and outputs of p-toluene sulfonic acid and 2-ethyl hexanol in *SimaPro*.

p-toluene sulfonic acid system		2-ethyl hexanol system	
<i>Inputs</i>		<i>Inputs</i>	
Toluene	92.14 g	Palladium	0.58 mg
Sulfuric acid	98.08 g	1-butanol	74.12 g
Heat from steam	0.05 MJ	Heat from steam	0.7 MJ
<i>Outputs</i>		<i>Outputs</i>	
p-toluene sulfonic acid	172.02 g	2-ethyl hexanol	130.23 g
Wastewater (water emission)	1.25 ml	Hydrogen (air emission)	2 g
		Wastewater (water emission)	18 g

### 3. Results

The environmental impact of the liquefied biomass was evaluated using the PEF methodology, and the results are presented in Figure 2. The total impact score of both cases is positive. Since the petcoke replacement credits were considered, this means that the impact of both bio-oils is higher than that of petcoke, and thus, they are not suitable as a substitute.

Bio-oil derived from eucalyptus presents a much lower impact score than the one derived from paper sludges. This fact is justified mainly because the first presents a much higher LCV than the latter, meaning that more significant amounts of paper sludge-derived bio-oil are necessary to produce 1 GJ.

Figure 2 – Comparison of the weighting values of impact categories of liquefied biomass with PEF method detailed by impact categories and contribution of processes with the petcoke credits.

In both cases, the impact categories that stand out the most are the use of fossil resources, climate change and the use of minerals and metals resources. These results are due to the manufacturing process of 2EH, which uses minerals, metals and fossil resources, and consequently will release prejudicial compounds to the environment that contribute to climate change.

### 3.1. Influence of glycerine in the solvent

Since the solvent used in the liquefaction process is the main contributor to the environmental impact of the bio-oil produced, new alternatives were searched to substitute 2EH. A component that may be part of the solvent is glycerine, which influences the solvent's behaviour. Using glycerine with 2EH improves the homogenisation of the medium and makes it possible to increase the process conversion and obtain added-value products with nitrogen. Glycerine derived from waste cooking oil biodiesel plants was selected since it had the lowest impact of all the available options in *SimaPro*.

Figure 3 presents the results of the environmental impact score of bio-oil with different proportions of 2EH and glycerine mixtures.

Figure 3 – Impact of glycerine from waste cooking oil on the bio-oil environmental impact. LCV is in GJ/ton.

As expected, the substitution of 2EH is beneficial to decrease the environmental impact of the liquified biomass. On the other hand, adding glycerine reduces the LCV of the resulting bio-oil, which might limit its utilisation in a clinker's kiln.

### 3.2. Continuous operation

A new environmental impact evaluation was performed, this time considering the liquefaction process operates in continuous mode (currently, the liquefaction pilot plant operates in BATCH), where less solvent is necessary per kg of bio-oil.

The results obtained in continuous operation (Figure 4) have a lower impact, associated with other benefits like less labour-intensive or less processing and holding time.

Considering the environmental impacts of bio-oil, the liquified biomass from eucalyptus has a higher impact. This is a consequence of the smaller amount of solvent used per kg of bio-oil.

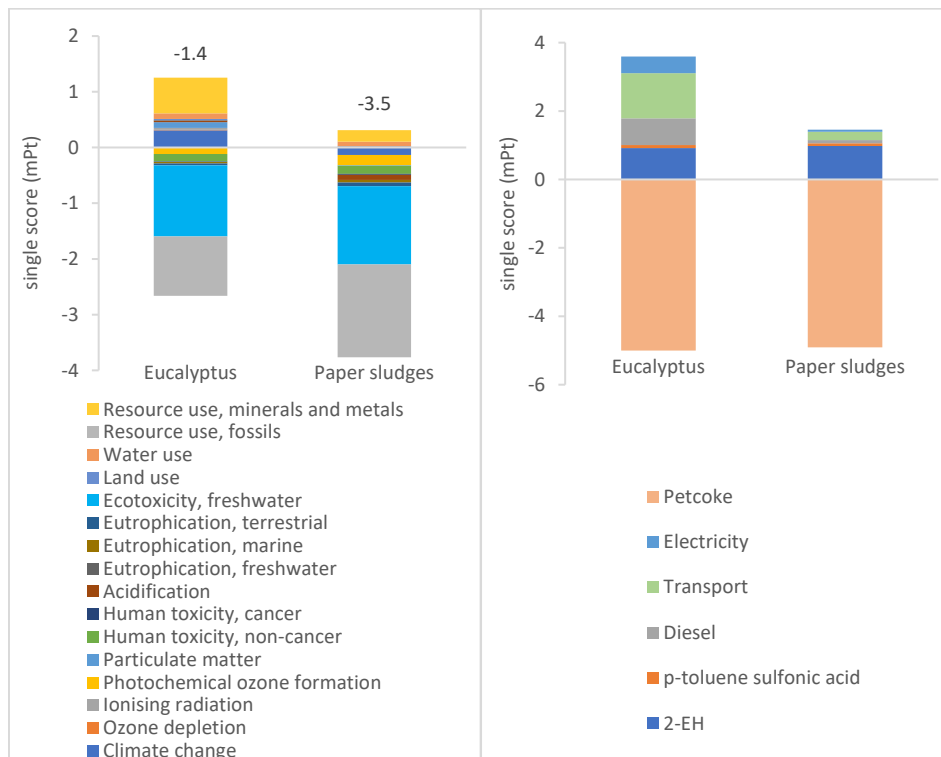

Figure 4 – Comparison of the weighting values of impact categories of liquefied biomass with PEF method detailed by impact categories and contribution of processes with the petcoke credits.

#### 4. Conclusions and Future Work

The main objective of this work was to evaluate the impact of the liquefied biomass production process. Different scenarios, such as working conditions, biomass source and glycerine presence, were studied. Based on the analysis, it can be concluded that it is possible to obtain a bio-oil suitable to replace petroleum coke if the unit is operating continuously. Eucalyptus residues are preferred as biomass sources because they form a bio-oil with a higher LCV. Adding glycerine as solvent up to 75 % is beneficial for eucalyptus-derived liquefied biomass, reducing the environmental impact while maintaining a reasonable LCV of the bio-oil. In the future, more studies on the impact of p-toluene sulfonic acid and 2EH should be done to decrease the uncertainty of the results.

## Abstract

Using alternative carbon sources (ACS) to produce downstream derivatives (DDs) is a promising option for defossilising the chemical industry. However, the potential consequences of using ACS in interconnected petrochemical clusters are generally overlooked. This paper aims to develop a methodological approach for systematically analysing defossilisation impacts at the value chain level. For this, a single value chain for producing methyl-tert-butyl-ether (MTBE) was used as a case study. The individual components of the value chain were modelled in Aspen Plus v12. Both ACS- and fossil-based value chains were compared in terms of (i) changes in the structure of the value chain and (ii) the magnitude of the impacts. The results show that the defossilisation of a single value chain causes additional impacts at the cluster level.

**Keywords:** Industrial defossilisation, downstream derivatives, interconnected cluster.

## 1. Introduction

The chemical sector is highly dependent on the usage of fossil carbon as feedstock for the production of chemicals (Nesbitt 2020). The launch of the EU chemicals strategy for sustainability has triggered the chemical industry to look for innovative solutions toward a green transition. One of the possible solutions is to defossilise the chemical industry by replacing fossil-based feedstock with alternative materials (EC 2020). Alternative carbon sources (CO<sub>2</sub>, biomass, waste) are increasingly considered as alternative feedstocks for bulk chemicals production (i.e. ethanol, methanol, ammonia). However, there is less research on the potential of defossilising downstream derivatives (DDs) (Moncada, Posada, and Ramírez 2015). DDs are the chemicals present at the end of value chains before they are distributed to potential customers, for instance, styrene, acetone, or polyvinyl chloride (Kramer et al. 2017).

DD's value chains are usually integrated into large petrochemical clusters (Porter 1998), through symbiotic relationships inside and between value chains within the clusters (Chertow 2000). The defossilisation of one DD process will likely affect other processes inside the value chain and within the cluster. Thereby, making uncertain what the total impact on the performance of the value chain and cluster could be. The goal of the current work is to develop and test a methodology to analyse how using alternative carbon materials for defossilising a single DD value chain can affect its existing interactions and performance in a petrochemical cluster. For this paper, MTBE (methyl tert-butyl ether) was selected as a case study.

## 2. Methodology

This paper departs from an in-house model of a representative petrochemical cluster. The model mimics a real petrochemical cluster and it is based on the 6 industrial sites of the Port of Rotterdam (PoR) petrochemical cluster (Ramirez-Ramirez 2019). The model includes a total of 22 plants with the production of 52 chemicals classified in 9 subclusters. Each plant was modelled in Aspen Plus v12, and the interconnections are modelled in an interface. The subclusters are chlorine, methanol, ethylene, propylene, ammonia, aromatics, olefins, bio-based and other chemical-based subclusters.

The representative cluster contains a diverse range of chemicals. In this paper, chemicals produced in the cluster are presented as follows (Figure 1): feedstock (F), auxiliary chemicals (AC), chemical building blocks (CBBs), commodity chemicals (CCs), and downstream derivatives (DDs). All these chemicals are interconnected by mass, energy and or waste flows. The connectivity of the value chain is represented by the number of mass flows interconnections within value chain boundaries (i.e. horizontal connections) and the number of subclusters involved in the production of a single DD (i.e. vertical connections). The methodology contains four main steps which are discussed below.

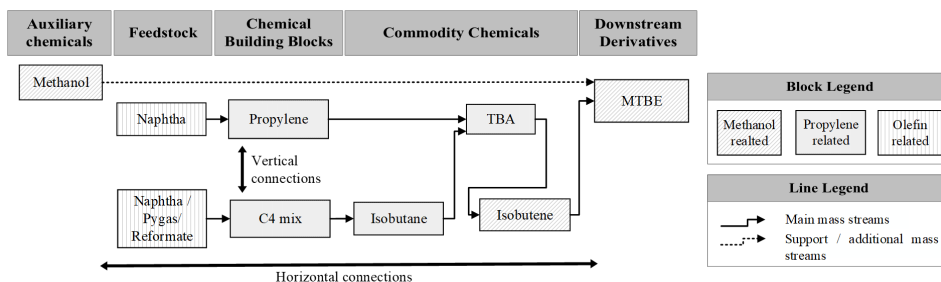

Figure 1: Schematic representation of MTBE value chain with existing mass flow interconnections.

### 2.1. Selection of key downstream derivatives

The representative cluster contains 13 DDs but not all of them have a large potential for defossilisation. Therefore, the selection of the most promising DDs was made based on three criteria: (i) embodied carbon, (ii) connectivity of the components in the value chains and (iii) availability of data of the ACS-based routes in the literature.

First, the amount of embodied carbon was assessed for each DD to identify the most promising derivatives for defossilisation. Embodied carbon (EC) is defined as the elemental carbon embodied in material flows of chemicals entering specific stages of production to meet process needs (Eq.(1)). For the assessment of embodied carbon, data was collected from each DDs' Aspen Plus model of the representative petrochemical cluster. The embodied carbon of each DD was calculated as follows:

$$EC_{DD} = \sum_{i=1}^n M_i * C_{wt\%_i} \quad (1)$$

where  $i = (1 \dots n)$  – number of material flows entering the production process of the DD;  $M_i$  – inlet capacity of particular material flow, ktonne/year;  $C_{wt\%_i}$  – weight percent of fossil-based carbon embodied in the chemical, %.

The next step involved identifying the existing connectivity of mass flows within value chains and representative clusters. This was done by mapping the network, i.e.,

identifying the interconnections (i.e. mass flows) between chemicals, and the connectivity of each value chain was assessed in terms of horizontal and vertical interconnections.

Last, a literature screening was performed to identify ACS-based production routes (i.e. from CO<sub>2</sub>, waste, biomass). Information was collected for each ACS-based route with a technology readiness level (TRL) of 4 or higher.

Based on three selection criteria, potential DDs were selected for further research. To evaluate the available defossilisation pathways (i.e. ACS-based routes) and develop the methodology to assess subsequent impacts at the value chain level, first, a single DD value chain (i.e. case study) was selected.

### *2.2. Selection of ACS-based route for the case study*

This step involved the selection of the most promising ACS-based production routes for the case study. Routes were further screened in terms of data availability (i.e. the more data, the better), type of options (i.e. thermochemical, electrochemical, biochemical and the process conditions, e.g., mild conditions were preferred over stringent conditions), complexity (i.e. the number of process steps, the fewer steps the better), and scalability. The routes were then ranked and the most promising option was selected for further study.

### *2.3. Process modelling of ACS-based route*

The selected ACS-based route was then modelled at the scale (i.e. capacity) and purity of the current fossil process. Here it is assumed that the alternative route will replace one-to-one the amount of product produced by the fossil-based route. For this, the development of the process flow diagram and Aspen Plus v12 model was done based on data collected for the selected ACS-based route. The model was assumed to be in continuous mode with a whole year of operation (i.e. 8000 hours per year). Properties for biomass components were introduced into Aspen Plus simulation by the usage of biomass property databases developed by the National Renewable Energy Laboratory (NREL).

### *2.4. Defossilisation impacts analysis*

Value chains can be represented graphically as a network, with nodes and links. Nodes refer to chemical processes involved in the value chain, while links represent material, waste and or energy flows between the nodes. Networks were developed for fossil- and ACS-based value chains of the case study, which allow to study changes that would occur when replacing a fossil-based process, a node, in the network with ACS-based process. Structural changes in nodes and links were categorized, as (i) removed - no longer required, (ii) affected - required, but capacities are changed, (iii) unchanged - required, capacities remain the same, and (iv) added – required, to be added (i.e. new chemicals/flows).

It is expected that structural changes in the value chain will affect its total performance. To quantify the magnitude of these impacts the following techno-economic and environmental KPIs were selected: (i) production rates, (ii) fossil-based carbon offset (i.e. the amount of fossil embodied carbon replaced by alternative carbon), and (iii) additional investment needed. Based on these indicators, the ACS-based value chain of the case study was assessed and compared to the fossil-based counterpart.

## **3. Results and discussion - MTBE case study**

### *3.1. Selection of case study – MTBE*

Based on the methodology for the selection of DDs presented in Section 2.1, 6 DDs were selected (see Table 1). First, priority was given to DDs with embodied carbon of

> 40 ktonne/year. Then, chemicals were examined in terms of connectivity and availability of ACS-based routes. DDs with a higher number of vertical connections were preferred because changes in the value chains of those DDs will more likely result in a higher probability of impacts at the cluster level. MTBE was selected as a case study. As can be seen from Table 1, it has high EC, is highly interconnected within the value chain and cluster, and has a wide range of ACS-based routes present in the literature.

Table 1: Key downstream derivatives.

Downstream Derivatives <i>name</i>	EC* <i>kt/y</i>	Connectivity		ACS-based routes			Research <i>selected</i>

### 3.1.1. Fossil-and ACS-based MTBE

MTBE is used in the fuel industry as an additive to increase the octane number. Conventionally, it is produced from a chemical reaction of methanol and isobutene. In the representative cluster, MTBE is produced in the amount of 400 ktonne/year. For its production, methanol and C4 mix are purchased from outside the cluster. Propylene is obtained from the cluster's olefin plant. Isobutane and tert-butyl alcohol (TBA) are produced within the propylene subcluster of the representative cluster (Section 2).

From the literature, the biomass-to-isobutanol-to-MTBE synthesis process was selected based on economic and technical constraints. The process involves different stages: (i) conversion of biomass to sugars through ethanol-based organosolv, (ii) enzymatic hydrolysis and fermentation of isobutanol, (iii) dehydration of isobutanol to isobutene, and (iv) conversion of isobutene to MTBE (Moncada, Posada, and Ramírez 2017). Ethanol is required as a solvent in a quantity of 5 L per kg of dry biomass and is completely recycled in the process. Simplified block diagrams of both fossil- and ACS-based value chains of MTBE are presented in Figure 2.

### 3.2. Defossilisation impacts analysis

Figure 2 shows a qualitative comparison of major changes in the structure of mass flows of MTBE value chain after defossilisation. Nearly 60% of the structure of MTBE value chain is changed. TBA, isobutane, C4 mix, and propylene are no longer required inside value chain and therefore their use is reduced by 100%. However, an additional chemical, ethanol, is needed as a solvent for isobutanol production. Although the quantity of ethanol is high, it is fully recovered within the value chain. Here, it was assumed that it does not affect the value chain carbon offset rate. The fossil-based carbon offset was calculated as the amount of alternative carbon replacing fossil embodied carbon of MTBE. The latter is a sum of fossil-based carbon embodied in material flows of isobutene and imported methanol entering the MTBE process. The fossil-based carbon offset is 80 %, as fossil-

based isobutene is completely replaced by an alternative one. Economic performance is also affected. Based on ongoing modelling work, additional investment is roughly 15% of the bare equipment costs of MTBE fossil-based value chain.

Figure 2: Simplified MTBE value chains with main mass flow interconnections for the production of 400 ktonne/year.

The majority of chemicals involved in fossil-based MTBE production are currently produced within the cluster and are involved in the value chains of other DDs (Table 2). Therefore, structural changes in the MTBE value chain will affect other value chains. For instance, tert-butyl alcohol is derived as a coproduct of propylene oxide production, requiring both C4 mix and propylene as feedstock materials. The defossilisation of the MTBE value chain will therefore affect the amount of C4 mix imported into the cluster as well as the isobutane and propylene capacities. Thereby impacting other DDs, such as styrene, and propylene glycol ether which also require propylene. The latter are highly interconnected within the cluster, resulting in further propagation of defossilisation impacts.

Table 2: Structural changes at the value chain and cluster level.

Chemical <i>name</i>	Present in the cluster				Required for MTBE value chain		Defossilisation impacts	
	<i>yes/no</i>	<i>*</i>	<i>**</i>	<i>kt/y</i>	<i>fossil</i>	<i>ACS</i>	<i>value chain</i>	<i>cluster</i>

Isobutanol	no	-	-	-	-	305	added	added

*\*B – is bought from the market, P- is produced within the representative cluster;  
\*\* involved in value chains of other DDs, yes/no.*

The impact assessment in this paper was done based on the changes in mass flows. However, to develop the full picture of potential impacts, it is crucial to also include impacts on energy and water flows due to defossilisation. This is part of the current research, which will be available at the time of the conference.

#### 4. Conclusions and future work

The defossilisation of a single DD can significantly have impacts beyond the process itself, especially in highly interconnected petrochemical clusters. This paper proposed a novel methodology for systematically analysing defossilisation impacts at the value chain level. The findings highlight the need for methodologies to be able to assess changes at the value chain level and their consequences at the cluster level (e.g. impacts on fossil-based carbon offset of other DDs due to defossilisation of MTBE). In future work, the ACS-based MTBE value chain will be assessed in terms of changes in energy and water flows and the methodology will be further developed to identify where the largest impacts in terms of defossilisation can be obtained in different DD value chains.

## Abstract

Methane side streams are produced in many different chemical processes and are normally combusted to provide process heat or to generate electricity. However, this practice is becoming less and less attractive as the industry strives towards net-zero targets and increasing the circularity of chemicals. Methane could instead be recovered and used as a valuable feedstock to produce other platform chemicals, such as H<sub>2</sub> or ethylene, which could be beneficial both for the economic performance and the carbon circularity of the system. In this work, seven different methane valorisation routes to produce additional chemicals are investigated. The considered routes include: i) five syngas-based routes combined with methanol synthesis and a methanol-to-olefins process; ii) plasma methane pyrolysis; and iii) oxidative coupling of methane. The results suggest that oxidative coupling of methane is the most profitable, with methane pyrolysis, tri-reforming and autothermal reforming also being more profitable in the base case. All routes have lower scope 1 and 2 emissions than the base case, however, dry-reforming and bi-reforming have the lowest emissions thanks to credited CO<sub>2</sub> feed streams.

**Keywords:** methane, olefins, hydrogen, techno-economic analysis, circular chemicals

## 1. Introduction

Methane is a by-product of many different chemical processes, including steam cracking for the production of olefins, pyrolysis and gasification processes, aromatic dealkylation and the anaerobic digestion of wastewater sludge. The most common use of these methane side streams is as a fuel, where it is combusted to either directly provide process heat or to produce additional electricity in a turbine. This use of methane helps chemical plants to close their energy balance and aids in their profitability. However, the chemical industry is moving towards a more sustainable future with both net-zero ambitions and carbon circularity at the forefront. The combustion of methane therefore becomes the antithesis of these goals due to the release of CO<sub>2</sub> and thus loss of carbon from the system (Lange, 2021). Additionally, methane itself is a potent greenhouse gas and a recent study discovered that flaring is less efficient than expected for the destruction of methane in oil and gas operations (Plant et al., 2022). The combination of these two factors reveals a critical need for alternative outlets for methane in the chemical sector.

A potential solution for this problem is using the methane as a feedstock to produce additional chemicals, such as H<sub>2</sub> or olefins. This would avoid the direct emissions from burning the side stream, but it would also maximise the value obtained from the feedstock in the original chemical process and improve the overall carbon circularity. In this paper, seven alternative processes are compared that convert methane into additional chemicals.

The routes considered are: i) five syngas-based routes which comprise of a methane reforming technology, methanol synthesis and finally a methanol-to-olefins conversion section; ii) a methane pyrolysis plant which decomposes methane into solid carbon and hydrogen; and iii) oxidative coupling of methane to produce ethylene. The main aim of this work is to conduct a comparative assessment of these seven methane valorisation routes by considering both their economic performance and their scope 1 and 2 emissions.

## 2. Methodology

Process flowsheets for the syngas-based routes, methane pyrolysis and oxidative coupling of methane were simulated using Aspen HYSYS® and are summarized in Figure 1. The results from these models are then used to perform a techno-economic analysis to compare the profitability of each route. A methane feed flowrate of 8 t/h was used in all routes, which is approximately the methane flowrate in an ethane steam cracker producing 700kt/y of ethylene (Belohlav et al., 2003). Note that a critical assumption made in this work is that separation units are already present and available in the base plant where the methane feed originates. Separation requirements were therefore assumed to be provided by the base plant and were not considered in this analysis.

### 2.1. Process Modelling

**Syngas-Based Routes:** These routes are comprised of three main sections: methane reforming; methanol (MeOH) synthesis; and MeOH-to-Olefins (MTO). In the reforming section, methane reacts with different oxidants to produce syngas, a mixture of carbon monoxide (CO) and hydrogen (H<sub>2</sub>). In this work, five different methane reforming options were considered: steam reforming of methane (SRM); dry-reforming (DRM); bi-reforming (BRM); tri-reforming (TRM); and auto-thermal reforming (ATR) (Arora et al., 2016). These reforming routes produce syngas at different CO:H<sub>2</sub> ratios as shown below:

All five of these reforming reactions were modelled in Gibbs reactors with the oxidants fed in their respective stoichiometric ratios. After the syngas has been produced, it is sent to the MeOH synthesis section, which is based on the work by Van-Dal and Bouallou (2013). Here, the syngas is cooled and then compressed to 78 bar via multistage compression with interstage cooling. The high-pressure syngas is sent to a packed bed isothermal reactor filled with a copper-based catalyst, where the syngas is converted into methanol via the following primary reaction:

Methanol and unconverted syngas are separated in a series of two flash vessels, with the syngas recycled to the reactor's inlet and the methanol sent to the MTO section. A purge is also present on the syngas recycle, which is sent to the base plant to recover any excess H<sub>2</sub>. The MTO section is based on the UOP/Norsk Hydro process, which consists of a recirculating fluidized bed reactor with a SAPO-34 catalyst along with a regenerator (Kuechler et al., 2000). Ethylene and propylene are the main hydrocarbon products, along with higher olefins, coke, H<sub>2</sub>, CO, CO<sub>2</sub>, alkanes and water. The higher olefins are sent to an additional olefin cracking process (OCP), which consists of a catalytic packed bed

reactor that converts the olefins into additional ethylene and propylene. The yields of the MTO and OCP reactors were taken from Hannula et al. (2015).

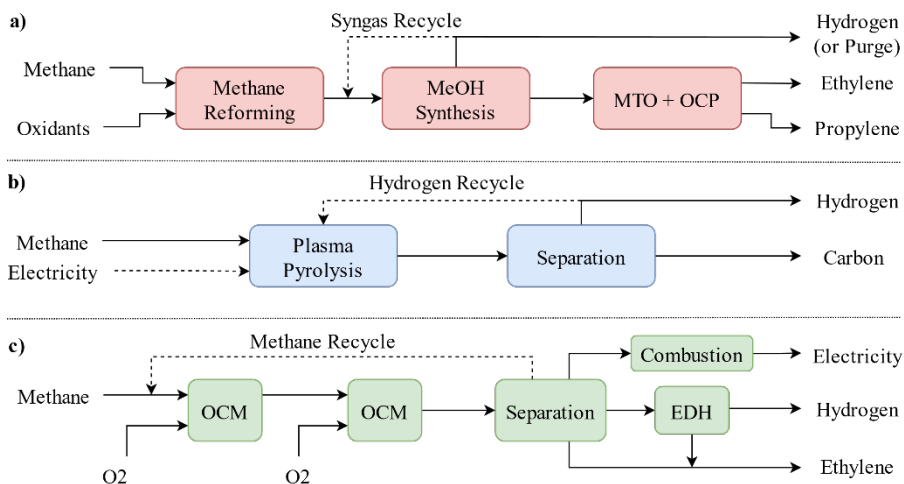

Figure 1: Schematic diagrams for the: a) syngas; b) plasma pyrolysis; and c) OCM routes

**Methane Pyrolysis (MP) Route:** In this route, methane is decomposed into its elemental components: solid carbon and H<sub>2</sub>. Multiple methods exist for the pyrolysis of methane and include using plasma, molten metals, catalytic conversion and thermal decomposition. In this work, the plasma pyrolysis route was modelled as it is the technology closest to commercialisation (Schneider et al., 2020). Methane is injected into a reactor vessel between carbon electrodes, which are fed with recycled H<sub>2</sub> and electricity to generate a plasma gas. The plasma reacts with the injected methane and decomposes into solid carbon and H<sub>2</sub> and was modelled using a conversion reactor achieving a 94% per-pass conversion (Hardman et al., 2020). Temperatures within the plasma reactor reach approximately 2100°C so the products are first cooled and then separated using cyclones and filters. If it is of sufficient quality, the solid carbon produced can be sold as ‘carbon black’, which is commonly used as a pigment and a reinforcing filler for tyre production.

**Oxidative Coupling of Methane (OCM):** This route has long been the subject of high industrial and academic interest for being able to produce ethylene directly from methane and for overcoming the highly endothermic nature of steam cracking. OCM is an exothermic process that is conducted over metal oxide catalysts at temperatures between 500-1000°C. The two primary reactions in OCM are first the formation of ethane via the oxidative coupling of methane (Eq. 8) and then the formation of ethylene via the oxidative dehydrogenation of ethane (Eq. 9) (Stansch et al., 1997):

OCM also forms CO, CO<sub>2</sub> and H<sub>2</sub> as unwanted side products and has typically low yields and selectivity towards both ethane and ethylene, which has restricted its commercialisation potential. In this work, the reaction flowsheet developed by Penteado et al. (2018) is used as a basis. Methane is fed into a series of two packed bed adiabatic reactors with oxygen in a CH<sub>4</sub>:O<sub>2</sub> molar ratio of 10:1, which improves selectivity towards C<sub>2</sub> components at the expense of per-pass-conversion rate. The reactors were sized so that

O<sub>2</sub> was completely consumed at the end of each reactor. Additional O<sub>2</sub> was added before the second reactor to restore the 10:1 ratio. The products are cooled and separated, and unreacted methane is recycled back to the start of the process. Unreacted ethane is sent to an ethane dehydrogenation reactor (EDH), where it is catalytically dehydrogenated into additional ethylene and hydrogen. For this reactor, 60% was assumed for both the per-pass-conversion and selectivity towards ethylene (Salerno et al., 2016). The H<sub>2</sub> and CO side products are combusted and used to generate electricity using a steam cycle.

### 2.2. Assessment

Purchased equipment cost curves and the factorial method were used to obtain the total capital investment (TCI) for each route and a plant life of 20 years and interest rate of 10% were used to annualize the TCI (Towler et al., 2022). Due to the lack of reliable data on the cost of a plasma pyrolysis reactor, the MP route was costed using the six-tenths rule on the TCI of a similar plant (Keipi et al., 2016). The levelised profit, which is defined as the profit obtained per kg of methane feed, was used to determine the economic performance of each route. A business-as-usual (BAU) case was used as a benchmark, which is the price of methane if it was sold to the National Grid as a natural gas substitute (0.17 USD/kg, Feb 2021). Utility and raw material costs were taken as market prices in 2021, with heating provided by blue H<sub>2</sub> at 2.01 USD/kg (Al-Qahtani et al., 2021). The methane feed is assumed to be free as it originates from the base plant. Sensitivity analysis on the natural gas price will be considered in future work to account for its volatility. The scope 1 and 2 emissions were calculated considering direct CO<sub>2</sub> emissions from each route as well as the carbon intensity of the electricity supply (UK 2021 average at 0.265 kg<sub>CO2</sub>/kWh) and the blue H<sub>2</sub> for heating (4.3 kg<sub>CO2</sub>/kg<sub>H2</sub>, Al-Qahtani et al., 2021). Credits were given for any CO<sub>2</sub> that was consumed as a feedstock.

## 3. Results and Discussion

The levelised profit and scope 1 and 2 emissions of each route are presented below in Figure 2 (a) and (b) respectively. For the economic assessment, initial observation reveals that four out of the seven routes are more profitable than the BAU case. OCM shows the highest profit at 0.38 USD/kg, followed by MP and TRM at 0.30 USD/kg and ATR at 0.23 USD/kg. The promising results for OCM are due to both its relatively low capital investment and the electricity generation from the side product combustion, which negates the utility cost. However, its total revenue is limited by its low ethylene selectivity as only 47% of the carbon from the methane feed ends up in ethylene. This carbon efficiency becomes 75% when ethane is included, however it presents a negligible contribution to the route's total revenue. Like OCM, MP benefits from a simple flowsheet with few units leading to a low capital investment, but it is hindered by the high electricity requirement in the plasma reactor. It is also dependent on the carbon black sale to remain more profitable than the BAU case. TRM produces syngas with a H<sub>2</sub>:CO ratio slightly greater than 2:1, which meets the minimum stoichiometric requirement for methanol synthesis. This maximises both the production of methanol from syngas and thus olefin yield in the MTO and OCP section. TRM also has the lowest utility requirement out of the syngas-based routes due to its very low heat of reaction in the reforming section, which in turn enables it to be less vulnerable to the high H<sub>2</sub> heating costs. ATR has a higher total revenue than TRM thanks to the excess H<sub>2</sub> produced; however, this is not sufficient to offset the increase in capital and utility costs due to a higher heating requirement in the reforming section and a higher cost for the heat exchange network.

The other three syngas-based routes are less profitable than the BAU case: SRM at 0.11 USD/kg; BRM at 0.08 USD/kg; and DRM at -0.24 USD/kg. All three of these routes have

highly endothermic reforming reactions and thus have significant heating requirements. Despite SRM and BRM having the highest revenues, this is not sufficient to offset the large utility cost. BRM performs slightly worse than SRM due to the additional cost of the CO<sub>2</sub> feed. Finally, DRM is the only route that is unprofitable. Since it generates syngas in a 1:1 ratio, most of the carbon in the methane feed is lost in the purge as excess CO. Further analysis revealed that only 42% of carbon in the DRM feed was converted into olefins. Another contributing factor to DRM's poor performance is the 1:1 CH<sub>4</sub>:CO<sub>2</sub> molar feed requirement, which generates a substantial total raw material cost.

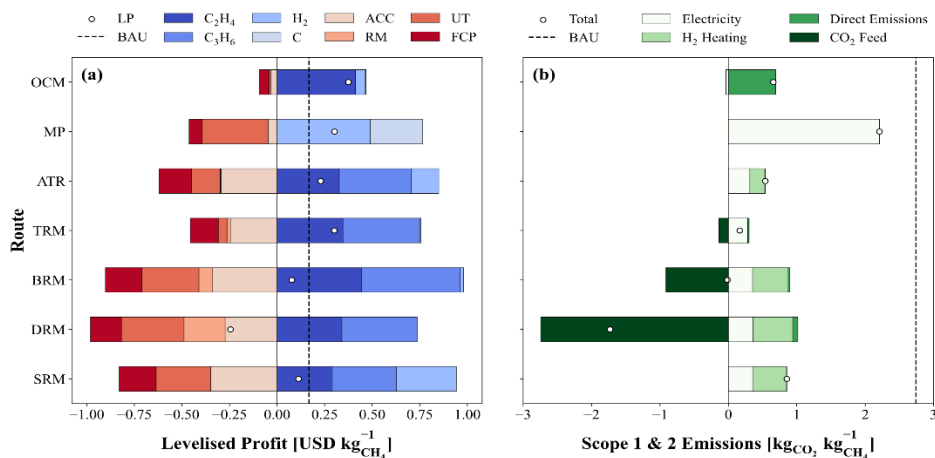

Figure 2: (a) Levelised profit and (b) Scope 1 & 2 emissions of each methane valorisation route. (LP = levelised profit; BAU = business-as-usual case; ACC = annual capital charge; RM = raw materials; UT = utilities; FCP = fixed costs of production)

Figure 2 (b) reveals that all routes have lower scope 1 and 2 emissions compared to the BAU case. However, the relative performance of the routes has somewhat reversed when compared to the economic results. MP has the highest emissions at 2.21 kg CO<sub>2</sub>, followed by SRM and OCM at 0.86 and 0.66 kg CO<sub>2</sub> respectively. All the emissions for MP come from the electricity source, whilst OCM is the only route that has a substantial contribution from direct emissions due to the side-product combustion. ATR and TRM are the other routes with positive scope 1 and 2 emissions at 0.54 and 0.17 kg CO<sub>2</sub> respectively. As seen in the economic assessment, the minimal heating requirement for TRM results in better performance compared to ATR. BRM achieves net-zero operation at -0.01 kg CO<sub>2</sub> and DRM shows net-negative emissions at -1.74 kg CO<sub>2</sub> thanks to the substantial CO<sub>2</sub> feed requirement. However, the promising results for DRM will likely be negated when scope 3 emissions are considered, as the unconverted CO stream would likely be combusted. Note that accounting for the product separations may impact both the economic and emissions results and will be considered in future work.

#### 4. Conclusions

This paper presented a model-based comparison between seven different methane valorisation routes to produce additional chemicals. The routes considered were i) five syngas-based routes which used different methane reforming technologies (steam, dry, bi, tri and autothermal reforming) followed by methanol synthesis and methanol-to-olefins; ii) methane plasma pyrolysis; and iii) oxidative coupling of methane. The results

show that OCM has the highest profit due to its low capital and operating costs, despite its low ethylene selectivity. MP, TRM and ATR are also more profitable than the base case, whilst SRM, BRM and DRM are less profitable in part due to their highly endothermic reforming reactions. However, DRM and BRM have the lowest scope 1 and 2 emissions owing to their large CO<sub>2</sub> feed streams, whilst MP has the highest thanks to its high electricity requirement. Nevertheless, all seven routes have lower scope 1 and 2 emissions compared to the base case. Further investigation is required to assess the overall environmental impact of each route (including analysing alternative heating and electricity sources), the robustness of each route to fluctuations in market conditions, and the scale effect of the methane side stream. The low-capital OCM and MP routes are expected to remain feasible at lower methane flowrates whilst the syngas routes will only be applicable to large operations to leverage economies of scale.

## Abstract

This paper investigates the production of bio-methanol from different origins feedstocks such as renewable and biological ones. The focus is on the analysis of the raw methanol composition's perturbations, dependent on the chosen feedstock, which impacts the design, the economics, and the environmental emissions of the downstream section. A thermodynamic analysis is computed to determine the final raw methanol purification depending on the utilized feedstocks. The conventional distillation column configuration is chosen as the process design for methanol purification. The purified methanol is AA grade, according to the ASTM D1152-97 standard specification. The entire section is simulated with ProSim software with a chosen Non-Random-Two-Liquid (NRTL) thermodynamic package. A two-directional flexibility analysis is performed to assess the impact of different perturbations under uncertain conditions in raw methanol compositions. The results of the flexibility analysis highlight optimal plant flexibility with around 7 % of the total cost deviation.

**Keywords:** Flexibility analysis; Biomethanol; Crude Methanol Purification.

## 1. Introduction

Methanol is one of the most produced bulk chemicals worldwide, with a global production of 160 Mton/y (Fedeli et al., 2022). Its production is a well-established technology which involves basically (i) syngas production; (ii) CO<sub>x</sub> hydrogenation (depicted in Eqs. 1-2); and (iii) raw methanol purification. The most utilized feedstocks for production are coal and natural gas. Recently biomethanol is gaining interest since is a promising advanced fuel for gasoline blends and especially for the disposal of marine fuels. Thus, could be helpful for the actual European policies and dictates. European RED II is currently set, to tackle the problem of increasing GreenHouse Gas (*GHG*) emissions, a target share of biofuel's final consumption of energy in the transport sector shall be at least 3,5 % in 2030 (EU SCIENCE HUB, 2022). Whatever feedstock wastes contain a good content of carbon and hydrogen is exploitable for the biomethanol production. Biogas, products waste gasification, and flue gases are considered the first candidates for this purpose. These new process technologies will increase worldwide biomethanol production despite several problems that are to figure out. The most highlightable obstacle of the feedstock wastes is the seasonability fluctuations and the produced raw biomethanol composition. Above mentioned feedstocks have a high CO<sub>2</sub> content compared to the natural gas one. Thus, will led to a higher production of methanol with the CO<sub>2</sub> hydrogenation pathway (Eq.2). Consequently, the produced raw methanol will

have higher water content depending by the feedstock quality. Even a slight variation could impact the design of the plant purification section.

This work aims to analyze the effects of the perturbation due to different feedstock utilization in the conventional raw methanol purification. Flexibility analysis is introduced to supply an optimum design which includes the probability that a perturbation could change the process performance.

## 2. Materials and Methods

The flexibility assessment consists of three different steps: (i) a thermodynamic analysis to classify feedstock quality (based on  $\text{CO}_2$  content) and the expected raw methanol composition; (ii) the design and the model of the biomethanol purification section in pre-defined nominal conditions; (iii) the evaluation of the process flexibility introducing the bi-directional system perturbations. In the first task, an Aspen HYSYS v11 process simulation is computed to understand how the  $\text{CO}_2$  content in the feedstock affects the outlet composition. The feedstock composition is split into three main compounds:  $\text{H}_2$ ,  $\text{CO}$ , and  $\text{CO}_2$ . The hydrogen molar fraction is kept constant while  $\text{CO}$  and  $\text{CO}_2$  are changed respectively respecting the constraint of constant overall flowrate. The thermodynamic model selected is SRK-Twu. An isothermal Gibbs reactor with a temperature of  $260^{\circ}\text{C}$  is used as a model to predict the final methanol composition. The final target is to correlate the  $\text{CO}_2$  to  $\text{CO}$  ratio with the final water content in the crude methanol. In this step, the by-products of the reaction such as higher alcohol, DME, and acetone are not considered. However, this final assumption is neglected in the second step where is important to model, with a good detail grade, the purification section.

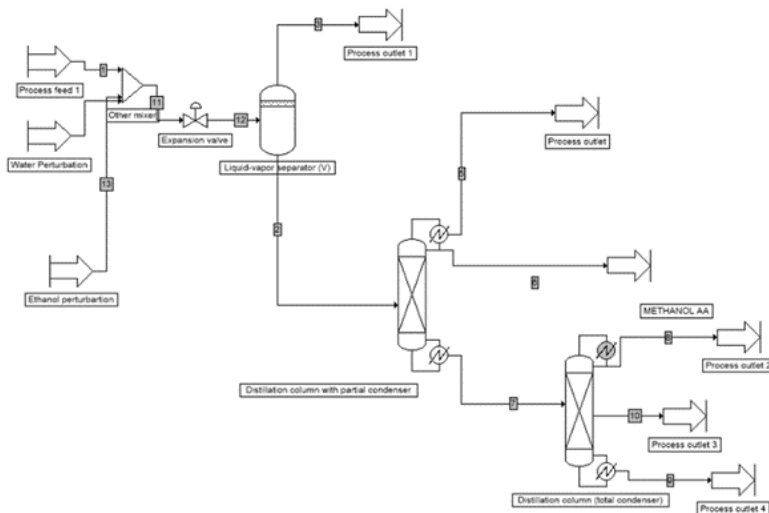

Figure 1: ProSim layout of raw methanol purification.

This is developed with ProSim software with a chosen Non-Random-Two-Liquid (NRTL) thermodynamic package. The typical impurities data is taken from the work of Xue et al., (2021). The crude biomethanol is characterized by 19 different compounds (Xue et al., 2021).

The purification process is modelled with the most used industrial applications: distillation column trains. Figure 1 depicts the process flow simulation. The purified methanol target is AA grade, according to the ASTM D1152-97 standard specification (ASTM, 1998). As a nominal case study to design the unit is chosen the raw methanol from biogas processing. Finally, in the third step, two-directional perturbations are applied to system to assess the plant flexibility. Water and ethanol content in the crude are selected as perturbation variables. Resilience index ( $RI$ ) and Swaney and Grossmann ( $F_{sg}$ ) are selected to evaluate the impact concerning economical assessment.  $RI$  expresses the largest total disturbance load and is independent of the direction of the perturbation.  $F_{sg}$  represents the maximum fraction of the expected deviations  $\delta$  that can be accommodated by the systems (Di Pretoro et al., 2022).

### 3. Results and Discussion

The thermodynamic analysis is useful to characterize and forecast the crude methanol composition among a wide range of syngas quality. This property is identified with the ratio between the inlet flowrates of  $\text{CO}_2$  and  $\text{CO}$ . Figure 2 shows the expected water production (in molar fraction) varying the  $\text{CO}_x$  ratio. It is quite clear that the chemical pathway  $\text{CO}_2$  hydrogenation is favoured increasing the carbon dioxide content. Considering syngas produced from biogas-based reforming processes, the  $\text{CO}_x$  ratio is close to the unity (Chein et al., 2021). In this case study, the estimated water molar fraction will be around 15% mol/mol<sub>tot</sub>. When the molar ratio tends to infinite values, i.e., methanol produced from flue gas and renewable hydrogen, the water produced overcomes the value products. In this case, is useful to add in the process a pre-treatment with a CO-shift unit to increase the feedstock CO quantity.

Figure 2: Thermodynamic analysis results, the x-axis represents the  $\text{CO}_2/\text{CO}$  ratio while the y-axis is the expected water molar fraction in the produced crude biomethanol.

The second step of this work is to develop a process simulation of the methanol purification section which includes all the crude impurities and the useful unit operation to reach the AA-grade methanol specification. The nominal case study is chosen as production of biomethanol from biogas-based reforming process. The syngas is laminated through a valve and passes through a separator which removes the uncondensable gases ( $\text{CO}$ ,  $\text{H}_2$ ). These are recycled back to enhance methanol production. After this operation,

the crude mixture enters a stabilizer column to remove the CO<sub>2</sub>. The last unit operation is a rectifier, with a total condenser, useful to refine until the desired specification. Both distillation columns work in atmospheric conditions. Table 1 describes the results of the process simulation.

Table 1: Main output variables of the ProSim process simulation.

<b>Variables</b>	<b>Stabilizer</b>	<b>Rectifier</b>
<b>Temperature</b>	64-67°C	64-67°C
<b>Pressure</b>	1 atm	1 atm
<b>Reflux ratio</b>	16.74	2.17
<b>Reboiler duty</b>	80.01 kW	575.25 kW
<b>Condenser duty</b>	30 kW	575.09 kW
<b>Recovery ratio</b>	100 %	70 %
<b>Number of trays</b>	5	51
<b>Specifications</b>	---	Methanol purity 0.99878 w/w  Ethanol recovery 98%

The actual operating conditions are low-energy demanding, the utilities are Cooling Water (CW) for the condensers and Low Pressure Steam (LPS) for the reboilers. The first column (stabilizer) works with only five trays to remove the CO<sub>2</sub> from the crude biomethanol. The rectifier requires fifty-one equilibrium stages to achieve very high purity separations. This one presents a stage with an ethanol spill useful to reach the solution convergence. CAPital EXpenditure (CAPEX) and OPERational EXpenditure (OPEX) related to the nominal case study have been estimated using Guthrie's method (Baillie and Whiting, 1998). 10 years of plant lifetime is chosen as parameter to normalize the fixed costs in a specified time range. In this way is possible to compute the Total Annual Cost (TAC) following Eq. 3:

$$TAC = \frac{CAPEX}{10 \text{ years}} + OPEX \quad (3)$$

The main OPEX contributions are the CW and LPS utility costs. The final step of the work is the economical flexibility assessment of the purification section in different operating conditions. As mentioned in section 2, the perturbations variables are the water and the ethanol content in the crude mixtures. The aim is to study how the perturbations affect the nominal design and its flexibility. The output variables to analyze are the column duties which are directly correlated to the CAPEX/OPEX voices. If a distillation system requires more LPS to work, this is reflected in higher OPEX or a different sizing of the kettle reboiler (CAPEX). The perturbation variables are written as vectors as reported in Table 2,  $\delta$  is the step deviation for each vector iteration.

Table 2 Property of the perturbation vectors

Perturbated variable	Value	$\delta$	Size
Water feed	250 kg/h	$\pm 50$ kg/h	11
Ethanol feed	4 kg/h	$\pm 0.8$ kg/h	11

The combination of each value associated with the vectors represents a case study. The size of the perturbation matrix is 121 case studies. Each of them is evaluated in the process simulation with the tool “case studies”, reporting convergence in the entire domain. The TAC is evaluated for each cell of the matrix, and the corresponding deviations are calculated concerning the nominal case study TAC. Figure 3 is the surface plot which correlates the TAC deviation (%) with the two flowrate perturbations.

Figure 3: Matrix of TAC deviation with water and ethanol flowrates perturbation.

The maximum deviation value corresponds to 6.34% of the nominal TAC, the associated case study is related to the maximal perturbation of both vectors. The perturbation matrix and its relative TAC deviation are useful to assess the purification section flexibility via deterministic indexes computation. The plot represented in Figure 4 correlates the deterministic index,  $F_{sg}$ , and  $RI$ , in the function of the relative cost deviation. It is easier to observe the economic investment to effort different probability of perturbations are quite feasible. The proposed and simulated system has an optimistic value of flexibility following the deterministic indexes. Considering the  $F_{sg}$ , with a total investment of 6.3% the plant could afford the entire range of selected perturbations. The  $RI$  value is lower than  $F_{sg}$  because considers only the effort load with a specific perturbation direction. The negative TAC deviations mean less investments in case of feedstock with minor content of water and ethanol. That area of TAC saving includes the conventional process plants, where natural gas and coal are utilized for the production.

Figure 4: Deterministic index comparison to additional costs.

#### 4. Conclusions

New processes to produce biomethanol consider the utilization of renewable and biological feedstock replacing conventional ones such as natural gas and coal. Different material input significantly affects the production introducing oscillating perturbations. Water and ethanol composition mostly impacts the crude methanol purification section. This work highlights the wide range of flexibility under uncertain conditions of conventional distillation columns. The results of flexibility analysis are quite good indicators of the potentiality to retrofit, revamp, and build process plants able to afford feedstock perturbations with relatively small investments.

# Life cycle assessment of Pine needle-based electricity generation in India

Pratham Khaitan,<sup>a</sup> Ankush Halba,<sup>a</sup> Pratham Arora,<sup>a,\*</sup>

<sup>a</sup>*Hydro and Renewable Energy Department, Indian Institute of Technology Roorkee, Roorkee-247667, India*

## Abstract

Electrification in the rural and remote areas and constant forest fires due to Pine needles are the major problems of the Uttarakhand state of India. Pine forests comprise 16.15% of the state's total forest area, producing  $1.91 \times 10^6$  tonnes of Pine needles annually. Gasification of Pine needles could be employed to generate localized electricity, thereby diminishing forest fire frequency. Nevertheless, a life cycle assessment (LCA) must be conducted to comprehend the environmental advantages of this process. Therefore, using the GaBi software, the LCA of Pine-needles to the electricity gasification supply chain is performed for two biomass pretreatment cases (1-shredding and 2-briquetting) for the Almora district of Uttarakhand state. The predicted global warming potential (GWP)-100-year emissions for case 1 and case 2 were 0.679 and 0.578 kg CO<sub>2</sub>-eq for 1 kWh of electricity production, respectively, compared to the national grid (0.86 kg CO<sub>2</sub>-eq kWh).

**Keywords:** LCA, Pine needles, Gasification, Electricity, Supply chain.

## 1. Introduction

Almost 3.5 million people live close to significant tracts of Pine forests, where firewood and electricity are in short supply in Uttarakhand (Dhaundiyal and Tewari, 2016). According to the Forest Department of Uttarakhand, Pine forests are spread over around 3,430 km<sup>2</sup> in 17 forestry divisions across 13 districts, producing two million tonnes of Pine needles (PNs) annually (Bisht et al., 2014). Since PNs are extremely flammable by nature, they can contribute to or even start forest fires, especially in the summer when temperatures are high and relative humidity is low. In addition, PN creates a covering on the earth that prevents rainwater from entering the soil and restricts nearby plants' growth, reducing the food available for cattle and resources such as wood, medicinal herbs, and flowers. Therefore, collecting PNs from forest floors and using them for energy production can promote energy sustainability in rural and remote parts of Uttarakhand, which will also aid in minimizing forest fires (Dhaundiyal and Gupta, 2014). Pine needle gasification is a promising route for harnessing its energy potential (Kala and Subbarao, 2017). Additionally, decentralized PN gasification could be a sustainable source of electricity in areas far from the main power system. However, an ineffective biomass supply chain is a major hindrance to utilizing biomass gasification-based plants for energy generation (Halba et al., 2022). Generally, the biomass supply chain consists of three major components: collection, transportation, and storage, where all three stages, directly or indirectly, impact the environment (González and Sandoval, 2020). Therefore, the environmental assessment of the biomass supply chain is mandatory to make any

biomass-based energy project successful in producing green energy and reducing greenhouse gas (GHG) emissions.

Life cycle assessment (LCA) is a commonly employed approach used to evaluate the environmental performance of any system or process. Whittaker et al. (2016) carried out the LCA using biomass (short rotation coppice) to predict the GHG and methane emissions from outside biomass storage. The study concluded that there were up to 20% dry matter losses during biomass storage and the biomass used provided up to 90% savings in GHG emissions. Another study by Beagle and Belmont (2019) used the LCA to evaluate the effects of transporting biomass (wood chips and wood pellets) on the overall amount of GHG emissions produced by bioenergy production. It was found that an integrated biomass facility could cut emissions by as much as 76% compared to coal. The research concluded using either of the two biomasses for electricity generation would result in lower GHG emissions in comparison to coal-powered stations. Costa et al. (2022) conducted the economic, environmental, and technical performance of the complete woodchips-to-energy supply chain using a commercially available biomass gasification-based system in Southern Italy. The study summarized that the impact of combustion and gasification accounted for almost 50% of the overall environmental impact. Gupta et al. (2022) employed LCA for bioenergy conversion via pyrolysis to produce bio-oil from the PNs, including the pyrolysis co-products (non-condensable gases and biochar). They integrated LCA with parameter sensitivity and economic analysis to evaluate processes more thoroughly. The study's main drawback was that the data came from a lab setting experimental investigation and not a commercial plant. The catalytic pyrolysis used led to a 42% decrease in the overall GWP of the process.

To the best of the author's knowledge, no researcher has examined the LCA of the PNs supply chain for electricity generation, including the biomass pretreatment scenario such as shredding and briquetting. Therefore, the current study has been undertaken to conduct the LCA of the PNs-to-electricity gasification supply chain, including the two biomass pretreatment cases (1-shredding and 2-briquetting) to check their environmental viability.

## 2. Methodology

A "cradle-to-gate" LCA analysis approach is adopted for the present study, which considers the environmental impacts from a product's life cycle, which start from the Pine tree plantation (cradle) to the factory gate (electricity). The PNs are assumed to be collected on foot in the forests of Uttarakhand's Almora district. Since the fallen PNs contain very little moisture throughout the summer, it is presumed that the PN was gathered during the 90-day interval (April to June). The biomass storage duration is assumed to be nine months, so the plant can function continuously throughout the year. The collected PNs are sent to primary storage (S1) via truck transportation (T1) in the next step. The biomass pretreatment routes (shredding and briquetting) for PNs are performed in a preprocessing plant (P1) located in the primary storage. The primary distinction between shredding and briquetting is that biomass briquettes often have larger shapes and sizes, calorific values, and densities than shredded biomass. The preprocessed PNs are then transported to a secondary storage facility (S2), where a gasification plant (P2) is installed. The gasification power generation system consists of a cooling and cleaning system, a gasifier, and a gas-to-electricity generator (Halba et al., 2022).

### 2.1. Life Cycle Analysis

The LCA process consists of four main steps: setting objectives and boundaries, conducting an inventory analysis, evaluating the effects of the process, and interpreting the results.

### *2.1.1. Goal and scope definition*

The LCA process begins with establishing its goals and scope in the first phase. According to ISO 14040, this phase must specify environmental impacts, functional units, assumptions, and system boundaries (Kalinci et al., 2012). The study's goal was to compare and evaluate the potential environmental footprints of the two different preprocessed PNs (Shredded and briquettes) for electricity production based on gasification. The LCA model was developed using GaBi (version: 10.6.0.110). For the present study, 1 kWh of electricity production from pine needle biomass has been considered the functional unit (FU) for estimating the environmental impacts. The following steps are considered for conducting the LCA: biomass transportation, pretreatment of biomass, storage of biomass, and power generation from gasification.

### *2.1.2. Inventory analysis*

This LCA combines and quantifies major inputs and outputs for the FUs. Energy inputs and raw materials for the LCA model were compiled from various sources like the GaBi-integrated Eco-invent database, research literature, and information acquired from local vendors and people. The India-specific database (available in GaBi) is utilized for creating the LCA model.

The PNs are assumed to be collected by foot in the forests surrounding Almora, Uttarakhand. It is assumed that raw PNs are delivered by diesel-powered Bharat Stage IV trucks (with 7.5, 11.4, and 25-ton payload capacities). The transportation distance from the collecting location to the preprocessing and storage site is assumed to be 11 km, whereas the transportation distance from the preprocessing site to the plant site is assumed to be 56 km for a decentralized plant.

The PNs shredding requires around 7.15 kWh of electricity to process per tonne of PNs (Gupta et al., 2022). In contrast, briquetting uses around 380.69 kWh of electricity to process per tonne of PNs (Singh et al., 2021). The factor used to calculate methane emissions from biomass storage is 0.0175 kg of CH<sub>4</sub> per kg of biomass (C. Whittaker et al., 2016). Raw, shredded, and briquette PNs are assumed to have a bulk density of 80 kg/m<sup>3</sup> (Houssami et al., 2018), 175 kg/m<sup>3</sup> (Dhaundiyal and Tewari, 2016), and 1200 kg/m<sup>3</sup> (Mandal et al., 2019), respectively. GaBi's Northern-India grid mix provided all the electricity input needed for chopping and briquetting (Gupta et al., 2022).

### *2.1.3. Impact assessment*

In this stage, the data of the inventory analysis (the measured inputs and outputs) are evaluated for their ecological impact. The life cycle impact assessment (LCIA) is used to identify potential environmental consequences of life cycle inventory (LCI) and to determine their magnitude. The current investigation applies an LCIA technique based on the CML 2016-Aug 2016 version.

### *2.1.4. Interpretation*

During the final phase of the LCA process, interpretation, it is crucial to confirm that the assessment's data align with its stated objective. In this regard, the two processes that yield useful information are the analysis of inventories and the evaluation of their environmental consequences (Kalinci et al., 2012). The qualitative interpretation of impact analysis data is made possible by addressing each effect category separately. The environmental effects of producing electricity from pine needles are evaluated and compared using impact categories such as Global Warming Potential (GWP), Acidification Potential (AP), and Eutrophication Potential (EP).

### 3. LCA Results and discussion

#### 3.1. GWP

It is observed that the shredded and briquette PNs gasification results in an overall GHG emission of 0.679 and 0.578 kg CO<sub>2</sub> equivalent per kWh, as illustrated in Figure 1. It is revealed that the overall GWP for both the gasification of briquettes and the shredding of PNs is less than that of India's Northern grid electricity (0.86 kg CO<sub>2</sub> equivalent per kWh). The Pine tree absorbs CO<sub>2</sub> for its growth to produce products (such as PNs) by photosynthesis, resulting in -3.24 kg CO<sub>2</sub> equivalent per kWh and -2.61 kg CO<sub>2</sub> equivalent per kWh emissions for shredded and briquette biomass, respectively. The disparity between the values could be explained by the variation in energy density between the shredded and briquette PNs. In both cases, the emissions of exhaust gases have the largest impact on the surrounding environment, with 2.23 kg CO<sub>2</sub> equivalent per kWh for shredded PNs and 1.36 kg CO<sub>2</sub> equivalent per kWh for briquette PNs. The reason for the difference in emissions between shredded PNs and PN briquettes is due to the difference in their bulk density and biomass quantity. 1.5 kg of shredded PNs were required to produce 1 kWh of electricity (Avani, 2016) while only 1.2 kg of PN briquettes were required for the same (Kala and Subbarao, 2017). Based on the methane emissions induced by the decomposition of the biomass over time, the storage phase is accounted for as the second greatest contributor to overall GWP. It is found that the emissions from transportation are minimal due to shorter travel distances (11 and 56 km) and higher bulk density of shredded and briquette PNs.

Figure 1: GWP results for shredded pine needles (PNS) and pine needle briquettes (PNB)

#### 3.2. AP and EP

The potential for acidification across both LCA scenarios is shown in Figure 2. Shredded PNs have an overall AP of  $0.35 \times 10^{-3}$  kg SO<sub>2</sub> equivalent, with exhaust gases ( $0.25 \times 10^{-3}$  kg SO<sub>2</sub> equivalent) as the primary contributor. Compared to shredded PNs, PNs briquettes have a higher AP of  $4.59 \times 10^{-3}$  kg SO<sub>2</sub> equivalent, with the most significant contribution resulting from the grid electricity required in the briquetting process. North Indian grid electricity has an AP of  $7.76 \times 10^{-3}$  kg SO<sub>2</sub> equivalent, which is higher in comparison to

the PNs used. Briquetting requires a substantial amount of electricity, due to which the emissions of PN briquettes were higher than shredded PNs.

Figure 2: AP results for shredded pine needles (PNS) and pine needle briquettes (PNB)

In comparison to the Northern grid ( $4.8 \times 10^{-4}$  kg PO<sub>4</sub> equivalent), the EP values of both PNs briquettes ( $3.23 \times 10^{-4}$  kg PO<sub>4</sub> equivalent) and shredded pine needles ( $0.71 \times 10^{-4}$  kg PO<sub>4</sub> equivalent) are lower. Figure 3 depicts the overall EP of both LCA scenarios. The difference in environmental impacts was due to the higher consumption of electricity in the case of briquetting.

Figure 3: EP results for shredded pine needles (PNS) and pine needle briquettes (PNB)

#### 4. Conclusions

The LCA approach was applied to carry out an analysis of the effects that either of the pre-treated biomasses has on the surrounding environment when gasified to produce electricity. In addition to this, the GWP, along with AP and EP, were investigated. For GWP, the exhaust gases from the gasification facility were responsible for the greatest amount of CO<sub>2</sub> emissions, while transportation had the least influence on the surrounding environment. Electricity used in the process was the leading contributor to acidification and eutrophication potentials. Both PN-based processes outperform the North-Indian grid in terms of GWP, AP, and EP for producing 1 kWh of electricity. Reduced emissions were a result of using plant biomass as an energy source instead of coal.

## Abstract

Due to the heavy dependence on fossil-fuels as raw materials, the defossilization of feedstocks in the petrochemical industry represents a challenge. A large number of possible process routes that use alternative carbon sources (ACS) like CO<sub>2</sub>, biomass, and waste are being developed for the feedstock replacement. For instance, to produce ethylene, more than 40 ACS process routes were identified. These multiple options make the selection of the promising process route a complex task. By replacing feedstocks, a process can change significantly and the impacts related to these changes in a highly interconnected industrial cluster can create cascading effects due to system interdependencies. This work aims to understand the cascading impacts in carbon flows and prices of implementing an ACS production process in an ethylene cluster. The results show that PVC will be the highest impacted and defossilizing one value-chain can have cascading effect on other value-chains as observed for PET.

**Keywords:** technology screening, feedstock defossilization, alternative raw materials, value chain impacts.

## 1. Introduction

Europe has set the ambitious goal to be carbon-neutral by 2050 and feedstock defossilization of carbon-based industrial processes is challenging (J.Rissman et al, 2020). For instance, the petrochemical industry depends on fossil fuels like naphtha, natural gas and ethane as carbon sources. Using alternative carbon sources (ACS) such as CO<sub>2</sub>, biomass and waste is considered an option for the replacement of oil and gas feedstocks (D. Saygain et al, 2021). A large number of possible processes using ACS are being developed to produce chemicals through electrochemical, biochemical, and thermochemical routes (M. Stork, 2018). The existence of multiple processing routes makes the decision-making process of selecting the promising alternative process route a complex task that relies on multiple techno-economic and environmental criteria. It can be expected that replacing feedstocks might significantly change process requirements like equipment, energy, water, utilities and safety, and production outputs like products, by-products, and waste. These changes can affect the overall system, for instance in terms of product prices and import-export dependencies, due to system interdependencies. This

work presents a systematic screening methodology for selecting promising ACS process technologies and aims to study cascading impacts (carbon and price), for the selected ACS ethylene production in an ethylene cluster as case study.

## 2. Methodology

For the production of ethylene using CO<sub>2</sub> and biomass as feedstocks, more than 40 different process routes were identified from the literature. In order to select the most promising alternative carbon-based ethylene production technologies a screening methodology was developed as explained in section 2.1. Then the value chain impacts of ACS technologies was studied for a base-case ethylene cluster, as explained in section 2.2 and section 2.3.

### 2.1. Technology screening

The screening methodology was developed based on a stage-gate concept and the selection was divided into five stages. The amount of information needed is reduced with this approach, as the processes are eliminated as stages progress. In stage-1, technology readiness level (TRL) is used for selection and technologies with TRL > 3 are selected to the next stage. In stage-2, the ideal stoichiometric reactions of each process route were used. Each stoichiometric reaction required to produce a chemical was assumed as individual unit operation or process step. Here, only ideal reactions are considered and side reactions are not taken into account. In stage-2, technologies with less than 4 process steps were selected. It was because as the number of steps increased, the number of routes as well as the level of complexity increased drastically. Then in stage-3, thermodynamic state functions; standard enthalpy change ( $\Delta H^0$ ), standard Gibbs energy change ( $\Delta G^0$ ) and standard entropy change ( $\Delta S^0$ ) for the overall reaction, were calculated at standard conditions using inputs from Aspen properties. Using these thermodynamic state functions, the theoretical overall heat need or generation and electricity need were calculated as:

$$\text{Heat production/need} = \sum_{\text{Biochemical+Thermochemical+Catalytic steps}} \Delta H^0 \quad (1)$$

$$\text{Electricity need} = \sum_{\text{Electrochemical step}} \Delta G^0 \quad (2)$$

At this stage, as the theoretical input and output components are known, the carbon utilization efficiency of the process route was calculated using Equation 3:

$$\text{Carbon utilisation efficiency (CUE)} = \frac{\text{Moles of carbon atom in product}}{\text{Moles of carbon atom in feedstock}} \quad (3)$$

Based on the energy need and CUE, technologies were then ranked. Using a comparative assessment, technologies with electricity need <1500 kJ/mol ethylene and CUE >50% were selected to the next stage. In stage-4, a basic economic constraint was calculated (Equation 4), using mass flow, component price and energy requirements. An in-house compiled price database with prices adjusted to 2018 as base-year using the PPI (producer prices indices) and price data from ICIS chemicals outlook was used.

$$\text{Economic constraint (EC)} = \frac{\sum_{\text{reactants}} \text{mass flow} * \text{Component price} + (\Delta H \text{ or } \Delta G)_{\text{endergonic}} * \text{Utility price}}{\sum_{\text{products}} \text{mass flow} * \text{Component price}} \quad (4)$$

Technologies with an economic constraint < 1 were selected. An EC ratio > 1 indicates that the input costs are higher than potential revenue and hence process is considered non-

profitable for assumed product prices. In stage-5, the process technologies which passed the previous gates were ranked based on the number of process steps and economic ratio, and one process route from each feedstock category (CO<sub>2</sub> and biomass) were selected.

## 2.2. Base-case ethylene cluster model

This paper used an in-house developed ethylene cluster model part of the project “Unravelling the impacts of using alternative raw materials in industrial clusters”, created in Aspen plus and based on existing processes in the Port of Rotterdam. The cluster model includes olefin, ethylene dichloride (EDC), vinyl chloride monomer (VCM), polyvinyl chloride (PVC), chlorine waste incineration (CKI), ethylene oxide (EO), ethylene glycol (EG), polyethylene terephthalate (PET), ethylbenzene (EB) and propylene oxide (PO)/styrene monomer (SM) synthesis units. The cluster has PVC, PET and SM value chains and these value-chains will be studied in this paper. The corresponding mass flows used as reference in this study are depicted in Figure 1.

Figure 1: Simplified ethylene cluster with main mass flows

## 2.3. Value chain impact propagation

### 2.3.1. Feedstock defossilization impact on value chain

In this study, value chain defossilization is defined as the replacement of fossil-based raw materials with ACS carbon-based raw materials. To understand the extend of the defossilization impact on a value chain, Equation 5 and Equation 6 are used. The carbon contribution of a chemical building block (CBB) is defined as the amount of carbon in the value chain that originates from the CBB molecule (see Equation 5).

$$CBB \text{ carbon contribution} = \frac{CBB \text{ carbon atoms}}{\text{Value chain product carbon atoms}} \quad (5)$$

As in a chemical process, all the carbon used in a process does not end-up in the required product as by-products or waste are also formed. Hence, to understand the carbon flow along a value chain, the carbon utilization efficiency was also evaluated. The value chain carbon utilization efficiency (CUE) is defined as the ratio of the carbon mass flow in the value chain to the carbon mass flow of raw materials, as given in Equation 6. This equation helps to understand how efficiently the CBB carbon is used in the value chain to make the target product.

$$\text{Value chain CUE} = \frac{\text{Value chain chemical carbon mass flow}}{\sum_{\text{CBB}} \text{Carbon mass flow}} \quad (6)$$

### 2.3.2. Price change impact on value chain

It was assumed that the new ACS ethylene plant has the same capacity as the base-case ethylene production and the downstream units acquire the ethylene from the new ACS plant as it happens in the base-case scenario. For the downstream plants, it is considered their CAPEX remains the same (as the same product is produced and therefore there are no changes in equipment) but their OPEX changes due to changes in raw material price. Hence, in order to maintain the same gross margin, it is proposed that the downstream products will increase their corresponding prices (see Equation 7, and Equation 8).

$$\begin{aligned} \text{Gross margin} &= \text{Revenue}_{\text{base case}} - \text{OPEX}_{\text{base case}} = \\ &= \text{Revenue}_{\text{ACS case}} - \text{OPEX}_{\text{ACS case}} \end{aligned} \quad (7)$$

$$\sum_{\text{Products}} \Delta \text{Price} * \text{Mass flow} = \sum_{\text{Raw materials}} \Delta \text{Cost} * \text{Mass flow} \quad (8)$$

For multi-product processes, the increase in a raw material cost needs to be allocated to different products. In this study, a constant revenue ratio between products was assumed for all of them and, based on Equation 9, product prices were allocated.

$$\begin{aligned} &\left[ \frac{\text{Product Price}_p * \text{Product mass flow}_p}{\sum_{\text{All products}} \text{Product Price} * \text{Product Mass flow}} \right]_{\text{base case}} \\ &= \left[ \frac{\text{Product Price}_p * \text{Product mass flow}_p}{\sum_{\text{All products}} \text{Product Price} * \text{Product Mass flow}} \right]_{\text{ACS case}} \end{aligned} \quad (9)$$

## 3. Results and discussion

For the production of ethylene from CO<sub>2</sub> and biomass feedstocks, multiple technologies at different TRL were identified (see for example in Figure 2 the overview of CO<sub>2</sub>-based routes).

Figure 2: CO<sub>2</sub>-based process routes for ethylene production

The identified technologies were evaluated using the screening methodology and a comparative assessment for a total of 48 process routes was performed (see for example in Table 1 the comparison of four process routes). It was observed that for CO<sub>2</sub>-based routes, the needed theoretical electricity for the direct electrochemical route is lower than for the indirect water electrolysis route. This increase in electricity is reflected in the EC

ratio, as the input cost is higher in the indirect route. For biomass routes, there is no electrochemical process step and hence the electricity need is zero. But these routes have lower CUE than electrochemical routes as biomass does not have sufficient inherent H<sub>2</sub> for complete conversion of carbon in biomass. Hence, carbon is not fully utilized although these routes theoretically seem economically better than electrochemical routes because of their lower EC ratio. Hence, based on the screening methodology as explained in section 2.1 using criteria: number of process steps, energy usage, CUE and EC; the selected process routes for the production of ethylene from biomass and CO<sub>2</sub> feedstocks respectively were: Biomass steam gasification (BSG) with Fischer-Tropsch (FT) process and direct electrochemical reduction (DER) of CO<sub>2</sub> to ethylene.

Table 1: Process route comparison using the described screening methodology for ethylene production (Abbreviations: DER-Direct electrochemical reduction, MTO-Methanol to olefins, BSG- Biomass steam gasification, FT- Fischer Tropsch)

Technology	No. of process steps	kJ/mol ethylene		CUE	EC
		Electricity need	Heat production		
DER of CO <sub>2</sub> to ethylene	1	1331	0	1.00	0.90
Water electrolysis + CO <sub>2</sub> to methanol + MTO	3	1423	-304	1.00	0.95
BSG + FT process	2	0	-82	0.67	0.14
BSG + syngas to methanol + MTO	3	0	-82	0.67	0.14

In this paper, only downstream plant impacts are studied using the preliminary results. The defossilization impact of ACS ethylene on an ethylene cluster, were studied as explained in section 2.3.1 and the results are tabulated in Table 2. The PVC value chain had the highest carbon impact due to the ACS ethylene production, as 100% of PVC carbon comes from ethylene. The least carbon impact was found for PET value chain, as significant part of the carbon in PET is provided by xylene, not ethylene. Hence, the impact of ethylene defossilization is non-identical for different value chains, despite sharing the same CBB. It means that different value chains based on the same carbon contribution molecule may require different defossilization strategies. The value chain carbon utilization efficiency shows that in the PVC value chain, only 66% of the ethylene entering ends-up in the PVC product. The CUE varies for different value chains based on the main reaction selectivity, conversion, product recovery rate and by-product demand. The significance of by-product demand can be observed in the PET value chain as some of the ethylene entering is used to make ethylene oxide (EO) which is an intermediate product used in other value chains. Therefore, for multi-product value chains, the defossilization impact is not just limited to the target product but can have wider impact on other dependent value chains.

Table 2: Ethylene cluster carbon impact

Value chain	Value chain theoretical carbon flow	CBB carbon contribution	Value chain CUE
PVC	$C_2H_4 + Cl_2 \rightarrow C_2H_4Cl_2 \xrightarrow{-HCl} C_2H_3Cl$	Ethylene= 100%	PVC= 66%, EDC=7%, VCM=20%, Waste=7%
PET	$C_2H_4 + 0.5 O_2 \rightarrow C_2H_4O + H_2O$ $\rightarrow C_2H_6O_2 + C_8H_6O_4$ $\rightarrow C_{10}H_8O_4 + 2H_2O$	Ethylene= 20% P-xylene= 80%	PET=33%, PTA=19%, EG=3%, EO= 25%, Waste=20%

SM	$C_2H_4 + C_6H_6 \rightarrow C_8H_{10}$ $\rightarrow C_8H_8 + H_2$	<b>Ethylene= 25%</b> <b>Benzene= 75%</b>	<b>SM= 82%</b> , EB= 3%, Waste=15%
----	---	---	---------------------------------------

The price impact of an ACS based ethylene plant on the value chains were studied as explained in section 2.3.2 and an ACS ethylene price increase of 67% was assumed as per literature (L.Berkelaar et al, 2022). As shown in Table 3, the PVC value chain will have the highest price impact due to the higher ACS ethylene price. This is because ethylene has the highest raw material purchase cost contribution in PVC due to its price and mass flow. However, in the PET and SM value chains, the respective product prices only increased by 17%. This is because ethylene is not the main raw material in these value chains, which can also be observed from the CBB carbon contribution values given in Table 2. This results also highlights how differently the price change impacts propagate in different value chains of the same CBB due to feedstock defossilization.

Table 3: Ethylene cluster price change impact

Value chain	Price change impact propagation (delta)
Ethylene→ EDC→ VCM→ <b>PVC</b>	67%→ 62%→ 62%→ <b>49%</b>
Ethylene→ EO→ EG→ <b>PET</b>	67%→ 47%→ 47%→ <b>17%</b>
Ethylene→ EB→ <b>SM</b>	67%→ 17%→ <b>17%</b>

#### 4. Conclusion

A screening methodology based on stage-gate concept was developed to select promising ACS technologies for ethylene production. From 48 process routes, the selected technologies were: DER (for CO<sub>2</sub> feedstock) and BSG with Fischer Tropsch (for biomass feedstock). The methodology showed how the concept of stage-gate can be used to screen large number of process routes. Then the value chain impacts of feedstock defossilization for an ethylene cluster in terms of product carbon flow and price change was studied. It was observed that for ethylene value chain, PVC will have the highest carbon and price impacts due to the mass and price significance of ethylene in PVC production. It was also observed that as in the case of PET value chain, how defossilization of one value chain can effect multiple value chains due to system interdependencies.

# Syngas fermentation to ethanol: the effects of gas recycling on economics

Haneef Shijaz,<sup>a,b</sup> Fausto Gallucci,<sup>b</sup> Adrie Straathof,<sup>a</sup> John Posada<sup>a</sup>

<sup>a</sup> *Department of Biotechnology, Faculty of Applied Sciences, Delft University of Technology, van der Maasweg 9, 2629 HZ, Delft, the Netherlands.*

<sup>b</sup> *Department of Chemical Engineering and Chemistry, Eindhoven University of Technology, 5600 MB, Eindhoven, the Netherlands*

## Abstract

Syngas fermentation is a biochemical pathway to produce ethanol and has been commercialized successfully. The economic viability of this process could be further improved to become more competitive in the existing ethanol market. Improving gas utilization is the key, and can be done by recycling the unreacted syngas. This work is an early-stage techno-economic assessment of recycling in producing ethanol from Basic Oxygen Furnace (BOF) gas. Economic viability is measured in terms of Relative Competitive Percentage (RCP) and is a measure of closeness to the current market. Two scenarios, firstly a once-through process, and secondly a process with recycling (0.9 split ratio: recycle/purge) of gas is considered. None of them showed a positive RCP as compared to the current ethanol market. Comparing these scenarios, beyond the single pass conversion of 60%, the additional production costs due to recycling become dominating and lead to a lower RCP compared to once-through systems.

**Keywords:** Syngas fermentation, Ethanol, Basic oxygen furnace Gas, Recycling, Profitability

## 1. Introduction

Syngas fermentation is a ground-breaking industrial biotechnology platform to produce Ethanol from various feedstocks. Lanzatech, a carbon recycling company has Commercialized this technology at various locations around the world. At the same time, the produced ethanol is not competitive enough to the existing ethanol market based on thermo-catalytic processes (Benalcázar 2017). One of the promising ways to improve the profitability of ethanol is by increasing gas utilization. This is possible via improving the mass transfer, genetic engineering to enhance the microbial rate or recycling the unreacted reactants. The latter is a possible scenario at the commercial scale, but the same has not been studied in detail in the large-scale syngas fermentation processes. Therefore, this work is an attempt to give an early-stage techno-economic evaluation of the recycling of unreacted reactants in the gas fermentation process.

## 2. Methodology

The process concept for ethanol from BOF is shown in figure 1. A bubble column fermenter and a distillation-based downstream process were considered as they are the most used types for ethanol production in large-scale syngas fermentation industries. Aspen Plus V8.8 was used to model this process concept in a steady state. The BOF gas

with a composition (mole %) of 0.65% CO, 0.03% H<sub>2</sub>, 0.16% CO<sub>2</sub>, and 0.16% N<sub>2</sub> was the feedstock and a process reaction to ethanol was developed by the black box thermodynamic approach (Heijnen 1992). Gas-liquid mass transfer rates of the reactants were also integrated into the model using the empirical relations of the bubble column reactor for the mass transfer coefficient, and Henry's law for the compositions. The sizing of the units for economic evaluations was carried out either manually or by using Aspen Process Economic Analyzer. The economic viability of ethanol via syngas fermentation was checked in terms of relative competitive percentage (RCP), which is the measure of its marketability compared to the current ethanol market. The effect of recycling unreacted gas was studied via sensitivity analysis, and RCPs were measured in each case.

### 2.1. Process Description

As shown in figure 1, a mixture of fresh BOF gas and recycle gas is adjusted to the inlet pressure and temperature of the fermenter. In the bubble column fermenter, the gas (syngas + NH<sub>3</sub>) and the medium (water+NH<sub>4</sub>OH) are fed counter currently. The ethanol is fully stripped off by the gas leaving the fermenter, and it mainly contains product, water, and other unreacted components of syngas. Therefore, the gas is condensed first and sent to a phase separator. The liquefied stream mainly contains ethanol and water with other dissolved gases. Ethanol is further purified in a distillation-based downstream separation section. A part of the unreacted gas is purged (10%) to avoid the accumulation of H<sub>2</sub> in the reactor. The rest of the gas (90%) is sent back to the fermenter after separating N<sub>2</sub>, and CO<sub>2</sub>. The fermenter broth mainly contains water, biomass, & ammonium acetate, and the solids are separated before reusing the water in the fermenter. The fermenter operating conditions (Temperature at 37°C, pH at 6) are selected based on the optimal growth conditions for acetogens. The top pressure in the fermenter is 1 atm and the bottom pressure was calculated based on the hydrostatic pressure as follows;

$$p_b = p_t + \rho_{broth} * g * h_g \quad (1)$$

Where,

$p_b$	Bottom Pressure (atm)
$p_t$	Top Pressure (atm)
$\rho_{broth}$	The density of broth (kg/m <sup>3</sup> )
$g$	acceleration due to gravity (m/s <sup>2</sup> )
$h_g$	Height of the broth (m)

Figure 1 schematic block diagram of ethanol from BOFG via syngas fermentation

### 2.2. Economic evaluation

To calculate the economic viability of the process, the capital expenditure (CAPEX), and the annual operating cost (OPEX) are estimated using the factorial method proposed by Peters and Timmerhaus (1959). As given in Table 1, The CAPEX is estimated based on the bare equipment cost (BEC) of the units. These values are adjusted to the scale, and the base year of 2019 using six tenth rule and cost indices respectively. OPEX is evaluated based on the direct calculations from the process models and is called process-related cost (PRC). PRC consists of the cost of raw materials, utilities, and waste management. Raw material includes syngas, NH<sub>3</sub>, NH<sub>4</sub>OH, and deionized water. The cost of utilities is evaluated from the energy balances and average utility price in the Netherlands (2019). The cost of waste management is estimated using the avg. carbon releasing tax in Europe (5 Euro/ ton CO<sub>2</sub> release, 2019). For the depreciation cost, a straight-line depreciation method is used with 10% of the purchase cost as salvage value after a plant life of 15 years. The annual tax paid is calculated from the annual sales and the tax rate which is taken as 25%.

To measure the economic viability, the relative competitive percentage (RCP) is measured as follows;

$$RCP = 100 * \frac{(MP - MSP)}{MP} \quad (2)$$

Where MP is the market price of ethanol in 2019 and is 780 €/kg. And Minimum Selling Price (MSP) is evaluated for a payback time of 3 years.

**Table 1 Calculation of CAPEX (Peters, 1959)**

	Items	Factors on FCI (%)
Direct cost (DC)	Bare Equipment cost	21.8
	Installation	7.6
	Process piping	11.1
	instrumentation	4
	insulation	1.4
	electrical	4.7
	buildings	8.4
	yard improvements	3.1
	service facilities	7.2
	land	1.7
Indirect cost (IDC)	Engineering	7.5
	construction	9.7
	contractor's fee	4
	contingency	7.8
Fixed Capital Investment (FCI)	Sum up above	100
Start-up related cost	working capital	OPEX/12
	start-up cost	9
CAPEX	FCI + working capital + start-up cost	

**Table 2 Calculation of OPEX (Peters,1959)**

	Items	Calculation
Facility-dependent costs	Depreciation	$(DC-PC*0.1)/10$
	maintenance	0.15 purchase cost
	insurance	0.01 TFC
	local taxes	0.01 TFC
	plant overhead	0.05 Revenue

Process related cost	Utility	
	Raw material cost	
	Waste management	
	(CO <sub>2</sub> tax)	
Labour-related cost	labour	0.07 (PRC+FDC)
	Laboratory charges	0.1 labour
OPEX	Sum up above	

2.3. Parametric studies

A sensitivity study was carried out for various conversions and the corresponding recycling ratios. The purge was fixed at 10%, and the rest 90% are recycled in all cases. In each case, the RCPs have been calculated.

3. Results

Figure 2 shows the relation between the single pass conversion of CO, and the recycle ratio (recycle flowrate/(fresh syngas+ recycle flowrate)). In all cases, the split ratio of recycle flow rate is fixed at 0.9. As we see, a lower conversion would lead to high recycle flow rates.

Figure 2 Single pass conversion vs Recycle ratio

unreacted CO. None of the cases showed positive viability compared to the existing market, and therefore further optimization of the process, and support (subsidies) may be required to bring ethanol from syngas fermentation to the market.

The effect of recycling on the economic feasibility of the process is shown in figure 3. The economic feasibility is represented in RCP as indicated in the previous section. It shows the positive or negative economic viability of ethanol as compared to the present market. Two scenarios are compared in this figure. Firstly, the RCP of the once-through process (no recycling) and secondly RCP of the process with recycling of

Figure 3 RCP (relative competitive percentage) for once through process and process with recycling in the production of ethanol from BOF gas via syngas fermentation.

Comparing the scenarios, recycling has improved the economic viability in multiple folds at lower conversions. It is due to the improved gas utilization, and production rates of ethanol. This is the trend up to around 60% of single pass conversion, and then the additional production cost of recycling is dominating. Therefore, at higher conversion rates, scenarios without recycling have better economic viability.

These results show a clear tradeoff between additional recycling costs and productivity improvement due to recycling. Therefore, to recycle the unreacted CO in improving the economic viability, the economic hot spots due to recycling must be identified, These units or variables must be optimized to minimize the recycling cost. Similarly, the limiting mechanism of improved production performance must be identified and must be tuned further to fully benefit from recycling CO back to the fermenter.

## Abstract

Many existing biorefineries use limited feedstocks and technologies to produce biofuels. However, an integrated biorefinery provides a variety of feedstocks and highly marketable final products leading to better economic viability. For this reason, this paper aims to perform a techno-economic analysis of the whole integrated biorefinery with modeling of the process in a flowsheet simulation tool, here Aspen Plus<sup>®</sup>. After having mass and energy balances, the assessment of technical aspects, and the economics of the integrated biorefinery process is the step forward in the development of a sustainable and biobased industrial process. In that matter, capital expenditures (CAPEX), operational expenditures (OPEX) and production costs are estimated for the integrated biorefinery, processing lignified halophyte biomass.

**Keywords:** Biorefinery, second-generation feedstock, value-added compounds, flowsheet simulation, cost-estimation.

## 1. Introduction

To cover the rising demand for food and energy is a strengthening challenge in today's world. Additionally, there is a strong need for sustainable production processes. Therefore, the concept of circular economy is more and more applied in biorefineries. There are numerous options to design a biorefinery based on feedstocks used, processes applied and products yielded. In second-generation feedstock biorefineries, wastes from agriculture and lignocellulosic biomass are processed. Thus, the decline in agriculturally usable land can be circumvented (Kamm et al. 2000). But the lignocellulosic and recalcitrant structure of the biomass with lignin, cellulose, and hemicellulose requires more process steps than first-generation feedstocks. For the production of biofuels, the thus higher production cost can make the biorefinery not competitive with fossil sources. Integrated biorefineries are advanced biorefineries including multiple processes and products for different industries to maximize the biomass valorization (Patel and Shah 2021). Hence, the incorporation of the extraction of value-added compounds in integrated biorefineries can improve economic performance (Kamm et al. 2000).

In this paper, the biomass category in focus is halophytes. These are salt-tolerant plants, which, in addition to their capability of growing without freshwater supply, are also yielding a range of bioactive compounds. These secondary metabolites are synthesized as part of the halophyte's survival mechanism in saline environments. Those phenolics

act as natural antioxidants and are of interest for their application in a variety of foods, cosmetics, and pharmaceuticals. This is additionally based on their antimicrobial activity against several pathogenic microorganisms (Jdey et al. 2017). Several halophyte species are traditional medical and nutritional plants, with the edible tips being part of gourmet foods (Antunes et al. 2021). But the dominant part of the plant is lignocellulosic biomass, which is to be valorized in circular economy biorefineries (Brown et al. 2014).

The halophyte species in the scope of this article is *Salicornia ramosissima*, which is already available on the market and can be harvested in saline areas across Europe. Further *S. ramosissima* biomass has elevated amounts of hydroxycinnamic acids and is therefore of interest for industrial valorization (Antunes et al. 2021). The lignified biomass contains extractable phenolic compounds such as hydroxycinnamic acids (HCAs) and polyphenolics, being of interest for the cosmetic and pharmaceutical industry.

Consequently, extraction methods are established also including the utilization of residual biomass for biogas and biochar production. Hence, it is a combination of different processing steps such as biomass fractionation and the production of biogas and biochar after the recovery of value-added compounds.

In the course of the process design of a whole integrated biorefinery, it is important to perform a techno-economic analysis to evaluate its technical feasibility and economic performance. Additionally, the choice of the technologies to be implemented, the operating conditions of the process units, and their sizing can be optimized through techno-economic assessment. (Bangalore Ashok et al. 2022).

## 2. Conceptual design of the integrated biorefinery

The conceptual process design of the integrated biorefinery with its individual process steps is shown in Figure 1.

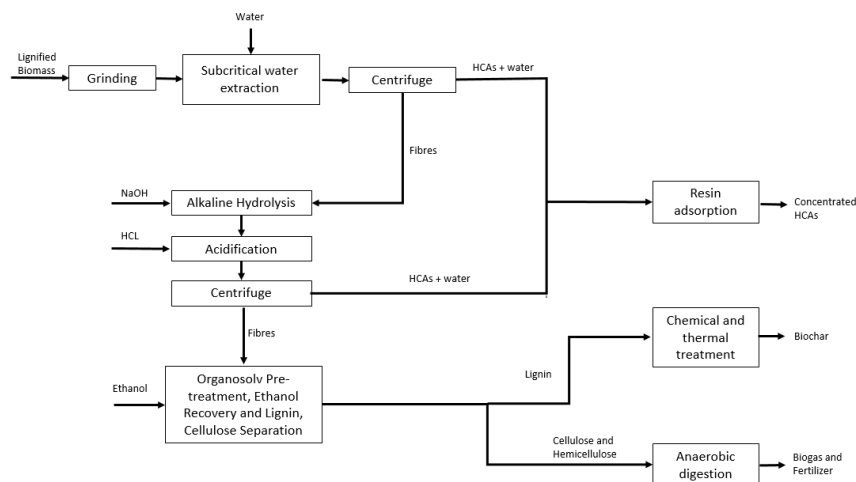

Figure 1: Conceptual process flowsheet of the integrated halophytes biorefinery

As a raw material for the process, lignified biomass was assumed to be sundried in the field, therefore grinding is the first step as pretreatment to reduce the particle size. It is followed by subcritical water extraction (SWE), a non-conventional extraction process (Taşçı Çilak et al. 2022). Downstream the SWE process, the remaining fibers are sent to alkaline hydrolysis to extract remaining HCAs. Alkaline hydrolysis at elevated

temperatures is used as post-treatment of SWE. After alkaline hydrolysis, extracts are acidified by using hydrochloric acid (HCl aq.) to lower the pH value. Consequently, both extracts from acidification and SWE are combined and by ion exchange resin to concentrate HCAs and remove sugars, salts, and all water-soluble contaminants. To realize maximum benefits, residual lignified fibers are subjected to organosolv pretreatment to generate streams that are rich in cellulose and lignin. In the organosolv process, lignin is separated from cellulose and hemicellulose by using 50/50 v/v ethanol and water solution. After that, the cellulose rich stream is valorized in anaerobic digestion to generate biogas while the lignin stream is sent to a biochar production unit.

The process flowsheet modelling and simulation of the integrated biorefinery is carried out in the commercial computer-aided process engineering (CAPE) tool Aspen Plus<sup>®</sup> V11 to enable mass and energy balance calculations.

### 3. Methods

#### 3.1. Process design and assumptions

In this study, the main focus is on the extraction of value-added compounds from the lignified biomass of the halophyte species, *S. ramosissima*. The respective approach offers the opportunity to expand the product portfolio by adding biogas and biochar as products along with high-value extracts. As a starting point to set the assumption regarding the capacity of the biorefinery, a production scenario of 1000 tons/year of lignified biomass is considered as the biorefinery capacity with 8000 h of operating hours. Furthermore, Germany is chosen for the biorefinery location. In the simulation tool (Aspen Plus<sup>®</sup>), the composition of the biomass is defined based on dry weight as 27 wt% ash, 5 wt% proteins, 3 wt% lipids, 9.5 wt% lignin, 11.5 wt% cellulose, 17 wt% hemicellulose, and 27 wt% extractives. Also, the moisture content in the feed is defined to be 15 wt%. In the process concept, recovery of lignin is assumed as 64 wt% whereas cellulose retention is 70 wt%. Also, the recovery of the targeted HCAs is estimated as 85 wt%. Assumptions, which are taken in this article, are inspired from the overall framework of the AQUACOMBINE project (AQUACOMBINE). In the flowsheet simulation model, the thermodynamic property packages ‘Solid’ and ‘NRTL’ have been applied. The physical properties such as boiling point, molecular weight and heat capacities of components being not available in the Aspen Plus<sup>®</sup> database (e.g. lignin, cellulose) have been entered by hand. Conventional compounds are selected from the AspenPlus<sup>®</sup> database. Moreover, the models that are used to define the unit operation of the process are given in Table 1.

Table 1: List of equipment and its model used in Aspen Plus<sup>®</sup>

Separation process for HCAs		Organosolv process and biochar generation	
Equipment	Model in Aspen Plus <sup>®</sup>	Equipment	Model in Aspen Plus <sup>®</sup>
Crusher	Gyratory Crusher	Mixer	Mixer
Reactor	Rstoic	Reactor	RStoic
Separator	Flash2	Separator	Flash2
Heat exchangers	Heater	Heat exchangers	Heater
Resin Adsorbtion	User Model	Washing	Swash
Centrifuge	Decanter	Separator	Sep
Pump	Pump	Distillation	RadFrac
		Precipitator	RStoic

### 3.2. Cost Estimation Method

In the simulation of the conceptual process, as shown in Figure 1, the various types of equipment such as heat exchangers, crushers, pumps, reactors, and vessels were used. The costs of each equipment have been calculated based on parameters like temperature, pressure, mass flow rate, and utilities which were compiled from the simulation. In addition to that, material of construction, efforts for installation, etc. were considered in the equipment costs. Furthermore, the whole economic assessment has been done with reference to the year 2019, using the chemical engineering plant costs index (CEPCI), a currency conversion rate of 0.87 USD/EUR and the estimated lifetime of the plant being 20 years. The cost estimation method based on the individual factor method of Guthrie (1969, 1974) is followed (Seider et al. 2009) to evaluate the total capital investment (TCI). Initially, the purchase costs of equipment are determined using empirical equations. Further, the respective cost estimation method is based on the bare module factors which are based on the type of equipment (e.g. pumps: 3.30, shell and tube heat exchanger: 3.17, crusher: 1.39). The sum of all bare module costs of equipment, process machinery, spares, costs of catalysts, etc. gives the total bare module investments (TBM). The direct permanent investment (DPI) includes the sum of the costs for site preparation, services facility and allocated cost for utility plant and related facilities as they are shown in Table 2.

Table 2: Assumptions for calculating total capital investment (Seider et al. 2009)

Item	Assumption
Total bare module investment TBM	Contains costs related to purchase and installation of equipment
Cost of site preparation	5 % of TBM
Cost of service facilities	1.5% of TBM
Allocated cost for utility plant and related facilities	14% of TBM
Total of direct permanent investment DPI	Contains costs of TBM, site preparation, service facility, utility plants and related facility
Cost of contingencies and contractor's fee	18% of DPI
Total depreciable capital TDC	Contains costs of DPI, contingencies and contractor's fees
Cost of land	2% of TDC
Cost of royalties	2% of TDC
Cost of plant start up	10% of TDC
Total permanent investment TPI	Contains costs of TDC, land, royalties and plant start up
Total permanent investment TPI corrected	120% of TPI
Working capital	18% of TPI corrected
Total capital investment TCI	Sum of costs of TPI and working capital

Along with the further costs such as costs of contingencies and contractor's fees, costs of land, royalties, plant start-up, and working capital are calculated based on the percentages of TDC. Finally, the TCI is calculated as the sum of total permanent investment corrected and working capital (Seider et al. 2009).

## 4. Results

Based on the simulation results and selected operational parameters, the sizing of equipment has been performed. The cost estimation has been performed and the TCI has been calculated as 6869 k€ which covers the investment required for the considered biorefinery concept. The breakdown of the TCI is depicted in Table 3. The TBM is 2993 k€ whereas the total permanent investment corrected is 5821 k€. The addition of working capital (1048 k€) into the total permanent investment corrected provides the TCI.

Table 3: Break down of TCI

Costs	k€
Total bare module investment TBM	<b>2993</b>
Cost of site preparation	150
Cost of service facilities	45
Allocated cost for utility plant and related facilities	419
Total of direct permanent investment DPI	<b>3606</b>
Cost of contingencies and contractor's fee	649
Total depreciable capital TDC	<b>4255</b>
Cost of land	85
Cost of royalties	85
Cost of plant start up	426
Total permanent investment TPI	<b>4851</b>
Total permanent investment TPI corrected	<b>5821</b>
Working capital	<b>1048</b>
Total capital investment TCI	<b>6869</b>

Along with the estimation of total capital investment, the annual production costs are calculated and amount 4210 k€/year which is shown in Table 4.

Table 4: Break down of total production costs

Costs	k€/year
Raw material costs (excl. Biomass costs)	0.24
Utility costs	880
Direct wages and benefits (DW&B)	1300
Labour related operations (O)	1773
Maintenance cost (M)	343
Operation overhead	383
Property tax and insurance	85
Depreciation, D	167
Licensing fees	87
Cost of manufacturing	2869
General expenses	461
<b>Total production cost</b>	<b>4210</b>

The total production costs have been performed as the sum of variable cost items such as operational expenditures (OPEX) including raw material (e.g. water, ethanol, etc.) and utility costs (e.g. steam (2 bara, 120°C), cooling water (15°C), electricity, etc.) and other cost items as fixed operating expenses and general expenses. Fixed operating expenses include direct wages and benefits (DW&B) with consideration of 5 shifts, including illness and holidays, costs of labour related operations, maintenance costs, costs of operation overhead, cost of property tax and insurance (2% of total depreciable capital (TDC)), licensing fees (2% of sales), and cost of manufacturing. Moreover, the depreciation (D) is taken into consideration which is 4% of total depreciable capital (TDC). Also, selling expenses, research and development costs, management incentive compensation have been included in general expenses.

## 5. Conclusion

A techno-economic analysis on the integrated biorefinery processing lignified halophyte biomass was presented with the conceptual process design. The corresponding energy and mass balances have been calculated by the flowsheet simulation tool Aspen Plus®.

The estimated TCI and production costs amount to 6869 k€ and 4210 k€/year respectively. The selling prices of the high-value products are not included in this study because they are depending on the target sectors such as food, cosmetics and pharmaceutical industries. Hence, in this study total capital cost and production cost were aimed to be evaluated without focusing on revenue from the products. Nevertheless, in the context of the economics of the conceptual process, many factors such as the capacity of the biorefinery, production rate, type of feedstock, and technologies have an impact. In that regard, the sensitivity analysis and energy integration are required to reduce the cost in upcoming work. Therefore, the presented results in this study are preliminary, as they will be optimized and improved in the future.

## Abstract

Inordinate consumption of natural resources by humans over the past century and unsustainable growth practices have necessitated a need for enforcing global policies to sustain the ecosystem and prevent irreversible changes. This study utilizes the Generalized Global Sustainability model (GGSM), which focuses on sustainability for the Food-Energy-Water (FEW) Nexus. GGSM is a 15-compartment model with components for the food web, microeconomic framework, energy, industry and water sectors, and humans. It was validated based on historical data for global sectors and can predict population, global and regional water stress, GHG emissions, and the gross domestic product (GDP) for the next century. GGSM shows that an increased per capita consumption scenario is unsustainable. In this study, an optimal-control theory-based approach is devised to address the unsustainable scenario through policy interventions to evaluate sustainability by employing multiple global indicators and controlling them.

**Keywords:** GGSM, global sustainability, Fisher information, optimal control

## 1. Introduction

Global models depicting the state of the world help in the study of the complex interconnected dynamics of sustainable growth and provide a scientific basis for the decision-making process behind global policies. Some of the noteworthy global models are given below.

- WORLD 3 Model (Meadows et al., 1972[1,2])
- GUMBO Model (Boumans et al., 2002[3])
- Puliato et al. (2008)[4]: “Predator-Prey” model for population and gross domestic product (GDP)
- HANDY Model (Motesarra et al., 2014[5])
- EARTH 3 Model (Randers et al., 2017[6])
- HARMONEY Model (King et al., 2020 [7])

However, these models have the following deficiencies.

- These models are mostly empirical models
- They are not focused on FEW nexus
- They are mostly descriptive and not Prescriptive.

To circumvent these deficiencies, we developed a new global model called Generalized Global Sustainability Model (GGSM). This model consists of differential-algebraic equations focused on FEW nexus, both descriptive and prescriptive.

## 2. The GGSM Model

In this section, the generalized global sustainability model and its various features will be described. The current model is conceptually similar to the previous model (Kotecha et al., 2013 [8]). This work's exception is that it is a global model and focuses on the food-energy-water (FEW) nexus. GGSM was created to represent a simplified global ecosystem with enough detail to allow the pursuit of further study. The 15-compartment model consists of a simplified ecological food web set in a macroeconomic framework and a rudimentary legal system. The different compartments in the model, shown in Fig 1, are three primary producers (P1, P2, and P3), three herbivores (H1, H2, and H3), two carnivores (C1 and C2), human households (HH), industry (IS), energy producer (EP), fuel source, water reservoir, resource pool (RP) and an inaccessible resource pool (IRP).

The food web is modeled by Lotka–Volterra type expressions, whereas the economy is represented by a price-setting model wherein firms and human households attempt to maximize their economic well-being. The model development is done using global-scale data for stocks and flows of food, energy, and water, which were used to parameterize this model. Appropriate proportions for some of the ecological compartments, like herbivores and carnivores, are used to model those compartments. The modeling of the human compartment was carried out using historical data for the global mortality rate. Historical data were used to parameterize the model.

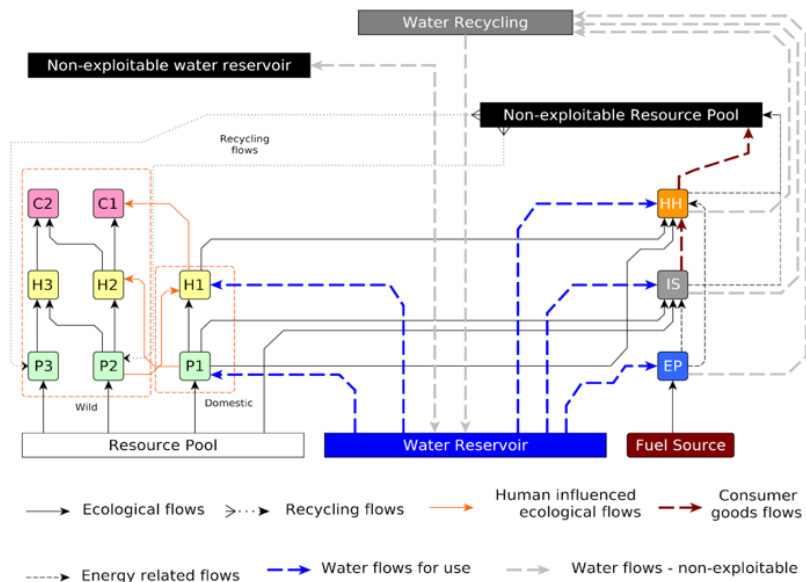

Fig 1. Generalized Global Sustainability Model (GGSM). Compartments: primary producers (P1, P2, P3), herbivores (H1, H2, H3), carnivores (C1, C2), human households (HH), industry sector (IS), energy producer (EP), fuel source, water reservoir, resource pool, inaccessible resource pool.

We used data for key variables like the human population, GDP growth, and greenhouse gases like CO2 and NOX emissions [9-12] to validate the model, as shown in Figure 2. The validated model becomes the foundation for the next part of the study and will be referred to in the following section as the "Base Case ."The model was then used to make long-term forecasts and study global sustainability over time.

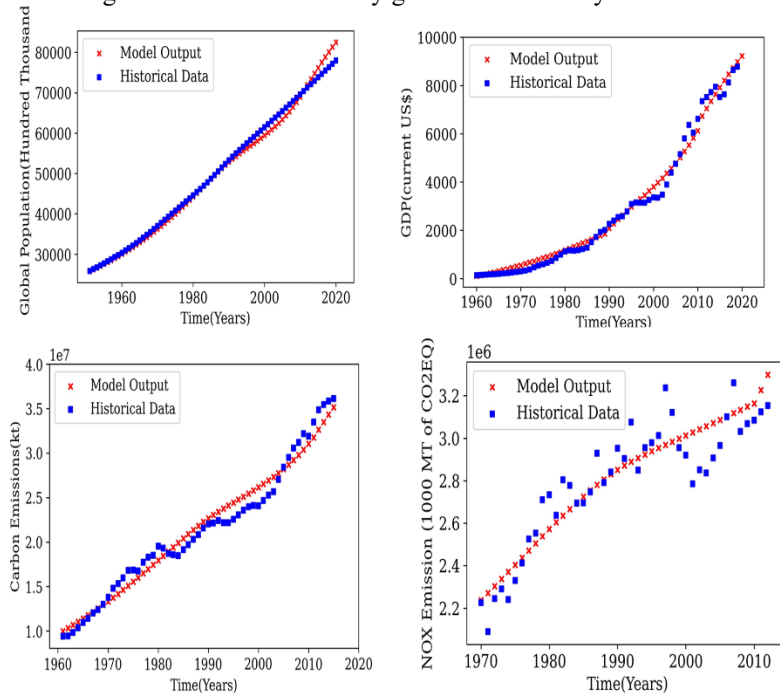

Figure 2: Results of Model Validation for Key Outputs

### 3. Scenario Analysis

The base case scenario represents the current state of the world. The other scenarios we considered are given below. We consider the forecast up to the year 2150.

- Scenario 1: Base Case: Business at the current level
- Scenario 2: Population Explosion: Human population grows at a rapid rate and then tapers off.
- Scenario 3: Consumption Increase: Consumption levels increase at a higher rate
- Scenario 4: Population Explosion with Consumption Increase: Both the population and consumption levels increase together

The ecological compartment results of scenarios 1 and 2 show that the planet can support the increase in population if human consumption does not increase significantly. However, for scenarios 3 and 4, the compartments start dying, as shown in Figure 3 for primary producer P1.

Figure 3: Scenarios 3 & 4, for P1

We know that these scenarios are the likely scenarios of our future. This means our planet will become unsustainable within this time frame. We are using optimal control theory to derive optimal techno-socioeconomic policies to make the planet sustainable in the above time frame.

#### 4. Deriving Techno-Socio-Economic Policies

GGSM showed that an increased per capita consumption scenario is unsustainable. In this study, an optimal-control theory-based approach is devised to address the unsustainable scenario through policy interventions to evaluate sustainability by employing multiple global indicators and controlling them given below.

- Fisher Information (FI): Measurement of the stability of the system
  - Fisher Information (FI) has been used as a measure of sustainability (Doshi et al. 2015 [13])
  - Thus, the objective for the optimal control problem is to minimize the variance of FI between the unsustainable system and an ideal sustainable system or the base case
- Ecological Buffer
  - Equivalent land demand of the population or land required to support the annual average consumption and the waste production of an individual
- Green Net Product(GNP)
  - Estimation of sustainability from a social welfare standpoint
  - Sum of the real value of consumption and real value of net investments
- Gross Domestic Product (GDP)
  - Economic performance evaluation
- Green House Gases (GHG)
  - CO<sub>2</sub> and NO<sub>x</sub> emissions to regulate total CO<sub>2</sub>EQ contribution by humans
- Global Water Stress
  - A measure of the stress on global water systems

The optimal control model assesses these multiple objectives by minimizing the variance in the Fisher Information. One significant result from this study is that optimizing for the Fisher Information-based objective is adequate to attain sustainability and manage the other objectives under consideration, as can be seen in Figure 4. Thus, forgoing a multi-objective problem framework. The results show that cross-dimensional policy interventions (Figure 5) such as increased vegetarianism (a), increased industrial efficiency (b), and increased penalty on industrial discharge (c) are shown to have a positive impact on scale. It should be noted that this increase in discharge fees for industries does not affect the GDP, as shown in Figure 4.

Figure 4: Behavior of Various Objectives when Fisher Information Variance Minimized

Figure 5: Optimal Profiles of Some of the Decision Variables

## 5. Summary

The Generalized Global Sustainability Model (GGSM), including ecological and economic dimensions to study the Food, Energy, and Water (FEW) Nexus is developed. Irrational human consumption would lead to an unsustainable future. Water availability is adequate, but regional water stress can be concerning. **Fisher Information**-based

optimization is enough to manage other sustainability objectives. GGSM can provide **techno-socioeconomic policy solutions** to make sustainable changes globally

## Abstract

In this study, we are tackling systems design with assessments for emerging technologies. Because of the data limitation on the systems and processes adopting emerging technologies, computer-aided process engineering (CAPE) tools such as process design heuristics, process simulation, optimization, parametric analysis for characterizing sensitivity and alternative generation. In this paper, we examine the feedstock recycling of waste plastics for raw materials in refineries. As for the pretreatment process of waste plastics, catalytic pyrolysis is applied. By modifying the condition of catalysts and reaction conditions, thermal decomposition of waste plastics into chemical feedstock was experimentally demonstrated to obtain low-molecular-weight hydrocarbons. This study converts the experimental results into process simulation models to conduct prospective life cycle assessment (LCA). For such purpose, the mathematical models on catalytic reactions and oil refinery were developed. The results showed that the performance of plastics pyrolysis could be linked with the improvements of environmental performances.

**Keywords:** catalytic pyrolysis, LCA, process modeling, process simulation.

## 1. Introduction

When carbon neutrality (CN) is achieved, assuming that no fossil carbon is used, carbon sources in the chemical industry will be largely limited to those from biomass, recycling, and CO<sub>2</sub> capture from the air (Meng et al., 2022). The current availabilities of these carbon sources are not sufficient to meet the demand for chemical raw materials due to their individual issues such as the limitation of the expansion of agriculture and forestry, the quality of waste-derived carbon, and the low technology readiness level (TRL). While the availability of biomass-derived carbon is limited (Energy Transition Commission, 2021), it should be utilized as carbon sources considering the effect of de-fossilization if waste biomass is included (Kikuchi et al., 2022) and the economic spill-over effects on agriculture and forestry (Kikuchi et al., 2020). Waste plastics as resources can be pyrolyzed to become hydrocarbons similar in composition to those used in conventional refineries (Koller et al., 2022). Although the qualities of waste plastics can be largely

different from the collection routes and the purpose of use of plastic products, there is a possibility that they can be converted into hydrocarbons inputted to refineries through appropriate treatment.

In this study, we are tackling systems design with assessments for emerging technologies. Because of the data limitation on the systems and processes adopting emerging technologies, computer-aided process engineering (CAPE) tools such as process design heuristics, process simulation, optimization, parametric analysis for characterizing sensitivity and alternative generation. In this paper, we examine the feedstock recycling of waste plastics for raw materials in refineries. As for the pretreatment process of waste plastics, catalytic pyrolysis is applied. By modifying the condition of catalysts and reaction conditions, thermal decomposition of waste plastics into chemical feedstock was experimentally demonstrated to obtain low-molecular-weight hydrocarbons. This study converts the experimental results into process simulation models to conduct prospective life cycle assessment (LCA). For such purpose, the mathematical models on catalytic reactions and oil refinery were developed. For catalytic cracking, the yield of the reaction was set and the inventory per unit of plastics was estimated by process simulation using Aspen HYSYS™. The yields and complexity factors for each unit operation in the refinery were taken from previous inventory data, and the energy consumption of the entire refinery was distributed to each process by the throughput and complexity factors. Naphtha reforming was assumed to be equivalent to that in the refinery, and inventory data for naphtha cracking were taken from a LCA database.

## 2. Materials and methods

### 2.1. Application of CAPE tools into prospective LCA

Figure 1 shows the description of systems assessments applying CAPE tools for prospective LCA. In management activity and resource provider, data estimation and interpretations are assigned to CAPE tools considering the conditions in prospective LCA.

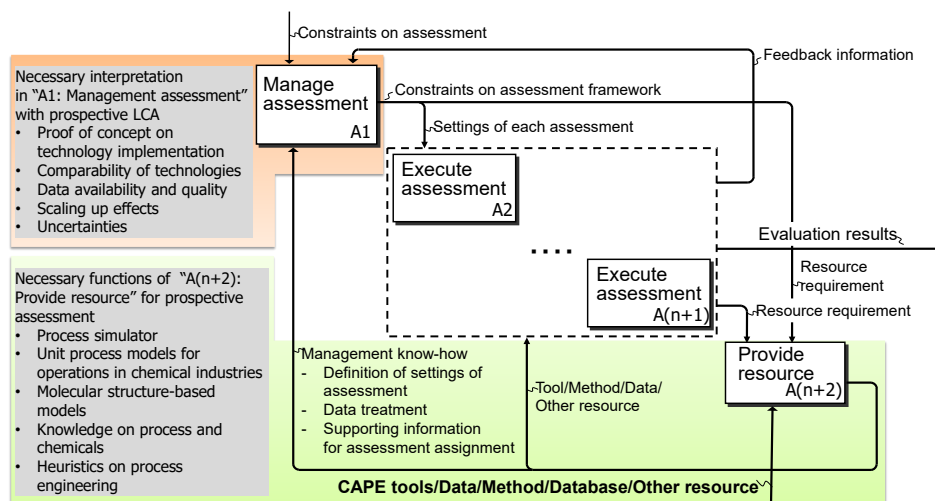

Figure 1 Description of multiple assessment activities with the necessary conditions for prospective LCA.  $n$  is the number of assessment methods. (Modified from previous studies (; Kikuchi, 2014; Kikuchi et al., 2010; Kikuchi and Hirao, 2009))

Life Cycle Thinking (LCT) is the process of considering the impact of a product throughout its entire life cycle, from the stage of raw material acquisition to its final disposal, when evaluating a product. LCA is a method for quantifying environmental impacts. There are two types of LCA: attributable LCA, which aims to visualize the environmental attributes of a product during its current life cycle, and consequential LCA, which aims to visualize the changes that occur when changes are made to the current life cycle (Ekvall, 2019). In the introduction of technological systems, where significant changes from the current system may occur, an analysis based on consequential LCT is necessary. The introduction of biomass-derived/waste-derived production technologies in chemical production and related life cycles, which are mainly based on the production of products derived from fossil resources, will bring about obvious changes and requires the design of the right type and scale of technical systems based on an assessment that takes into account the consequential impacts induced by these changes.

Conventional LCA can be carried out by collecting data on the target technology or system from actual production sites and combining other data extracted from LCA databases and other sources. On the other hand, in order to consider the development and introduction of CN and other sustainability-oriented technologies and systems, it is necessary to obtain information on non-existing life cycles and to carry out LCA. The applicability of LCA methods for the future of such technologies and systems is discussed (van der Giesen, 2020). LCA methods such as Consequential LCA, Dynamic LCA, Anticipatory LCA, Prospective LCA, and Ex-Ante LCA can be used for LCA of technologies under development, in other words technologies with low TRL, and systems after their introduction on a larger scale than at present, and for LCA of technologies that do not yet exist.

For the generation of life cycle inventory data, CAPE tools could be applicable. The previous review (Parvatker and Eckelman, 2019) demonstrated that the generation methods of inventory data should be selected in terms of the accuracy and the data/time requirements considering assessment objectives. For estimating inventory data, the applicable CAPE tools include process simulation, process input and output calculations, stoichiometry, and molecular structure-based models such as quantitative structure activity relationship (QSAR) models. Even if no stoichiometric/synthesis information is available, the inventory data of proxy chemical, which has already registered in LCA databases, can be selected with the understandings of chemistry of the technologies. While these CAPE tools have been developed mainly for chemical process systems, the inventory data of mechanical process systems such as metal processing and assembling might be estimated in the same manner.

### *2.2. Case study: Feedstock recycling of waste plastics*

Figure 2 shows the life cycle boundary of plastics including catalytic pyrolysis as feedstock recycling of waste plastics for raw materials in refineries. Catalytic pyrolysis can produce hydrocarbons similar in compositions to those used in conventional oil refineries. The profiles of obtained hydrocarbons have various patterns based on the temperature of pyrolysis and compositions of resins in waste plastics. There is a distribution of carbon chains in the pyrolysis products, and it is not easy to extract only specific hydrocarbons. Therefore, if the pyrolysis products are fed directly into the refinery flow, they may be fed together with crude oil into an atmospheric distillation column. The catalytic cracking process can be followed by a separation process to

separate the pyrolysis products into groups of certain carbon chains. This allows the products to be fed directly into certain unit operations of the refinery, thereby omitting some unit operations of the refinery.

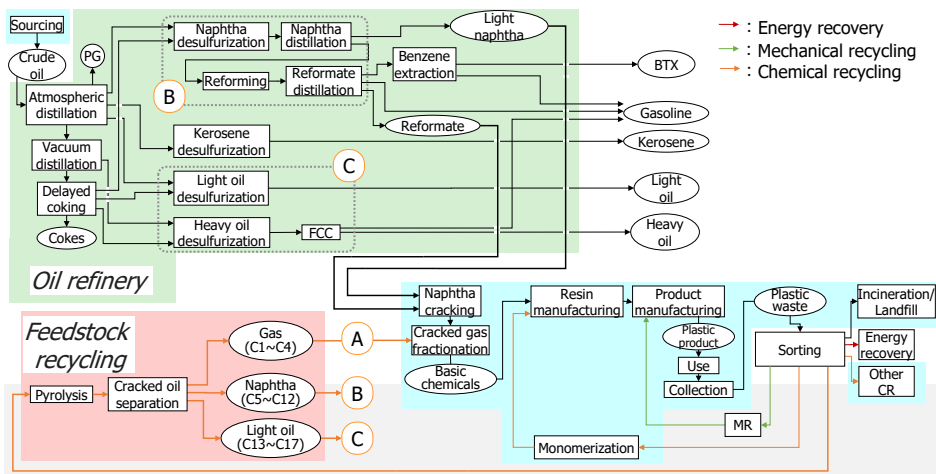

Figure 2 Life cycle boundary of plastics including catalytic pyrolysis as feedstock recycling of waste plastics for raw materials in refineries, where CR means chemical recycling, MR is material recycling, PG is purged gas, and FCC is fluidized-bed catalytic cracking.

The pyrolysis products were separated into three groups based on their carbon chains. Product A contains hydrocarbons (C1 to C4) which could be directly used as raw materials for basic chemical products through fractionation processes. This is similar to the stream after naphtha cracking in conventional petrochemical process systems. Product B is similar to naphtha, containing hydrocarbons (C5 to C12). This is fed to the unit operations around naphtha production in oil refinery. Product C contains heavy content and must be fed to FCC for further cracking. The unit operations and flows inside of oil refinery were extracted from the reports on existing refinery (Yoshitome et al., 2022).

Process simulation was applied as a CAPE tool to estimate inventory data. For catalytic cracking, the temperature dependence of pyrolysis products was collected from literature values, and the production yield from waste plastics was calculated (Keller et al., 2022). For the utility of catalytic cracking, inventory data for existing pyrolysis were used (Kikuchi et al., 2022). For inventory data in the separation system after catalytic cracking, the data were estimated using Aspen HYSYS<sup>TM</sup>. For unit operations in the refinery, the inventory of the existing refinery was calculated from the complexity factors and the utility of the entire refinery. For unit operations where the flow rate increases due to the merging of waste plastic-derived components, the increase in energy input due to the increased flow rate was calculated using a linear approximation. For each unit operation, a facility capacity was set.

### 3. Results and discussion

Figure 3 shows the example of process simulation results; greenhouse gas (GHG) emission for oil refinery and petrochemical process for a conventional oil refinery in Japan, the throughput of which is 18,115 kL-crude oil per day. The functional unit is set as the operation of this oil refinery plant. The results of this prospective LCA

demonstrated that the catalytic pyrolysis of waste plastics could reduce the GHG emissions attributable to oil refinery by reducing refined crude oil. Based on the compositions of pyrolysis products, for example, the flowrates in oil refinery were changed, which resulted in the changes of the product ratios in oil refinery. If the pyrolysis products contain hydrocarbons similar to naphtha or ones from naphtha cracker, the carbon source from waste plastics can be easily circulated as raw materials of chemicals.

Figure 3 Example of process simulation results; GHG emission for oil refinery and petrochemical process for a conventional oil refinery in Japan, the throughput of which is 18,115 kL-crude oil per day. The inputted waste plastics were capped by the capacity of FCC. The background process inventories were extracted from Japanese LCA database (IDEA v3.2).

Converting waste plastics to oil through pyrolysis allows the reuse of existing refinery equipment, which may reduce the barriers to the introduction of new technologies. On the other hand, the composition of hydrocarbons obtained by catalytic cracking of waste plastics is different from that contained in crude oil. Therefore, when pyrolysis products derived from waste plastics are fed into refineries, the composition of the products obtained as petroleum derivative products will change. Although it is possible to adjust the composition of the product system by changing the temperature and catalyst in catalytic cracking, it is necessary to modify the refinery to meet future demand for petroleum products. These issues need to be analyzed through LCAs that take into account the consequences of other social scenarios, such as reduced gasoline consumption due to the electrification of automobiles and reduced demand for fossil fuels due to changes in the composition of power sources.

#### 4. Conclusions

In this study, a mathematical model was constructed for catalytic pyrolysis of waste plastics and oil refinery receiving the pyrolysis products as raw materials as feedstock recycling of plastics. As a result, we confirmed the changes in GHG emissions from the production of various petroleum-based products and products due to the introduction of catalytic pyrolysis. The effect of conversion of waste plastics to chemical feedstock aimed at reducing fossil resource consumption cannot be fully assessed only by evaluating the GHG emissions resulting from the substitution of fuel oil and chemical feedstock. Changes in demands of energy and chemicals in society should be taken into account. As a sustainable or recyclable carbon sources, waste plastics should be able to become a

stable source which can be gathered from industries and municipalities. However, the current waste plastics are contaminated with other materials such as papers, metals, sands, garbage, and so on. Additionally, the resin types are also mixed in waste plastics. The pretreatment process, i.e., sorters, is important for the quality of raw materials for catalytic pyrolysis. The prospective design of life cycle should be conducted with social systems and supported by LCA with CAPE tools.

## Abstract

The global economy must restrict net greenhouse gas emissions to the environment to zero by 2050. However, in the absence of rigorous methods, the precise path to net-zero remains ambiguous, despite the overabundance of candidate solutions. Our formulation builds on the existing net-zero roadmapping literature by including technologies at various readiness levels within the life-cycle network superstructure. A case study for chemicals and plastics value chains demonstrates the framework. We model the current global plastics and chemicals industry and the promising low carbon solutions, based on electrification, biomass, carbon capture and circularization. Our framework allows the evolution of background emissions and maturities of technological solutions. We solve a multi-objective optimization problem at discrete time steps to roadmap for projected chemicals production till 2050. Our results show that net-zero value chains are only possible with a combination of energy efficiency and material recycling. Lower TRL technologies enable this transition, but only on upfront investments into their development. Our framework incorporates the realistic limitations of adopting emerging technologies with low TRL values into the decision-making process. The product specific insights gained may be used to guide future strategies.

**Keywords:** net-zero, circular economy, multi-objective optimization, life cycle

## 1. Introduction

The irreversible repercussions of incumbent climate change threaten the future of humankind. This has led policymakers across the world to seek to steer the global economy to operate with net-zero emissions. While most current research efforts in this direction are geared towards delivering cleaner energy with minimum emissions to industrial and residential systems, “net-zero” cannot be reached unless material value-chains are reinvented.<sup>1</sup> The direct emissions from the chemicals sector account for a humble 7% of the global emissions. However, as chemical energy carriers like hydrogen and methanol become increasingly important in other residential sectors, eliminating emissions from this hard-to-decarbonize sector becomes critical.

Many new technologies and innovations have been developed in the recent past to address this transition. However, in the absence of modelling techniques, choosing the most

sustainable, economic and robust solutions is impossible. In addition to numerous life-cycle studies evaluating the emissions abatement potential of emerging technologies in isolation, research has compared the net-zero potential of technology combinations in product systems such as methanol.<sup>2</sup> Existing research has also evaluated the precise combination of technologies for the global chemicals industry to get to net-zero, while investigating possible cost drivers.<sup>3</sup> This steady state analysis, however, does not evaluate nascent innovations or the temporal evolution of technologies. Even though research, such as that by Zibunas et al. account for the capital investments required for technologies to become viable, the gap in developing roadmaps to reach net-zero chemical systems, remains unbridged.<sup>4</sup> The evolution of innovations through time is a crucial consideration in the design of roadmaps and remains unaddressed in current literature.

In this paper, we design a roadmap to guide the transition of the global chemical industry towards net-zero greenhouse gas emissions. Life-cycle assessment methods and the Sustainable Circular Economy (SCE) framework are used to model emerging technologies.<sup>5</sup> The temporal evolution of emerging technologies is utilized to design roadmaps i.e., value chains of chemicals and plastics with the least greenhouse gas emissions or generate the greatest possible value. The linear evolution model that we assume for innovations can be easily replaced by deterministic models and eventually surrogated with simpler functions in the optimization problem.

## 2. Methodology

### 2.1. Model of Chemical Industry

The global chemical industry is modelled as a network of individual processes. We use bottom-up linear steady state models to represent individual processes in the network. These processes are assumed to scale linearly to meet the global demand of chemicals and plastics. This assumption allows the scale-up of linear life-cycle models to meet demands at the economy scale. This version of the study does not model fractional yield and assumes stoichiometric conversion of reactants to products instead. Since the global demand of chemicals and plastics is used to solve for the optimal resource use, the calculated resource use via stoichiometric calculations essentially serves as a lower limit on resource use, which is the worst case scenario. Chemical value chains are modelled including refinery processes to convert fossil feedstock to olefins and aromatics, production of various chemical intermediates, solvents, monomers, fertilizers, and polymerization reactions to produce rubbers, plastics, and plasticizers. The thermal energy and electricity needs of these processes are modelled using global averages of industrial heating and electricity mixes. Our model covers all high-volume chemicals and plastics, and most minor flows in the industry.<sup>9,10</sup> Publicly available data are used to populate the network. These models are represented as a matrix of linear equations, similar to the LCA framework. Processes at the refinery stage are populated with globally averaged data over multiple refineries from industrial reports. Averaged composition of inputs to and outputs from refineries are used for the calculations. Further downstream, conversion and polymerization reactions are modelled using chemical reaction data. The model contains multiple production pathways and final demands are assumed to be fulfilled by appropriate contributions from these pathways. Energy demands of the processes are calculated from specific energy consumption data from IEA.<sup>11</sup> A detailed version of the approach can be found in the authors' past publication.<sup>9</sup>

### 2.2. Modelling emerging technologies

We supplement the baseline network of conventional technologies by models of emerging technologies to obtain a superstructure network with alternatives at all life-cycle stages.

At present, the sector of chemicals production is inherently dependent on carbonaceous fossil feedstock. These feedstocks can be bypassed by more circular pathways such as the utilization of carbon dioxide captured from other emission sources. In this work, we model the conversion of carbon dioxide by electrochemical and thermochemical means to ethylene and methanol, with and without the intermediate formation of syngas. We also model the electrolytic production of hydrogen via water splitting (green hydrogen).

Biomass feedstock may replace most hydrocarbons produced by refinery operations. Our model includes the production of syngas from woody biomass, such as pine and eucalyptus, as well as the catalytic biomass-to-aromatics processes discovered at the Catalysis Center of Energy Innovation, University of Delaware, referred to henceforth as the CCEI process. Since the emerging technologies modelled thus far only produce methanol as a platform chemical, we also include the acid catalyzed transformation of methanol to aromatics to allow production of aromatics derived products.

Mixed plastic waste generated from residential and industrial sectors may be landfilled or recycled to maintain some fraction of its original value. Our superstructure network includes the mechanical (primary) recycling of PET bottles, the chemical (secondary) recycling of PET viz enzymatic hydrolysis and methanolysis reactions, pyrolysis (tertiary recycling) of mixed plastic waste to produce pyrolysis gas as well as syngas, and the transformation of waste to energy (tertiary recycling) via incineration. We also model the recovery of monomers from polyethylene by pyrolysis to produce a mixture of hydrocarbons. Recycling is included in the superstructure network as circular flows which intrinsically determine the emissions associated with circular flows, instead of estimating them with stationary emission factors, using the SCE framework.<sup>5</sup>

Refinery operations, boilers and furnaces are responsible for the majority of the emissions from the chemical industry. We model steam methane reforming of natural gas, partial oxidation of coal and oil, steam cracking of natural gas and naphtha, and catalytic reforming of naphtha to be amenable to post combustion capture using Monoethanol amine (MEA), since flue gases from these processes have relatively high concentrations of carbon dioxide (5-15%).<sup>6</sup> The carbon dioxide thus captured is considered available for utilization i.e., conversion to value added products.

### 2.3 Cost Models

We model the costs of each module as the difference between product and resource costs. This formulation allows the estimation of emerging technological pathways with unknown costs, in terms of costs of input and output flows. We implicitly assume that emerging technologies replace conventionally made products at the same price point. This assumption requires investments into research and development, policy intervention and sharing of environmental burden across stakeholders.

### 2.4 Road-mapping Framework

$$\begin{aligned}
 \min_{s_t} Z(s_t) &:= -T_t = -C^{Module} s_t \\
 \min_{s_t} Z(s_t) &:= h_{GWP} = \phi_{GWP} r_t \\
 \text{s. t. } &As_t \geq f_t \\
 &r_t \leq r_t^U \\
 &0 \leq s_t \leq s_t^U y_t \\
 &\mathcal{F}(s_t \geq 0) \\
 \text{where } &f_t = f_0 + f_0 \gamma t \\
 &r_t = B s_t \\
 &r_t^U = r_0^U + r_0^U \beta T \\
 &t \in T; T = \{0, 1, 2, \dots, 10\}
 \end{aligned}$$

$$\begin{aligned}
 y_t &= \{y_{i,t}\}; i \leq m; y_{i,t} \in \{0,1\} \\
 y_{i,(t+1)} &= 1 \text{ if } t \geq (11 - TRL_{i,t}) \forall i \in I \\
 TRL_{i,t+1} &= 1 + TRL_{i,t}
 \end{aligned}$$

We perform a multi-objective optimization on our superstructure network, minimizing greenhouse gas emissions or maximizing the value generated by chemicals production. The epsilon constraint method is used to draw Pareto fronts through the optimal points. The underlying superstructure network is subjected to fulfillment of societal needs of chemicals. The global chemicals capacity  $f_t$  is used to impose a lower limit on production, which evolves linearly through subsequent time steps at current growth rates.  $\gamma$  is the vector of growth rates. An upper limit  $r_t^U$  is imposed on the availability of some resources like biomass, which also evolve linearly over time. The growth rate of biomass availability,  $\beta$ , is estimated using the current availability of 35 EJ of bioenergy and the assumption that, of the 150 EJ biomass required for sustainable bio-energy production by 2050, 90 EJ will be available for chemicals production by 2050.<sup>7</sup> Renewable electricity is also assumed to evolve linearly from generating at the most, 30% of the supply at the beginning, to 85% at the last time step.<sup>8</sup> Our formulation restricts the inclusion of technologies within the superstructure, depending upon their Technology Readiness Levels (TRL). The parameter  $y_{i,t}$  determines whether a technology is available at time constraining the scale up of technologies until they are mature enough. All immature technologies ( $TRL < 10$ ) are assumed to reach the next TRL at each time step.  $y_{i,t}$  is updated accordingly, A technology is considered to be mature and ready to be adopted once its TRL reaches 10. Finally, governing equations are imposed as inequality constraints, ensuring no non-negative product accumulation.

### 3. Results and Discussions

This optimization problem, formulated as a linear program with 136 variables and 259 constraints, yields globally optimal solutions within reasonable time ( $\leq 1$  min) on an Intel Core i7-1165G7 CPU 2.8 GHz with 12 GB RAM. We visualize the trade-offs between emissions and cost as Pareto curves at each time step in Fig 1. Individual Pareto fronts indicate the lowering of value addition as emissions are progressively decreased. Any point on a Pareto front represents a value chain, all of which are equivalent solutions and improving one of the objectives worsens the other. However, as more technologies mature with each time step, the Pareto curves shift, allowing improvement in both objectives. The technologies introduced at each time step are indicated on the figure. We observe greater value generation even as emissions decrease, as products of the same value can now be generated with consumption of less valuable resources and inputs. The introduction of mechanical recycling shows greater value creation with the retention of plastics within the economy, even though emissions do not decrease significantly. The first net-zero solution is obtained on the introduction of biomass-based processes, which allow the sequestration of carbon during growth phase of the biomass. The shift of Pareto fronts between time steps 3 and 4 is win-lose as thermochemical carbon dioxide conversion pathways can lower emissions but are unable to create greater value. A huge jump in value addition results when plastic waste pyrolysis is introduced in the superstructure, allowing value creation in the form of chemical products and diesel, from waste. Finally, as electrochemical processes mature enough to be adopted, the resource

cost decreases significantly, along with emissions. We plot the adoption of individual technologies at each time step to better analyze how the value chains change with time.

Figure 2 shows the amounts of key hydrocarbons produced by technologies. Benzene is initially produced by a combination of steam cracking and toluene dehydrogenation and disproportionation. As soon as the recovery of monomers from polyethylene matures, it becomes economically viable to produce benzene primarily by the chemical recycling of polyethylene. The use of toluene as feedstock for benzene production is completely replaced. Methanol, initially produced by syngas from steam methane reforming, first switches to being produced thermochemically from carbon dioxide, and eventually to production from syngas. To track the generation of syngas, we look at hydrogen production. Initially, renewables support the production of green hydrogen. However, as more biomass becomes available, the system adopts syngas production from woody biomass. Finally, as the pyrolysis of mixed plastic wastes matures, the pyrolysis of plastics is adopted to supplement biomass. We also see the re-adoption of methane reforming when carbon capture becomes viable. Lastly, the production of xylene from catalytic reforming is phased out and replaced by production from methanol and biobased syngas when readiness levels permit.

Figure 1: Improvement of both emissions and value addition objectives with adoption of new technologies over time

#### 4. Conclusions and Future Work

Our results reconfirm the need to combine all low carbon solutions to cross the net-zero obstacle and get win-win solutions. Solutions like electrochemical conversion of carbon dioxide to hydrocarbons and bio-based chemicals emerge as robust solutions. Refinery operations such as catalytic reforming are replaced unless they can be retrofit with carbon capture technologies. Additionally, unless constraints are levied on landfilling for example, fossil based CCU solutions are preferred to the recycling of plastics. Ultimately, the ability of nascent technologies to ensure net-zero emissions is contingent on upfront investments into their research and development as well as policy interventions to ensure they are economically competitive with their fossil derived counterparts. The preliminary

findings from our work indicate that emissions abatement, as well as cost, are highly sensitive to the constraints imposed on the network. Therefore, utilizing predictions of renewables and resource availabilities, assessing climate change scenarios to ensure resilience to background emissions, and utilizing historical data to predict technological advancements are crucial. This work will be extended in the near future, to include integrated assessment models, utilize research and development costs as well as patent literature to stochastically predict technology evolution.

Figure 2: Contribution of processes to key hydrocarbon production. Bio-based and electrochemical processes are readily adopted as soon as they mature.

## Abstract

The increasing concern about global warming presses for a transition to more sustainable energy sources such as solar and wind power. To tackle the associated intermittency, chemical energy storage is witnessing a surge in interest from investors and policymakers. The efficient development of such technologies requires comprehensive analyses encompassing: (1) power-to-chemicals (P2C), (2) storage, and (3) chemicals-to-power (C2P). This work aims to compare ammonia and methanol as chemical energy vectors with other energy storage technologies. Data envelopment analysis (DEA) was used to compare the assessed technologies in terms of economic and environmental life cycle assessment (LCA) indicators, ranking the different technologies and estimating their required improvement targets. Overall, this work sheds light on the potential role of chemicals in energy storage applications, analyzing their advantages and disadvantages, and proposing improvement strategies to facilitate their development and future implementation.

**Keywords:** ammonia, methanol, energy storage, life cycle assessment, data envelopment analysis.

## 1. Introduction

A sustainable transition of the power sector to a decarbonized economy calls for an increased penetration of renewables, primarily solar and wind power. However, the intermittency of such technologies constitutes a challenge: new energy storage solutions are urgently needed, featuring high scalability and long-duration support. Highly suitable vectors for such a purpose are platform chemicals able to effectively store hydrogen (H<sub>2</sub>) in high energy density forms, such as ammonia (NH<sub>3</sub>) and methanol (MeOH) (Davies et al., 2020). Accordingly, a large set of technologies to convert power to chemical storage vectors (P2C) and then back to power (C2P) has been recently investigated, giving rise to a plethora of routes with wide variations in economic and environmental performance and inherent trade-offs. Systematic approaches to quantify and assess such trade-offs could, thus, support informed decisions in developing more sustainable routes.

In this work, acknowledging the scarce literature using similar case studies (Rostami et al., 2022), we apply for the first time Data Envelopment Analysis (DEA) to a large set of routes for power-to-chemical-to-power (P2C2P) involving NH<sub>3</sub> and MeOH. The goal is to assess their efficiency by considering multiple criteria simultaneously and to identify margins of improvement for suboptimal scenarios. DEA originally stems from the field of economics (Charnes et al., 1979) and has been only recently applied to sustainability problems (Vázquez-Rowe et al., 2010). Unlike other multi-criteria decision-making tools

(Tzeng and Huang, 2011), DEA does not rely on user-defined weight preferences to quantitatively assess and classify sets of alternatives based on multiple decision criteria simultaneously. Here we shall use DEA to gauge the efficiency of a chemical storage route based on all the considered economic and environmental decision criteria, further ranking all the overall efficient alternatives through the use of super-efficiencies, and estimating the required improvement targets for the sub-efficient routes.

## 2. Methodology

### 2.1. Generation of scenarios

For the P2C section, the Haber-Bosch process was simulated in Aspen Plus<sup>®</sup> to produce NH<sub>3</sub>, using H<sub>2</sub> from different sources and nitrogen from an air separation unit (D'Angelo et al., 2021). For MeOH, the single-step hydrogenation of CO<sub>2</sub> was assumed (González-Garay et al., 2019). Several H<sub>2</sub> routes were considered, including steam methane reforming (H<sub>2</sub>-SMR), H<sub>2</sub>-SMR using carbon capture and storage (CCS) (H<sub>2</sub>-SMR-CCS), biomass gasification with CCS (H<sub>2</sub>-G), and water electrolysis powered by a set of different sources: grid mix (H<sub>2</sub>-CE), nuclear (H<sub>2</sub>-N), wind (H<sub>2</sub>-W), solar (H<sub>2</sub>-S), bioenergy with CCS (H<sub>2</sub>-B), and hydropower (H<sub>2</sub>-H) (D'Angelo et al., 2021). CO<sub>2</sub> from carbon capture from combined cycle power plants (CC) or from direct air capture (DAC) powered by the same sources as for electrolytic H<sub>2</sub> was considered. For the C2P section, for NH<sub>3</sub>, a power plant was simulated (Sánchez et al., 2021) considering three different downstream treatments for the flue gas: H<sub>2</sub> recovery with nitrogen-argon separation (HR-NAS), H<sub>2</sub> recovery with subsequent flue gas release (HR-FGR), and H<sub>2</sub> combustion with nitrogen-argon separation (HC-NAS). For MeOH, the C2P section considered direct combustion (MC), MeOH decomposition (MD), and steam reforming (MR) (Deng and Hynes, 2012), with CCS applied for the flue gas in all cases. The results of all the combinations of feedstocks and C2P alternatives were compared with an adiabatic compressed air energy storage with a modified Kalina cycle (CAES) (Liu and Wang, 2016) and pumped hydro energy storage (PHES) (Dones et al., 2007).

### 2.2. Environmental assessment

The life cycle assessment (LCA) was performed following the ISO 14040 (ISO, 2014). A cradle-to-gate study based on an attributional approach was adopted, considering the whole life cycle until the P2C step. The selected functional unit was 1 kWh of delivered electrical energy from the various storage routes.

In the second LCA phase, the life cycle inventories (LCIs) are modeled. The foreground system includes all the steps from P2C to C2P, according to the defined scenarios. At the same time, the underlying energy and raw materials suppliers belong to the background system, here modeled with Ecoinvent v3.5, accessed through SimaPro v9.2. All the inventories assumed global (GLO) regionalization where available and Rest-of-the-World (RoW) otherwise. For the NH<sub>3</sub> and MeOH P2C steps, the average global grid power mix was considered for the processes, excluding H<sub>2</sub> and CO<sub>2</sub> generation. Salt caverns were assumed for intermediate H<sub>2</sub> storage (D'Angelo et al., 2021), and the oxygen by-product from water splitting was considered vented. In the third LCA phase, ReCiPe 2016 with the hierarchical approach (Huijbregts et al., 2017) was selected, with a focus on the midpoint indicators, namely: global warming (GW), stratospheric ozone depletion (SOD), ionizing radiation (IR), fine particulate matter formation (FPMF), human health ozone formation (OFHH), terrestrial ecosystem ozone formation (OFTE), terrestrial acidification (TA), freshwater eutrophication (FWE), marine eutrophication (ME), water consumption (WC), land use (LU), mineral resource scarcity (MRS), fossil resource scarcity (FRS), marine ecotoxicity (MECOTOX), freshwater ecotoxicity

(FWECOTOX), terrestrial ecotoxicity (TECOTOX), human carcinogenic toxicity (HCT), human non-carcinogenic toxicity (HNCT). Finally, in the last step of LCA, the results are interpreted, and recommendations are drawn. Here, we applied DEA to provide additional insights into the environmental efficiency of the generated scenarios.

### 2.3. Mathematical models of DEA

DEA provides relative efficiencies of the different alternatives (n) as the maximum ratio between the weighted sum of outputs (j, criteria to maximize) to the weighted sum of inputs (i, criteria to minimize). To this end, it solves a linear programming (LP) model, which, when reformulated into its dual form, also provides improvement targets for the different sub-efficient alternatives. In this work, we consider the input-oriented variable return to scale dual model M1, presented below as described by Cooper et al. (2007):

$$\begin{aligned}
 \text{M1} \quad & \min_{\theta_{n'}, S_i^-, S_j^+, \lambda_{n'n}} \theta_{n'} - \varepsilon (\sum_i S_i^- + \sum_j S_j^+) & (1) \\
 \text{s.t.} \quad & \sum_n \lambda_{n'n} x_{ni} + S_i^- = \theta_{n'} x_{n'i}, \forall i \\
 & \sum_n \lambda_{n'n} y_{nj} - S_j^+ = y_{n'j}, \forall j \\
 & \sum_n \lambda_{n'n} = 1 \\
 & \lambda_{n'n}, S_i^-, S_j^+ \geq 0, \forall n, i, j
 \end{aligned}$$

where the model variables include  $\theta_{n'}$ , the efficiency value of alternative  $n'$ ,  $S_i^-$  and  $S_j^+$ , the input and output, respectively, slack variables, and  $\lambda_{n'n}$ , the calculated efficiency projection weights of alternative  $n'$  on the efficient alternatives  $n$ . The model parameters include  $x_{ni}$ , the input  $i$  value for alternative  $n$ ,  $y_{nj}$ , the output  $j$  value for alternative  $n$ , and  $\varepsilon$ , a non-archimedean infinitesimal value.

Model M1 is solved for each of the considered alternatives  $n'$ , obtaining for each one its respective efficiency and projection weights. In essence, the best technologies are those with an efficiency score equal to one, while the rest could match the best-performing units by attaining some improvement targets provided by DEA. More precisely, it is possible to estimate the relative input improvement targets  $\tau_{n'i}$  for the different sub-efficient alternatives  $n'$  and input criteria  $i$  as the relative difference between the current input value  $x_{n'i}$  and the value projected onto the efficient frontier  $\sum_n \lambda_{n'n} x_{ni}$ . The relative input improvement target can be calculated as follows:

$$\tau_{n'i} = 1 - \frac{\sum_n \lambda_{n'n} x_{ni}}{x_{n'i}} \quad (2)$$

In order to rank the alternatives defined as efficient in model M1, it is possible to use super-efficiency models to calculate the super-efficiency scores  $\hat{\theta}_{n'}$  for the already efficient alternatives. These super-efficiency scores can be calculated by model M2, which only differs from model M1 in that the projection constraints consider only the other alternatives  $n$  and not the alternative being evaluated  $n'$ , as seen in the equations below. As in model M1, model M2 is solved for each of the efficient alternatives  $n'$ , obtaining the super-efficiency score  $\hat{\theta}_{n'}$ .

$$\begin{aligned}
 & \sum_{n \neq n'} \lambda_{n'n} x_{ni} + S_i^- = \hat{\theta}_{n'} x_{n'i}, \forall i \\
 & \sum_{n \neq n'} \lambda_{n'n} y_{nj} - S_j^+ = y_{n'j}, \forall j
 \end{aligned} \quad (3)$$

In essence, DEA is applied to identify the best technologies, which are further ranked according to their super-efficiency values, while providing valuable insight via improvement targets on how to make sub-optimal technologies efficient.

### 3. Case study: an application to chemical energy vectors route selection

The DEA method has been applied to 218 energy storage alternatives, encompassing 189 MeOH routes, 27 NH<sub>3</sub> routes, and 2 conventional technologies (compressed air energy storage, CAES, and pumped hydro energy storage, PHES). These alternatives have been analyzed considering their economic performance (i.e., relative cost of storage, RCS) and environmental performance. The latter has been evaluated through 18 LCA mid-point indicators in the ReCiPe2016 methodology (Huijbregts et al., 2017).

In total, these 19 economic and environmental indicators represent the input decision criteria (i.e., indicators to be minimized) for the DEA methodology. The electricity output of the system, 1 kWh for all alternatives, is the only output indicator considered. In order to ensure the numerical stability and robustness of the DEA results, all indicators have been linearly normalized between 0 and 1. The DEA model was implemented in GAMS 39.3.0 and solved with CPLEX 22.1.0.0 on an Intel® Core™ i7-4790 processor operating at 3.6 GHz. On average, each DEA model instance was solved with a zero optimality gap, taking between 0.03 and 0.14 CPU seconds. Models M1 and M2 consist of 240 variables and 22 constraints.

In addition to the considered economic and environmental indicators, the technical performance of each route was estimated through its total energy efficiency  $\eta_E = \frac{1}{E_{In} + T_{In}}$ , which considers the amount of electricity ( $E_{In}$ ) and thermal energy ( $T_{In}$ ) required through the entire route to obtain 1 kWh after releasing the stored energy. This indicator is not considered in the DEA, instead it is compared with the super-efficiency scores to determine whether super-efficient alternatives also present high energy efficiencies.

### 4. Results and discussion

Out of a total of 218 processes, only 52 (24% of them) were found to be efficient. Inspecting the efficient cases, no correlation was found between energy efficiency and super-efficiency scores (Figure 1). Thus, energy efficiency is not sufficient to establish the optimality level of an energy storage process from an economic and environmental perspective. The ten most super-efficient scenarios consist of eight NH<sub>3</sub>-based scenarios, CAES, and PHES, with the NH<sub>3</sub> | H<sub>2</sub>-B+HC-NAS scenario performing best, followed by CAES. Although not shown in Figure 1, efficient MeOH routes represent the majority of the remaining 42 alternatives, albeit their super-efficiency scores are strikingly smaller than the NH<sub>3</sub> and conventional storage alternatives.

Moving to the inefficient scenarios, the distribution of the relative improvement targets along the different indicators (Figure 2A) highlights that the worst-performing indicators, especially environmental metrics such as FWE, TA, and FPMF, require sensible improvements (39% on average). Moreover, the average improvement targets of the 12 metrics with the worst results lie within a narrow range (28-39%), and the 13 worst-performing indicators, on average, require substantial improvements (75-86% improvement margin). Conversely, the three best-performing indicators (GW, WC, LU) require an improvement below 10%, on average, and lower than 25%, even when accounting for extreme cases. Notably, the RCS is the fourth metric requiring the lowest improvement on average (12%) and in the worst case (37%). Such a result highlights how most technologies present relatively similar operational costs and greenhouse gas emissions in their life cycle, as well as in other generally considered environmental indicators (e.g., water and land use). This finding reflects how particular emphasis should be placed on often disregarded environmental metrics (e.g., FWE, TA) rather than solely GHG emissions or economic indicators when aiming to design fully sustainable energy storage strategies.

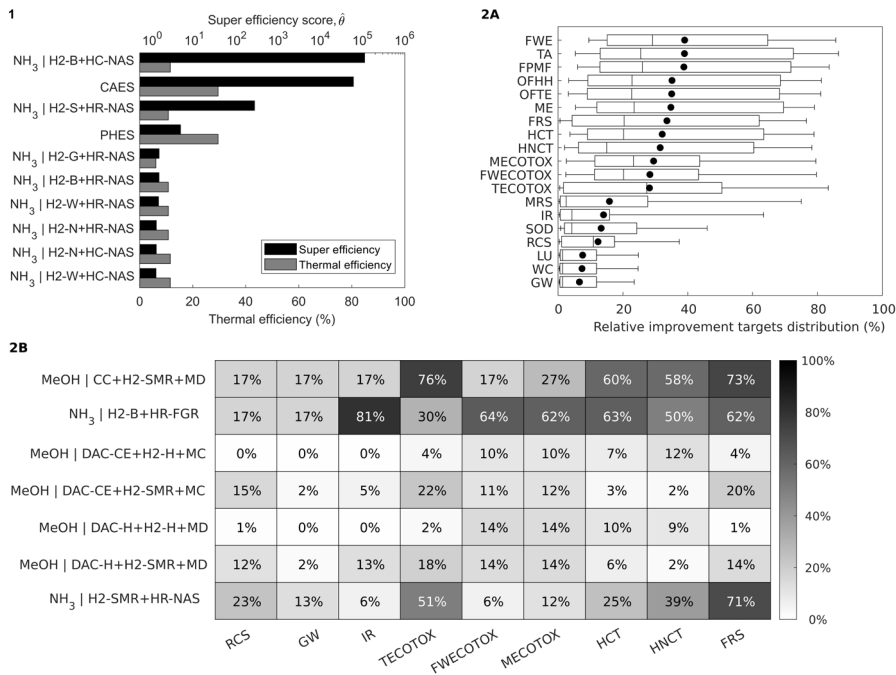

Figure 1. Super-efficiency (upper x-axis) and thermal efficiency (lower x-axis) scores for 10 alternatives with the highest super-efficiency scores.

Figure 2A. Relative improvement target distributions for all 19 input categories and their means (dots). Boxplots represent the 5<sup>th</sup>, 25<sup>th</sup>, 50<sup>th</sup>, 75<sup>th</sup>, and 95<sup>th</sup> percentiles.

Figure 2B. Relative improvement targets for sub-efficient alternatives with the best performance (not considering the efficient alternatives) in one or more input indicators.

Finally, Figure 2B presents the disaggregated relative improvement targets for the sub-efficient scenarios with the best performance in one or more of the considered 19 indicators. In contrast with previous results, MeOH-based technologies represent the majority of this set of sub-efficient technologies, with some of these alternatives presenting very high improvement targets in toxicity (e.g., TECOTOX) and resource scarcity (e.g., FRS) related indicators. This highlights how seemingly promising scenarios may still perform suboptimally, with only a few alternatives performing efficiently in these specific metrics. Among other scenarios, NH<sub>3</sub> | H2-B+HR-FGR would require significant improvements in toxicity-related categories due to the use of fertilizers in biomass cultivation. On the other hand, scenario MeOH | DAC-CE+H2-H+MC presents relatively low improvement targets (in some cases performing as other efficient alternatives), indicating how grid-powered DAC CO<sub>2</sub> capture and sequestration may be seen as a promising energy storage strategy based on methanol.

## 5. Conclusions

With the increasing number of developed alternative pathways involving energy storage, there is a spiking need for decision-support tools to systematically assess the current state of the art and optimally drive research efforts in this field. In this work, we apply a systematic methodology based on DEA to analyze a large representative set of P2C2P routes involving NH<sub>3</sub> and MeOH as energy storage vectors, considering both economic

and environmental criteria. The approach here considered has been able to, given a set of economic and environmental metrics and without the use of user-defined weights, identify and rank the overall best-performing energy storage alternatives and provide necessary improvement targets for inefficient alternatives. Our results highlight how energy efficiency is not correlated with the overall economic and environmental performance of the different routes. Also, NH<sub>3</sub>-based routes seem to be the most promising alternatives, along with CAES and PHES. Overall, this work aims to shed light on the potential of chemical energy storage by evaluating and comparing multiple alternative routes, highlighting the benefits that decision-support tools such as DEA can bring to the study and development of more sustainable energy systems.

## Abstract

In this study, the thermochemical plastic recycling process namely gasification has been investigated to process 10,000 kg/h of plastic waste. This study rigorously modeled and simulated the thermochemical processes that can recycle the plastic wastes efficiently to useful chemical such as di-methyl ether (DME). Currently, the cost of recycled plastic is not competitive compared to the fossil-based virgin plastics, which leads to the lack of industrial willingness for recycling. This study explored the technical feasibility to understand the processing of recycled plastics to useful chemical conversion. The results show that the gasification can provide a competitive solution with flexibility in terms of waste feed composition to produce DME at a large scale.

## 1. Introduction

Plastic production has readily invaded the global market by the middle of the previous century due to its wide range of applications in construction, textiles packaging, transportation, healthcare, and electronics sectors. Plastics have replaced the traditional materials such as wood, steel, and ceramics due to its versatile properties, i.e., low density, durability, low price, and corrosion resistance. Polyethylene (PE) and polypropylene (PP) represent nearly the half of production of plastics, on the other hand, polyvinyl chloride (PVC), polystyrene (PS), polyurethane (PUR), and polyethylene terephthalate (PET) are also produced significantly as shown in figure 1 (Lopez et al., 2018). Currently, the plastic production rate is increasing approximately at 4% per year, reaching an annual production of more than 353 million metric tons in 2019 (OECD, 2022). Owing to this mega-scale utilization of plastics in everyday domestic and industrial products poses a dramatic problem of plastic waste management that needs firm decisions be taken. According to Organization for Economic Co-operation and Development (OECD), only 9% of global plastic waste is recycled, while 49% of waste plastic was discarded, mainly in landfills, 19 % wastes were incinerated, and 22% of the waste remained uncollected and mismanaged (OECD, 2022). Due to plastics low degradability, landfilling of plastics represents a significant problem to the planet's ecosystem. Besides, plastic incineration has several environmental issues, such as formation of dioxins, fly ash, sulfur, nitrous oxides, and other hazardous chemicals. At the same time, the world is facing a real challenge from climate change, where plastics contribute around 3.4 % of greenhouse gas emissions globally (OECD, 2022).

Figure 1: Global plastics production by type.

Figure 2: Global plastic production.

Some developed countries have started a waste plastic management plan; however, the required efforts are not enough, and mandate local, regional, and global actions be taken. Currently, different waste plastic recycling methods are already under investigation. Mechanical recycling is an efficient method that reconstruct the plastic into simpler shape while preserving the chemical structure. Although mechanical recycling of plastics is the most common plastic waste management method, it has some limitations. The feedstock needs first to be purified before proceeding further to achieve a high product quality; also, recycled product's market feasibility is still not proved (Ragaert et al., 2017). Recently, several countries are evaluating alternative fossil fuel options, and waste plastic is one such opportunity that is seen as lost resource that could be useful economically to produce valuable chemicals. Thermochemical plastic recycling is a technology where the heat is used to break a larger molecule to a smaller one that already made the plastic. Hence, chemical recycling is a potential route to enable a sustainable life cycle of plastic, and it is more flexible with feedstock than mechanical recycling [1,5]. Both pyrolysis and gasification processes fall under the category of thermochemical recycling. Gasification is a process where the waste plastic is heated at a high temperature with a limited amount of  $O_2$ . On the other hand, pyrolysis is a process where the plastic is being heated at a relatively lower temperature in the absence of  $O_2$ . The main advantage of gasification over pyrolysis is less sensitivity to different feed compositions or mixtures of plastics waste. Gasification of plastic mainly produces a gas stream that is rich in  $H_2$ ,  $CO_2$ ,  $CO$ , and  $CH_4$ . This syngas stream can then be employed either to produce energy or can serve as a raw material to produce a wide-range of important chemicals such as methanol, ammonia, di-methyl ether (DME) and others. DME has gained significant attention due to its clean combustion properties and easy handling as a fuel (Sansaniwal et al., 2017). DME can be synthesized from syngas in two ways, indirect and direct method. In the indirect method, methanol is first produced from syngas followed by the dehydration process. The direct method employs a bifunctional catalyst where methanol synthesis reaction, water gas shift reaction, and dehydration reaction co-occur as shown below in Eq. (1) – (4):

Direct synthesis of DME is a potential route as it can overcome the strong thermodynamic limitations of syngas conversion to methanol by shifting the equilibrium. This study is

focused on the DME production from the gasification of waste plastic. Some previous works studied the plastic gasification. Shehzad et al., (2016) investigated the municipal solid waste (MSW) performance by varying gasification operational conditions. They reported that a higher gasification temperature has a significant impact on syngas composition. The results showed that gasification process has lower efficiency when utilizing MSW for electricity generation application, compared to the incineration; however, since chemicals could be produced from syngas, further economic analysis to make a suitable judgment was recommended. Weiland et al., (2021) studied the gasification of complex plastics and found that high temperature gasification processes that are usually assisted with high purity oxygen can generate syngas with heating value in the range of 10 – 13 MJ/Nm<sup>3</sup>. Similarly, many studies explored the DME synthesis through a one-step route. For example, Chen et al., (2012) studied the DME direct route synthesis from the syngas by developing a bifunctional Cu–ZnO–Al<sub>2</sub>O<sub>3</sub>/ZSM5 catalyst. They found that the DME yield decreases as the CO<sub>2</sub> concentration in the syngas increases. Guo et al., (2022) studied the DME one-step synthesis from the syngas produced by the biomass. This study was mainly focused on the catalyst development and reported that a hybrid catalyst comprised of CuO–ZnO–Al<sub>2</sub>O<sub>3</sub> and HZSM-5 has a synergetic effect on the DME synthesis. Most of the previous works shed light on the waste plastic gasification experimentally and one-step direct DME synthesis independently. Besides, there are no remarkable studies that evaluated the DME production from waste plastic gasification. Therefore, the aim of this study is to design and simulate a commercial scale DME production unit considering waste plastic as a feedstock.

## 2. Process and Simulation details

The process contains three main sections: waste plastic gasification, acid gas removal (AGR) unit, and DME production and purification, as shown in figure 3.

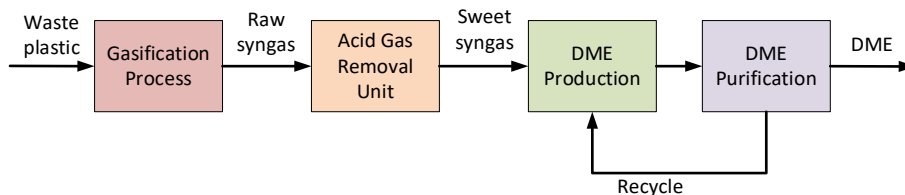

Figure 3: Simplified block diagram of plastic waste to DME production process.

### 2.1. Gasification Process

The waste plastic is first shredded before feeding it to the gasification process. The gasification reactor operates at 887°C and 1 bar in the presence of high purity oxygen. The gasifier effluent produces syngas rich in H<sub>2</sub>, CO<sub>2</sub>, CO, and CH<sub>4</sub> and slag which comprise of ash and unconverted carbon. One operational trouble with plastic gasification is the sticky nature of plastic material, however, this problem can be minimized by operating gasification at higher temperatures. A multi-stage cooler system is used to cool the reactor effluent before separating the syngas from the slag. Waste plastic is simulated as a non-conventional component in Aspen Plus by defining its ultimate and proximate analysis. Peng-Robinson thermodynamics property was utilized to model the gasification process. The base assumes the plastic waste feed rate of 10000 kg/h, while the oxidant is assumed to be 98 mol.% pure oxygen. The gasifier has been modeled using a RGIBBS subroutine that works on the principle of minimization of Gibbs free energy.

### 2.2. Acid gas removal (AGR) unit

A cleaning unit is an important process needed to reduce the CO<sub>2</sub> concentration before directly utilizing the raw syngas. In general, absorption with amines is the most convenient method to decrease the CO<sub>2</sub> level. A typical AGR unit consists of an absorber where the acid gases are absorbed by the amine, and a regenerator column where the rich amine is regenerated by stripping of the absorbed acid gases from the amine solvent. In this study, mono-ethanol-amine (MEA) has been utilized for the removal of acid gases. The AGR process has been modeled using AMINES thermodynamic package. The absorber is modeled using a RADFRAC block that removes 98% of the CO<sub>2</sub> in the syngas stream coming from the gasifier. The rich amine solvent is then sent to the regenerator (also modeled using RADFRAC) where the MEA solvent is regenerated, cooled, and recirculated to the absorber column. The calculator block in the Aspen plus is utilized to calculate the make-up solvent.

### 2.3. DME synthesis and purification unit

Sweet syngas from the AGR unit is first compressed in a multi-stage compressor stage with intercooling to reach the favorable reaction conditions (250°C and 60 bar). The compressed syngas is then fed to the DME synthesis reactor where a bifunctional catalyst yield DME via a one-step process explained earlier. The reactor effluent mainly contains unreacted syngas, DME, and methanol. The reactor effluent is sent to a series of separation units for the separation of product from the unreacted syngas and by-products. First, a flash drum is employed to separate most of the gas phase which mainly consists of unreacted syngas. The liquid phase leaving at the bottom of the flash drum is then sent to a series of distillation column where CO<sub>2</sub> is removed in the first column, product DME is recovered in the second column, and by-product methanol is separated in the third column which is recycled back to the DME synthesis reactor. DME synthesis and purification section has been modeled using Soave-Redlich-Kwong (SRK) equation of state. DME synthesis reactor is modeled using RPLUG by employing the Langmuir–Hinshelwood–Hougen–Watson (LHHW) kinetics. Figure 4 shows the process flow diagram of the overall plastic waste to DME process.

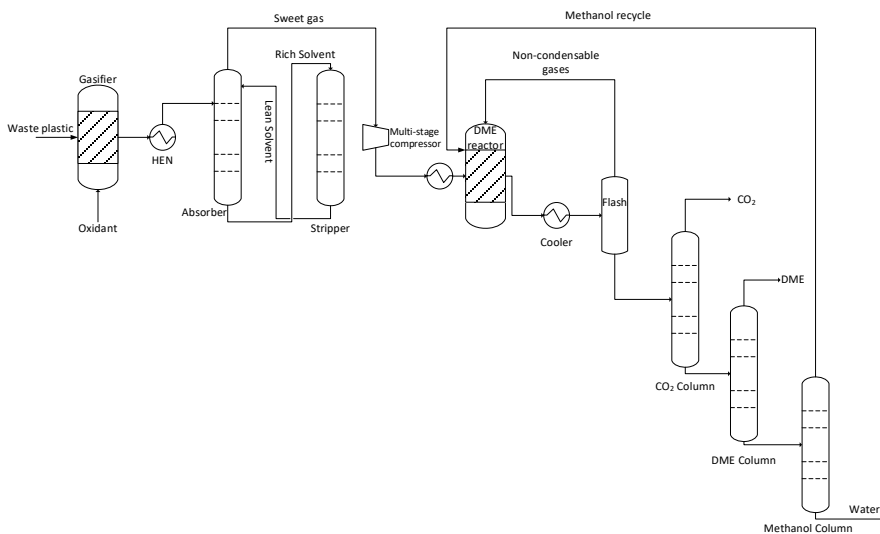

Figure 4: Process flow diagram of waste plastic to DME production process.

### 3. Results and discussions

#### 3.1. Model validation

Model Validation is a crucial step in the design process that should not be overlooked before analyzing or extending the model to different operational conditions. Therefore, model validation is performed to ascertain how rigorous the designed model is. Figure 5 shows the validation of the DME synthesis reactor compared to the experimental data reported in the literature. The results show an amicable agreement between the simulation results and experimental data. In addition, composition of DME synthesis reactor effluent stream has been compared using RGIBBS and REQUIL reactors, and the results show a fair agreement with RPLUG reactor results as shown in Figure 6.

Figure 5: Validation of DME synthesis reactor.

Figure 6: Comparison of different reactor models for DME synthesis.

#### 3.2. Energy analysis

A detailed energy analysis has been performed to explore the energy consumption in various sections of the process. The results for the main sections of the plastic waste to DME process are presented in Figure 7 and 8. The results show that the DME synthesis and purification section consumes the most energy in the process amounting to around 52% of the complete process. This is obvious because of intensive separation system in the DME purification section. AGR unit and gasification section contribute around 34.4% and 13.6% of the energy consumption respectively.

Figure 7: Energy consumption in various sections of the plastic waste to DME process.

Figure 8: Energy share in various section of the plastic waste to DME process.

#### 4. Conclusion

Plastic wastes are produced in significant amounts every year and can be utilized to produce useful clean chemicals such as DME. In this work, a conceptual design has been proposed for the production of high purity DME from the waste plastic gasification. This study showed the technical feasibility of DME production from waste plastic. The results showed that the proposed DME production process requires around 2.88 MJ per kg of DME production.

## Abstract

The use of refrigerants has been continuously increasing in thermal control systems employed in residential premises, offices, storage, process operations and many more. Widely used refrigerants such as R-410A have become a target for regulations to prohibit their use because of environmental issues. R-410A is a blend of R-32 (Difluoromethane) and R-125 (Pentafluoroethane). Because of high global warming potential (GWP) of R-125, it has become a target for removal from R-410A and reuse. An additional issue is the recovery of the refrigerant from current and decommissioned thermal control units. This paper reports the results of an investigation related to the separation of refrigeration blend compounds, recycle and reuse of the refrigerant mixture compounds and alternative blend compositions, with emphasis on environmental, health and physical hazards as well as optimal refrigeration cycle operation. Two alternatives for feasibility of operating a continuous separation-recycling process are studied.

**Keywords:** Refrigerant blends, R-32, R-125, R-410A, recycling, global warming potential, safety-health-environmental hazards.

## 1. Introduction

Hydrofluorocarbons (HFCs) are known for their excellent performance as refrigeration fluids. Their durability, inertness and thermal stability have made them the selection of choice in air-conditioning (AC) units. Nevertheless, their stability makes their presence persistent when released to the atmosphere, with a lifetime between 15 and 29 years (Xu, 2013). Furthermore, their capacity to absorb infrared light make them potent greenhouse gases (Castro et al. 2021).

R-410A is an HFC-based refrigerant, initially invented and patented by Allied Signal (now Honeywell) in 1991, that became popular as a substitute for R-22 (Chlorodifluoromethane) after the Montreal Protocol (UNEP, 2021) took place. The commercial R-410A consists of 50 wt% of R-32 and R-125 whose individual global warming potential (GWP) values are 677 and 3170, respectively, and giving the blend GWP value of 1923. Note that the mixture of R-32 and R-125 forms an azeotrope at 91 mol% R-32 (Castro et al. 2021). The objective of this paper is checking the feasibility of

removal of R-125 from R-410A as well as recycling and reuse of the separated compounds. Monjur et al. (2022) have reported the separation of R-32 and R-125 by a continuous extractive distillation process with ionic liquids as the solvent. The feasibility of this process is compared with a pressure-swing distillation process, which also generates various R-410A blend alternatives. The performance of the generated alternatives is compared in terms of coefficient of performance (COP) of the refrigerant within the refrigeration cycle. Also, the effect of hazardous properties (health, physical and environmental) is considered from the points of view of safe and optimal refrigeration cycle operation.

Because of limited space, calculation details, hazardous properties of chemicals, etc., are not given in this manuscript. They can be obtained from the corresponding author.

## 2. Data-based Analysis of Opportunities for Recycling of F-gases

According to EU F-Gas legislation, all HFC refrigerants from refrigeration systems and air-conditioning systems must be recovered (European Parliament and Council of European Union, 2014) and replaced. If recovered material is too contaminated for further recycling, it should be decomposed. According to the European Environmental Agency, by 2020, the refrigerant HFC-23 account for nearly 90% of F-gases destroyed in the EU. Considering limitations of resources as well as undesirable impacts, the recovery and reuse of refrigerants is an option worth considering (Castro et al. 2021), provided they satisfy the safety, health and environmental concerns as well as operability of the refrigerant cycles. For R-410A and its components (R-32, R-125) requirements mentioned below are applied:

- Vapor phase contaminants: Air and other non-condensables must be < 1.5% by volume at 25.0 °C
- Liquid phase contaminants: Water must be <10 ppm by weight; all other volatile impurities must be < 0.5 wt%; high boiling residue must be < 0.01 wt%

Note that the above requirements are not an issue as R-410A is considered to be a blend of only R-32 and R-125.

### 2.1. R-410A recycling capacity limitations

The main use for R-410A as a refrigerant is in air-conditioning and heat pumps. In 2013 around 86% of all R-410A produced was used for HVAC systems only. Therefore, this study has selected R-410A as a representative example for the study of recycling of refrigeration fluids.

The global production of R-410A increased from 193 kMT in 2012 to 238 kMT in 2016, and the estimated production in 2022 will be 292 kMT. China is the leading producer of R-410A, with about 45% of the global production in 2016, followed by North America, with a production share of around 30% (360 Research Reports, 2020). The share of R-410A produced in EU in the years 2009 and 2013 was around 12% (Makhnatch & Khodabandeh, 2019).

Analysis of the technical data on HVAC systems indicate a life cycle of an AC unit is in the range of 10-15 years. Therefore, in China, the USA and the EU, the total maximum capacity of R-410A available for recycling in the years 2022-2027 is expected to be around 12, 8, and 3 MT/h, respectively (assuming 8000 h/yr). To understand the amount of bulk material (AC units) to be recycled, the assumption made is that R-410A can be extracted only from small-scale AC units (less than 150 kg). Based on the available information on commercial AC units, the average unit weights of 70 kg and as a mass fraction of R-410A of 4 wt%. Therefore, to obtain 1 ton of refrigerant, recovery from 26

tons or 370 units of decommissioned cooling devices should be done. Considering an average recovery time from one unit of around 20 min, and costing USD 16 per hour as a median manufacturing operator salary in USA, together with the average mass of refrigerant mentioned above, recovery costs for R-410A in USA would be 2200 \$/MT.

## 2.2. R-410A separation

In the case of R-410A, separation of the pure compounds is complex due to an azeotrope for a R-32 purity of 91% mol. Monjur et al. (2022) proposed separation via extractive distillation with an ionic liquid in a continuous process.

An alternative to solvent-based extractive distillation is pressure-swing distillation if the azeotrope composition changes when the pressure is changed. Figure 1 shows the process flowsheet for separation of R-32 from R-125, along with the changes in the Txy diagrams. In the first column, operation at 17 bara yields a distillate with a near azeotropic composition of 90 mol% R-32 (80 wt%) at a temperature of 25 °C, allowing the use of cooling water in the condenser. Then, pressure is lowered to 1 bara, shifting the system to the right side of the azeotrope and resulting in a bottom product which is 99.5 mol% R-32 (99 wt%). Details regarding the process and the comparative study can be obtained from the authors. Operational expenses derived from consumption of utilities are 18 times higher for distillation at pressure. Since distillation at pressure is more energy intensive than extractive distillation, this result was expected. Nonetheless, when considering the cost of replenishing the ionic liquid BMIN PF<sub>6</sub>, processing costs for extractive distillation increase from 0.004 \$/hr to 2.4 \$/hr, while remaining at 0.07 \$/kg for the proposed process. An additional advantage of not using an ionic liquid is that, as seen in section 3.2, the coefficient of performance of the recycled R-32 could be affected considering the low vapour pressures which characterize ionic liquids, even at small concentrations.

Figure 1: Flowsheet of pressure-swing distillation for separation of R-410A compounds, with Txy diagrams

Note, that the discussion in Section 2.1 indicates that reclaiming enough refrigerant to sustain a continuous process in a processing plant is not feasible, unless a periodic operational policy of collection followed by short periods of operation is applied. The design of the continuous process is sufficiently flexible to allow changes in production rates.

### 3. Evaluation of Alternatives: Recycle of F-gases

The high-pressure azeotropic distillation method provides opportunities for separation of R-32 and R-125 with individual purities of up to 95 and 99.5 wt%, respectively. In addition to the pure component product streams, the pressure swing distillation process allows intermediate product fractioning resulting in R-32 / R-125 mixtures of different compositions, which are investigated below

#### 3.1. R-32 / R-125 mixture as a blend

Recently, several options were proposed as a substitute for phasing-out of R-410A. Among the options are:

- Non-flammable (A1 rating) blends: R-448A, R-449A,B,C, R-458A, and R-407C,F with high GWP rating (>1000)
- A2L safety class blends such as R-447A (GWP = 572), R-447B (GWP = 714), R-452B (GWP = 674), with a fraction of R-32 and R-125 in the range of 89.5 – 95.1 and 4.9 – 10.5 wt% respectively

A1-rated refrigerants are available ranging from light commercial systems (0.15 – 5kW) to industrial solutions (up to 10MW). In contrast, A2L refrigerants due to safety concerns have limited use in low-power capacity units (Danfoss A/S, 2022). The full list of patented and approved blends can be obtained from the authors. Tailor-made blends can also be generated (Udomwong et al. 2021).

#### 3.2. Evaluation of performance of R-32 / R-125 blend systems

To investigate the effect of the R-125 composition in the refrigerant mix on the mixture's GWP and coefficient of performance COP a refrigerant cycle (shown in Fig 2a) has been simulated with Aspen HYSYS using the Peng-Robinson equation of state as the thermodynamic model for phase equilibrium. The refrigerant cycle has four operations: compressor, evaporator, condenser, and valve. The ProREFD software (Udomwong et al. 2021) and ChemSub (Syeda et al. 2022) software also allows a detailed cycle simulation, hazardous effects analysis and refrigerant substitution.

(2a)

(2b)

Figure 2: Refrigeration cycle and effect of R-32 composition on COP of refrigeration cycle

At first, the standard composition of R-410A, which is 70 mol% of R-32, was simulated resulting in a GWP of 1924 and a COP of 7.5. It is shown that increasing the composition of R-32 results in a lower GWP but does not decrease the COP (see Fig 2b). A total

replacement of R-125 with R-32 towards a pure compound product, results in a GWP reduction of 65% and a COP increase of 4%. Nevertheless, there is an inherent safety risk associated to R-32 as it is classified with a safety level of A2L, meaning that it does not pose a toxicity risk at concentrations of less than or equal to 400 parts per million, but it is a mildly flammable gas. Its flammability limits are between 14.4% to 29.3%, which poses a risk of explosion if leakage occurred in the AC system (Osuagwu, 2022). Conversely, R-410A is classified as an A1 refrigerant (highest rank in safety classification), meaning that it is non-toxic, non-flammable and relatively safe to store, use and distribute (Osuagwu, 2022).

### 3.3. Evaluation of second life of recycled R-125

R-125 has recently found limited application in other sectors rather than thermal control systems, even though 99% of R-125 produced worldwide by the reporting companies is used as a blend component for commercial refrigerants. It could also be used as a fire suppression agent because it is odorless, colorless, electrically non-conductive, non-corrosive, and leaves no residue. It was also reported to act as a foam-blowing agent (Yelisetty & Visco, 2009) for making polyurethane, as the polyurethane foams are made by reacting a di-isocyanate molecule with a polyol in the presence of a blowing agent. R-125 is to substitute chlorofluorocarbons and hydrochlorofluorocarbons, because of the ozone-depleting potential of the latter ones. It only works as an interim solution because of R125's GWP concerns. According to Karecki (2000), R-125 can also be used as a substitute for 1,1-difluoroethane for a Dielectric Etch Application in an Inductively Coupled Plasma Etch Tool. A comparison of the emissions from R-125/R-152a processes and a reference C<sub>2</sub>F<sub>6</sub>-based process showed that emissions reductions of 68 to 76% were attainable, in large part due to much higher feed gas conversion efficiency (Karecki, 2000).

## 4. Conclusions

It is found that, while the separation by ionic liquid based extractive distillation is theoretically feasible, its implementation is not practical as the amount of R-410A available for recovery would not sustain a continuous process. For a processing capacity of 100 kg/h of R-410A, the number of average-size units to be recovered per day is 900. This is equivalent to 270,000 average-size AC units per year, or 4% of the R-410A units that are estimated to go out of service in China in 2022. Considering the vast area for which the availability of refrigerant is calculated, the process capacity is deemed infeasible, while pressure swing distillation is found to give 34 times lower operating costs. Increasing the pressure shifts the azeotrope to 91 mol% of R-32 at 17 bara (from 80 mol% R-32, at 1 bara), making separation of both components possible by shifting between both sides of the azeotrope in two distillation columns operating at 1 and 17 bara. However, both continuous operations need to be operated in a periodic (or batch) mode with periods of collection and short separation operation. Additionally, the presence of ionic liquid in recycled R-32, even at small concentrations, presents a health hazard for humans. Regarding the use of R-32 as a stand-alone refrigerant, coefficient of Performance (COP) value is found to increase by up to 4% with respect to R-410A, while displaying a 65% reduction in GWP. However, the flammability and health hazard concerns for R-32 also need to be considered and a stricter monitoring of the safety issues would need to be implemented. As the ionic liquid does not vaporize, the batch operation mode for ionic liquid based extractive distillation may need new batch operations designs, unlike the organic solvent-based batch extraction operations.

## Abstract

The market of 2-Propanol is expected to reach a value of 4.8 billion dollars by 2032, considering that one possible use of this alcohol is as substitute or as additive to fossil fuels, with the aim of employing biofuels to increase the use of renewable energies. To dehydrate alcoholic mixtures containing azeotropes advanced processes are needed, as a heterogeneous azeotropic distillation process. To select the thermodynamic method best representing the binary mixture IPA+water for the simulation in ASPEN Plus<sup>®</sup>, new experimental data of Vapor-Liquid Equilibrium (VLE) have been collected at the Process Thermodynamics laboratory (PT lab) of Politecnico di Milano at conditions for which no information was found in the literature and used with other literature points for the thermodynamic description of the system IPA+water. The selected model has then been employed for the simulation of the novel azeotropic distillation process, that has been optimized.

**Keywords:** biofuels, isopropanol, azeotrope, distillation, PT lab.

## 1. Introduction

The industrial relevance of 2-Propanol (IsoPropyl Alcohol, IPA) is outstanding. It can be not only used as substitute or as additive to fossil fuels, but also as solvent and cleaning agent in a high number of industries as the medical (Guang et al., 2019) and the semi-conductor ones (Arifin and Chien, 2008). Its market, in 2021 of about 3.2 billion \$, is estimated to grow reaching about 1% of the consumption of organic chemicals by 2032 (Fact.MR, 2022).

In several IPA production processes as the indirect hydrogenation or the fermentation of cellulosic materials, the raw product stream contains water and needs to be dehydrated to obtain pure IPA (De Guido et al., 2021). The process of water removal cannot be performed by employing one standard distillation column because the IPA+water mixture forms an azeotrope (at 101.3 kPa of about 87.5% (Moioli et al., 2021)), and the system, as other alcohol+water systems (CRC Handbook of Chemistry and Physics), is strongly non ideal. Advanced processes are therefore needed, as the one proposed by GASP and studied elsewhere (Spatolisano and Pellegrini, 2022).

To select the thermodynamic model for carrying out the simulation of the dehydration process, experimental data of Vapor-Liquid Equilibrium (VLE) are needed. The experimental activity carried out by GASP at the Process Thermodynamics laboratory (PT lab), part of the Process Design & Process Thermodynamics laboratory (PD&PT lab)

of Politecnico di Milano, strives to fill the gaps of experimental data that the literature presents and it is a further development of the research started in 2021 (Moioli et al., 2021). In particular in this work VLE points of the 2-Propanol+water mixture have been collected at the pressure of 800 mbar. The new equilibrium data, together with other points at different pressures from the literature, have been used for the thermodynamic description of the system IPA+water. Then, the selected model has been employed for the simulation of a novel heterogeneous azeotropic distillation process of the mixture of interest. The process has been optimized taking into account several variables as the solvent flowrate, the number of theoretical stages of the column and the reflux flowrate.

## 2. Experimental set up and protocol

### 2.1. Chemicals

Demineralized water (ISO 3696 Q3, ASTM D 1193 TYPE 4) was used and isopropanol (CAS 67- 63 - 0) was supplied by Sigma-Aldrich, with a purity of at least 99.8% wt., molecular weight equal to 60.10 g/mol and specific gravity < 0.7840. Nitrogen (>99.99%, mole), coming from a tank storing N<sub>2</sub> in the liquid phase, was used to create the vacuum condition inside the VLLE unit (Fischer Labodest VLLE 602) up to the desired pressure and as a carrier for the gas chromatograph.

### 2.2. Apparatus

The Fischer® Labodest® VLLE 602 unit has been employed to collect the VLE data at PT lab. The condensed vapor and the liquid samples at the equilibrium conditions have been drawn from this unit and analyzed with the Agilent 7820A Gas Chromatograph equipped with a Thermal Conductivity Detector (TCD).

The details of the experimental protocol are reported in Moioli et al. (2021). In this work the mixture has been prepared under the hood in a container provided with a cap (400 mL) and, after mixing, part (100 mL) of it has been fed to the feed tank of the VLLE unit. After sampling, the unit is emptied and then refilled by another portion of the already prepared mixture. In order to ensure the repeatability of the test and to check the accuracy of the results obtained, each test (complete procedure) was repeated at least three times.

## 3. Results and Discussion

### 3.1. Experimental results and thermodynamic model

Figure 1 reports the experimental points collected at PT lab for a pressure of 800 mbar. The minimum temperature azeotrope occurs at about 68% mol of 2-Propanol. The bubble point curve becomes very close to the dew point curve on the right side of the azeotrope and this underlines the strong non-ideality of this mixture. However this behavior is expected also on the basis of the experimental data already collected at PT lab (Moioli et al., 2021) and from the literature at different pressures.

To describe the thermodynamic behavior of the system, the performance of the NRTL model (Renon et al., 1968) and the one of the UNIFAC-Dortmund modified (Gmehling et al., 1993) model have been tested, by considering 48 sets of isobaric or isothermal VLE data from NIST databank (detailed in Barbieri, 2022) and 8 sets of data collected at the PT lab at different pressures. As from Figure 1 and Table 1, reporting the percent Absolute Average Deviation (%AAD) of the two considered models, the UNIFAC-Dortmund modified (Gmehling et al., 1993) model best represents the system.

The UNIFAC (Dortmund modified) has therefore been selected as the thermodynamic package to be used for the simulation of the novel azeotropic distillation process in ASPEN Plus®.

**Figure 1:** VLE experimental data for the IPA and water system collected at PT lab at 800 mbar and results obtained with the NRTL model with ASPEN Plus® V11.0 default parameters and the UNIFAC Dortmund modified model.

	Isobaric VLE data			Isothermal VLE data		
	AAD% T	AAD% Y <sub>2-Propanol</sub>	AAD% Y <sub>water</sub>	AAD% P	AAD% Y <sub>2-Propanol</sub>	AAD% Y <sub>water</sub>
<b>NRTL</b>	0.17395	7.77114	4.93413	18.722	50.383	11.214
<b>UNIFAC</b>	0.15138	6.63100	4.47493	10.113	19.061	7.256

**Table 1:** %AAD of the temperature for isobaric data or the pressure for isothermal data and the mole fraction of IPA and water in the vapor phase estimated with NRTL and UNIFAC (Dortmund modified) for all the considered sources of data.

### 3.2. Solvent selection

The literature offers two main alternatives in order to carry out the separation of the IPA+water mixture in its pure components: the extractive distillation (Arifin and Chien, 2008) and the heterogeneous azeotropic distillation (Arifin and Chien, 2007; Cho and Jeon, 2006).

In the extractive distillation the entrainer alters the separation factor of the mixture without introducing azeotropic behaviors with all the components of the system to be separated. On the other hand, in the case of the heterogeneous azeotropic distillation, the solvent is added in order to introduce a new lower boiling azeotrope which for its part can easily be separated. The solvent selection is crucial and, if properly done, can significantly affect the process performances. Among the high number of possibilities, disclosed in literature (Gmehling et al., 1998), the methyl butyl ether has been selected in this work. In fact it obeys to the criterion disclosed in a recent article by GASP (Spatolisano and

Pellegrini, 2022), where it is demonstrated that the best ideal entrainer, thus the one that minimizes the vapor flowrate and, ultimately, the reboiler duty, is the one that forms a binary azeotrope with water, as the methyl butyl ether does. In addition, its boiling point is lower than the boiling point of the IPA, which can be recovered as the bottom product. The other big advantage is that if some traces of methyl butyl ether are present in the IPA product, they are considered acceptable for the use of 2-Propanol as bio-fuel.

### 3.3. Process scheme and simulation

**Figure 2:** Scheme of the heterogeneous azeotropic distillation process with binary azeotrope for the 2-Propanol+water mixture in ASPEN Plus® V11.0.

The proposed flow sheet for the IPA-water separation exploiting methyl butyl ether as solvent is reported in Figure 2. The IPA-water mixture (FEED) and the solvent (S1) are fed into the distillation column at stage 25 and 20 respectively (the stages are counted from top to bottom with the first tray as the first stage and the reboiler as the last stage). The feed, an equimolar mixture of IPA and water, is available at atmospheric pressure and 30°C and has a flowrate of 100 kmol/hr. In the base-case configuration the column has 50 stages and the solvent flow rate is 250 kmol/h. The column separates IPA as bottom product, whose water content has to be lower than 3000 ppm in weight, and the binary water-solvent heterogeneous azeotrope, from the top, which can be separated into two liquid phases. The organic phase, exiting from the decanter, very rich in methyl butyl ether, is refluxed back to the column. A solvent make up stream is provided in order to counterbalance unavoidable solvent losses through the product streams.

The base-case configuration has been optimized in ASPEN Plus® V11.0 taking into account several variables as the solvent flow rate, the number of theoretical stages of the column and the reflux ratio (here defined as the ratio between the reflux flow rate and the organic flow rate exiting the decanter). The objective function, to be minimized, was the reboiler heat duty, as it is the main cost item of the process.

The initial solvent flow rate of 250 kmol/h has been decreased during each simulation (a delta of 10 kmol/h among each simulation has been considered) and within each run of the simulator the IPA bottom purity has been checked. If the bottom product purity was not enough, the reflux ratio would have been increased. This means that the solvent flow

rate and the reflux ratio have been optimized simultaneously. The results of the simulation are reported in Figure 3a).

**Figure 3:** Duty of the reboiler as a function of a) the ratio between the solvent flowrate and the feed flow rate [100 kmol/h] and b) the number of theoretical stages, with a solvent flowrate equal to the optimum value of 120 [kmol/h].

The trend is almost constant (some little fluctuation are due to numerical issues) up to a solvent/feed ratio equal to 1.2. Then the reboiler heat duty tends to increase as the ratio further decreases. This means that the optimum solvent/feed ratio is 1.2, which corresponds to a solvent flowrate of 120 kmol/h. The optimum reflux ratio is equal to 0.56325.

Optimized the solvent flowrate and the reflux ratio, the theoretical number of stages was reduced with respect to the initial value of 50. Indeed the thermal profile and the composition profile of the vapor and liquid mole fractions of the IPA inside the column turned to be almost flat in a high number of stages inside the column, meaning that a lot of stages are not making any contribution to the separation process.

The results of the optimization are reported in the Figure 3b). Again the trend is almost flat up to a number of stages equal to 34 and then it tends to increase as the  $N$  decreases further. Therefore 34 is the optimum number of stages.

#### 4. Conclusions

The isobaric vapor-liquid equilibrium for the system IPA+water at 800 mbar, conditions not already reported in the literature, has been experimentally investigated at the PT lab of Politecnico di Milano. The collected experimental points and the data from the literature have been used to select the thermodynamic model for the simulation and optimization in ASPEN Plus<sup>®</sup> of a novel azeotropic distillation process based on a binary water-solvent azeotrope. The future developments of this work could focus on the collection of more experimental data of phase equilibria in deeper vacuum conditions and on the economic evaluation of the simulated process of azeotropic distillation.

## Abstract

This study presents sustainability assessment of poly(butylene succinate) (PBS) production from wheat straw and post-consumer alternative End-of-Life (EoL) recirculation routes of the used biopolymer, under both techno-economic and environmental perspective. The processing steps for the whole life cycle of PBS production have been designed and simulated using the UniSim Design software (Honeywell). Techno-economic assessment employing discounted cash flow analysis has been implemented to compare the profitability of PBS production against the appropriate reference product, by estimating important techno-economic indicators. The EoL options for PBS recirculation have been evaluated, targeting the recycling of the material back into the production process, with emphasis on chemical recycling. The environmental impact of the production process and the EoL recirculation route have been evaluated via Life Cycle Assessment. A holistic evaluation of sustainability that takes into account the environmental and techno-economic pillars and combines them into a final life cycle cost has been presented.

**Keywords:** Biopolymer, Lignocellulosic residues, Life Cycle Costing, Sustainability assessment, Poly(butylene succinate)

## 1. Introduction

Global plastic production reached ca. 370 million t in 2019 with an annual increase of 2.5% [1]. The transition towards the bio-economy era necessitates the production of bio-based and biodegradable polymers to reduce the fossil resources used for the current production of the majority of plastics. Poly(butylene succinate) (PBS) is among the most widely used biopolymers, having an annual worldwide production capacity of 86,500 t [2], and constitute a biodegradable polyester produced via polycondensation of succinic acid (SA) and 1,4-butanediol (BDO). It has similar properties to polystyrene (PS), polypropylene (PP) and polyethylene terephthalate (PET) [3], fact that make it ideal candidate for the replacement of such polymers.

The development and implementation of the biorefinery concept are of great importance in order to reinforce the vision toward a sustainable economy based on bioresources. The goal within the integrated biorefinery concept is to start with a biomass feedstock and produce multiple end-products in a systematic and technologically feasible way so as to improve the overall financial performance. The combination of two principles: exploiting the residual biomass use and reducing the associated emissions are approached in the biorefinery concept [4]. Wheat is the most extensively cultivated crop worldwide, playing a vital crop in food supply chains [5]. The wheat residues are a valuable natural resource and their efficient management is essential for sustainable crop production. This study aims to assess potential valorisation of wheat residues, including major processing steps such as pre-extraction, pre-treatment, fermentation, downstream separation and purification (DSP) and polymerization, for the evaluation of the production process of PBS under the life cycle costing perspective.

## 2. Methodology

Process design has been carried out with the design software UniSim (Honeywell). The proposed biorefinery is based on the utilisation of wheat straw, as residue of wheat production. The chemical analysis of raw material used is based on the study of Ballesteros et al. (2006), while the pretreatment process is designed according to Al-Zuhair et al. (2013) [6-7] (Figure 1). Steam explosion and subsequent hydrolysis are utilized for the pretreatment of wheat straw and the production of the sugar rich hydrolysate. More specifically, the straw is mixed with saturated steam at 180°C for 10 min to break the fibers of the lignocellulosic material, and then the pressure is drastically reduced to atmospheric level. After cooling to 45°C, the enzymatic hydrolysis takes place where the lignocellulosic material are degraded into corresponding monomers with the aid of suitable enzymes.

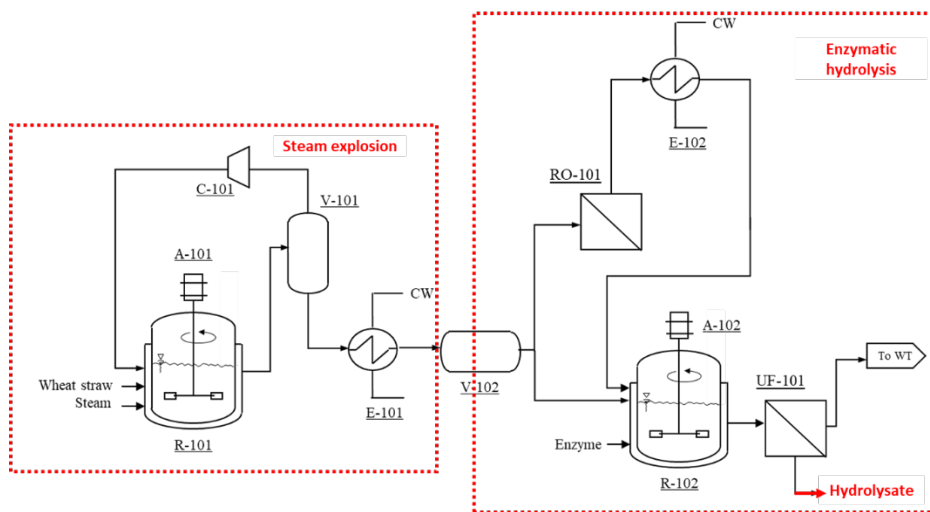

Figure 1: Process flow diagram for wheat straw pretreatment.

The sugar-rich hydrolysate produced from the pretreatment stage is then utilized for the fermentative production of PBS' monomers, e.g. SA and 1,4-BDO. Figure 2 presents the different stages of all production process. The bioconversion stage for both monomers

includes a heat-sterilisation in a continuous process consisting of two heat exchangers and a holding tube. The fermentation medium is sterilized at 140°C and then cooled to the fermentation temperature before addition into the bioreactors. In case of SA, The selected parameters for the fermentation are selected from Ma et al. (2011) and are equal to 101.0 g<sub>SA</sub>·L<sup>-1</sup> concentration, 0.78 g<sub>SA</sub>·g<sup>-1</sup><sub>sugars</sub> yield and 1.18 g<sub>SA</sub>·L<sup>-1</sup>h<sup>-1</sup> productivity [8]. CO<sub>2</sub> supply is used during fermentation due to metabolic requirements in the reductive TCA cycle to produce SA. Likewise, in case of 1,4-BDO the fermentation efficiency is reported by Burgard et al. (2016) using a genetically engineered *E. coli* strain. The final concentration of BDO is 125 g<sub>BDO</sub>·L<sup>-1</sup> with a yield of 0.40 g<sub>BDO</sub>·g<sup>-1</sup><sub>sugars</sub> and a productivity of 3.5 g<sub>BDO</sub>·L<sup>-1</sup>h<sup>-1</sup>, while microaerobic conditions are used during fermentation (0.02 vvm) [9].

The DSP of SA is designed according to Alexandri et al. (2019) [10]. The fermented broth is centrifuged (CF<sub>PBS</sub>-201) to remove the bacterial biomass, fed into the activated carbon columns (V<sub>PBS</sub>-202) for decolorisation and impurity removal and processed by cation-exchange resin columns (V<sub>PBS</sub>-203) in order to transform organic acid salts into their corresponding organic acids. The acidified liquid is concentrated using the MVR-forced circulation evaporator system (EV<sub>PBS</sub>-201) and the concentrated liquid is subsequently treated via crystallisation in continuous crystallizers (CR<sub>PBS</sub>-201-202) at 4°C. The wet succinic acid crystals are dried in a spray dryer (DR<sub>PBS</sub>-201), while the remaining liquid is recycled at the evaporation stage. The SA crystal purity achieved is higher than 99.5%, while the overall succinic acid recovery yield in the DSP is ca. 95% (w/w). In the DSP stage of 1,4-BDO, product is purified to 99.7% purity with recovery yield of 92%. The microbial biomass is initially removed via centrifugation (CF<sub>PBS</sub>-202). The bacterial mass free liquid stream is processed through a series of cation- (V<sub>PBS</sub>-206) and anion-exchange (V<sub>PBS</sub>-207) resin columns to remove the minerals and organic acid salts that are present in the fermentation broth. The outlet liquid stream is subsequently concentrated using a MVR-forced circulation evaporator system (EV<sub>PBS</sub>-202). BDO is purified via distillation (T<sub>PBS</sub>-201) at atmospheric pressure and 180°C in order to separate the water and GBL.

The final stage of the production process is the polymerization stage to form the polymer PBS. The unit operations and the process conditions for the polymerization of PBS were taken from Kamikawa et al. (2013) [11]. This process is divided into three sections, the preparation of raw materials, esterification and polymerization. BDO and SA are initially mixed in a mixing tank (VPBS-301) at a molar ratio of 1.3:1 and 80°C using low pressure steam (LPS). The liquid outflow enters the esterification reactor (R<sub>PBS</sub>-301), after it is heated to 180°C. The reaction takes place at 230°C and 1 bar in order for an appropriate rate of reaction to be achieved and the ester of succinic acid and BDO is formed after 3 h. The polymerization of ester is a polycondensation reaction in the presence of titanium tetrabutoxide as catalyst with a concentration of 2000 ppm (with respect to succinic acid) (R<sub>PBS</sub>-302). The temperature of the reaction is 240°C and the vacuum applied is 2 torr. After 16.5h, the final product from the polycondensation reactor contains PBS with molecular weight of 70,000 Da.

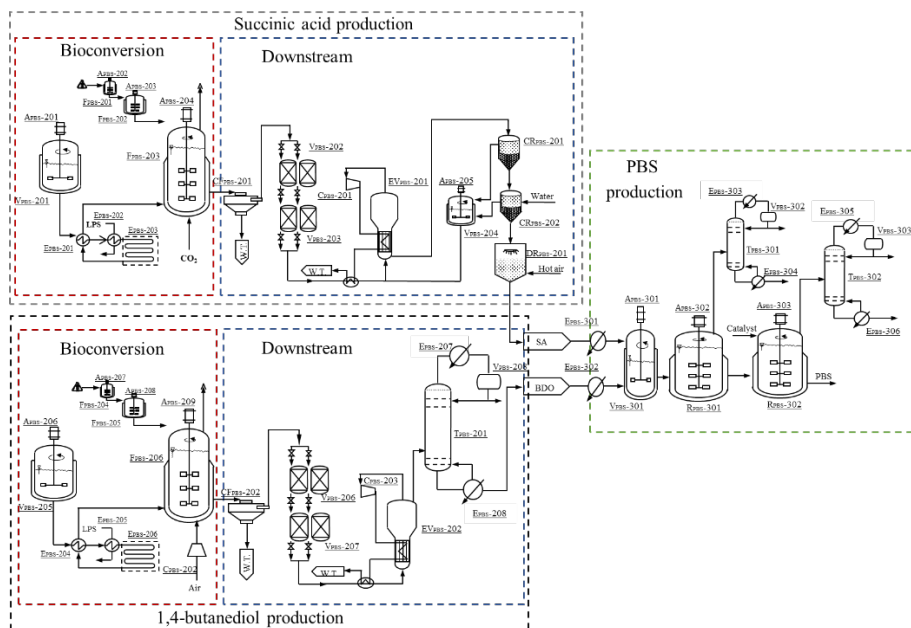

Figure 2: Process flow diagram for PBS production process.

The chemical recycling of PBS is finally performed to evaluate the potential recirculation of the monomer back to the process. The lipase-catalyzed degradation of PBS into cyclic 2-mer is designed according to Okajima et al. (2003) [18]. The reaction is carried out using a mixture of PBS and toluene having a solid to liquid ratio 1:1 (w/v) and 300% immobilized lipase CA (with respect to PBS) at 85 °C for 24 h. The repolymerization of the oligomer product obtained by the degradation reaction is also evaluated with employment of toluene under azeotropic dehydration conditions.

Techno-economic evaluation is based on preliminary economic analysis (accuracy up to  $\pm 30\%$ ). Process design data were used for the estimation of fixed capital investment (FCI) and other important techno-economic indicators. Equipment sizing was based on established methodologies, while the estimation of free-on-board purchased equipment costs estimation was based on established textbooks and literature-cited reports [12-15]. The techno-economic indicators used in this study are the Cost of Manufacture (COM), Minimum Selling Price (MSP), Optimum Plant Capacity (OPC) leading to minimum COM, Discounted Payback Period (DPP) and Minimum Feedstock Requirements (MFR). MSP and DPP are estimated after a discounted cash flow (DCF) is performed. Life Cycle Assessment (LCA) is carried out using the GaBi software and the the ReCiPe 1.08 LCA methodology. The system boundaries for the analysis is “cradle to gate” and the functional unit is 1 kg of PBS. Finally, LCC is performed by estimating twelve different environmental categories followed by their conversion into monetized environmental externalities. The principal stages for the implementation of methodology are described by Bickel and Friedrich (2005) [16]. The monetization of the estimated impacts is based on the environmental prices reported by De Bruyn et al. (2018) for EU28 countries using a dollar to euro exchange rate of 0.856 [17].

### 3. Results and Discussion

Table 1 presents the results for the techno-economic evaluation of the production process of PBS, including monomers production and polymerization stages, without considering the cost of sugars production, as the wheat straw pretreatment is under development.

The FCI and COM per kg PBS are estimated at different plant capacities (10-120 kt/y) to identify the one where these indicators reach a constant value is reached (OPC 58.63 kt PBS per year). The MSP of PBS is lower than its current market price \$4/kg<sub>PBS</sub> [19] with a decrease percentage of 45%. As regards the LCA, some representative results for the Global Warming Potential and the Abiotic Depletion Fossil potential, the most typical environmental indicators, are 2.31 kg CO<sub>2</sub>-eq/kg<sub>PBS</sub> and 15.78 MJ/kg<sub>PBS</sub> when only the production process is taken into consideration. The results for both techno-economic and environmental assessment are expected to be varied when the pretreatment stage is also added in the estimations.

Finally, regarding chemical recycling, it was found that PBS having an Mw of 99000 was quantitatively degraded by lipase to produce cyclic oligomers mainly consisting of the cyclic diester of BS units.

*Table 1. Techno-economic indicators for PBS and PLA production at the optimum plant capacity*

Indicator	PBS
OPC (kt/year)	58,630
FCI (\$/kg)	2.40
COM (\$/kg)	1.85
NPV (M\$)	649.8
MSP (\$/kg)	2.18

## Abstract

This paper presents a simulation study of a plastic-waste-based combined heat and power (CHP) generation system. The process was modeled using the Aspen Plus V10 simulation software. The proposed power generation system is divided into two sections. The first is the plastic gasification system containing a pyrolyzer and a gasifier. The second part is the electrical power generation process with a pre-reformer, a solid oxide fuel cell (SOFC), and a gas turbine. Sensitivity analysis is done on the gasification process to find the optimum condition for gasification. It was observed that the combinations of relatively moderate temperature and steam to PE mass ratio are beneficial to the performance of the overall gasification system in terms of producing more syngas with greater energy/ exergy efficiency. This study still in the simulation stage aims to pave a way for establishing the plastic-waste-based CHP system as an alternative source of energy.

**Keywords:** Gasification, waste plastic, power generation, solid oxide fuel cell.

## 1. Introduction

Plastic manufacturing began commercially in the 1950s and has grown rapidly to the current worldwide annual production of 368 million tons in 2019 (Errera, 2022). According to the Geneva Environment Network, plastic is one of the major environmental threats (Geneva Environment Network, 2023). Plastic has had a severe impact on the natural ecology, causing problems for humans and wildlife, such as hurting plant life and putting animals in danger (Kumar *et al.*, 2021). Plastic contamination in the oceans is a growing problem all around the world.

Furthermore, harmful chemicals are released when plastic is burned or buried in soil (Verma *et al.*, 2016). Recycling is probably the best way to cut down on plastic waste. Plastic wastes are used in thermo-chemical processes such as combustion, hydrogenation, pyrolysis, and gasification due to their high energy content. These processes have been shown to be effective waste treatment alternatives. They not only eliminate waste, but also convert it into fuel. Separation of feedstock is not required here, unlike in mechanical recycling. Different feed materials, for example, can be combined and transformed to fuel in the same gasifier. Chemical recycling is a potential approach for the treatment of plastic waste for these reasons. This technology can be used to convert a variety of plastic waste materials, such as polyethylene terephthalate (PET), polystyrene (PS), polymethylmethacrylate (PMMA), polypropylene (PP), polyethylene (PE), low and high-

density polyethylene (LDPE and HDPE), and polyvinyl chloride (PVC) (McKeown and Jones, 2020).

On the other hand, there is a growing demand for electricity in present world. Fossil fuels are still the primary source of energy for electricity generation around the world. Using fossil fuels has resulted in global warming and pollution due to the release of greenhouse gases, acid gases, and aerosol particles (Wang et al., 2019). It is crucial to use alternative fuel to generate power in sustainable approach. A recent study by Zhao et al., 2021, on biomass-based combined heat and power (CHP) system consisting of solid oxide fuel cell and gas turbine fed by syngas from a gasifier is reported to have achieved high efficiency for the generation of electrical power. Since plastic waste gasification gives similar products as biomass gasification, a plastic waste based CHP system can be envisioned, which may also be able to generate electrical power.

The aim of this work is to simulate a plastic waste-based small-scale power generation system where all the conversion steps are optimized within the limits of the simulation. This work uses Aspen Plus as the simulation software and waste PE (polyethylene) as the fuel for the simulation. It provides some preliminary qualitative and quantitative data on the gasification process's overall behavior, as well as the sensitivity of process parameters. Moreover, in the plastic waste-based CHP system, along with the optimization of the gasification process, consequent electrical power generation from SOFC is also simulated in Aspen Plus. The overall energy and exergy efficiency of the process is calculated and evaluated in comparison with already existing data.

## 2. Model Development

### 2.1. Modeling the gasification process

Plastic wastes considered in this work consist of polyethylene (PE). The equilibrium model utilized in this study to investigate the simulation of PE gasification is based on the previous work by Mitta *et al.*, 2006. The simplified PE gasification model's process flow sheet is shown in Figure 1. At the very outset, the non-conventional fuel polyethylene was defined, and the ultimate and proximate analyses were provided as input to the model based on previous literature (He *et al.*, 2009). The polymer NRTL/Redlich-Kwong equation of state with Henry's law "POLYNRTL" and "POLYSRK" were chosen as parameter models to calculate the thermo-physical properties of the components. The simulation began with unit processes of drying and separation which was used on the polyethylene sample to rid it of any moisture. The dried fuel is first pyrolyzed by adding external heat to facilitate breaking it down into simpler components suitable for normal gasification. Before being transferred to the gasifier, the gasifying mediums, air and steam, are preheated and combined.

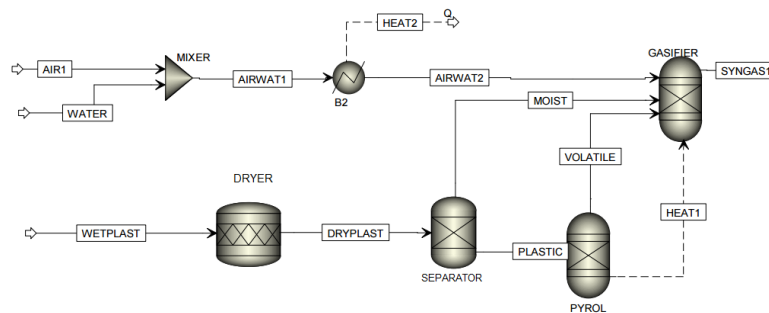

Figure 1: Gasification process flowsheet

2.2. SOFC Stack and Gas Turbine modelling

The SOFC stack model is developed based on the previous works by Doherty *et al.*, 2010. The process flow sheet is shown in Figure 2. Since ion cross-over across the electrolyte cannot be modeled in Aspen Plus, the overall oxidation of H<sub>2</sub> was studied rather than the cell half-reactions; and because only H<sub>2</sub> is electrochemically reacted, it is presumed that CO is shifted to CO<sub>2</sub> and CH<sub>4</sub> is reformed to H<sub>2</sub> (Panopoulos *et al.*, 2006). A fraction of processed air and unreacted CH<sub>4</sub> at SOFC output react in a burner. The high temperature flue gas is then introduced into a gas turbine to produce additional electrical power. In addition, coupling the syngas and air compressors to the gas turbine on the same shaft reduces energy consumption. The description of the simulation blocks in Figures 1 and 2 is given in Table 1.

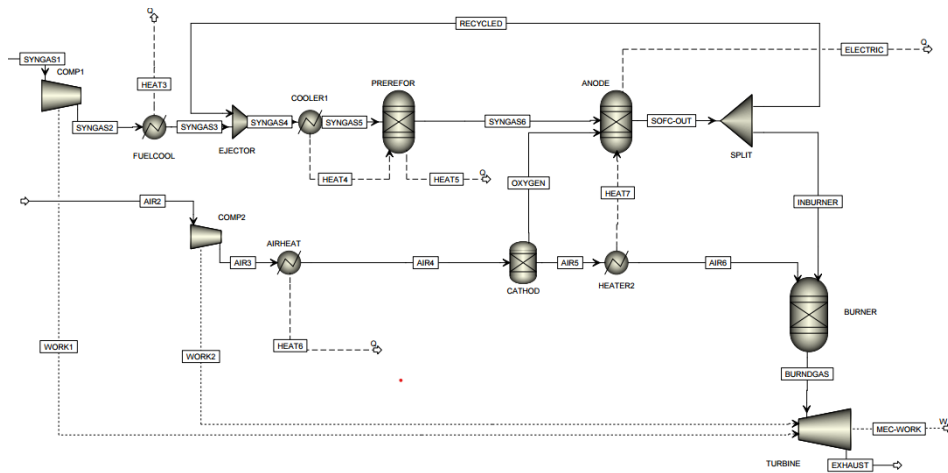

Figure 2: SOFC and Gas Turbine Process Flowsheet

Table 1: Description of Aspen Plus flowsheet unit operation blocks presented in Figure 1 and 2.

Simulation Model	Block ID	Unit	Operating Conditions
RStoic	DRYER	Dryer	Temperature: 110 °C, Pressure: 1atm
Sep	SEPARATOR	Separator	
	CATHODE	SOFC Cathode	
Ryield	PYRO	Pyrolyzer	Temperature: 500 °C, Pressure: 1 atm
RGibbs	GASIFIER	Plastic Gasifier	Temperature: 850–1100 °C (Reactions were specified with equilibrium restricted), Pressure: 1 atm
	PREREFOR	Pre-reformer	Temperature: 571.4 °C (Doherty <i>et al.</i> , 2010), Pressure: 3 atm
	ANODE	SOFC Anode	Temperature: 850 °C (Doherty <i>et al.</i> , 2010), Pressure: 3 atm
	BURNER	Combustor	Temperature: 910 °C (Zhao <i>et al.</i> , 2021), Pressure: 3 atm
Compr	COMP1	Compressor	Isentropic, Pressure ratio: 3 (Doherty <i>et al.</i> , 2010) Mechanical Efficiency: 75%
	COMP2	Compressor	Isentropic, Pressure ratio: 3 (Doherty <i>et al.</i> , 2010) Mechanical Efficiency: 75%
	TURBINE	Gas Turbine	Isentropic, Pressure ratio: 0.33 Mechanical Efficiency: 75%

### 3. Results and Discussion

#### 3.1. Sensitivity analysis of the gasification process

The simulation predicted equilibrium temperature for the gasification process to be 805°C. The effect of O<sub>2</sub> flow rate on the PE gasification process has been investigated in the range of 20 kg/h to 220 kg/h with a constant PE feed rate of 100 kg/h. As demonstrated in Figure 3, an O<sub>2</sub> flow rate of 99.78 kg/h maximizes CO and minimizes CO<sub>2</sub> production. It corresponds to the optimum O<sub>2</sub> to PE mass ratio of nearly 1. Similarly, the effect of steam flow rate is investigated in the range of 50 kg/h to 500 kg/h keeping the PE feed rate constant as before. Figure 4 shows that a steam flow rate of 50.04 kg/h maximizes CO and minimizes CO<sub>2</sub> production. It corresponds to the optimum steam to PE mass ratio of 0.5. Figure 5 shows that operating pressure does not affect the syngas composition much. For this reason, the operating pressure is selected to be 1 atmosphere.

Figure 3: Effect of O<sub>2</sub> flow rate on syngas composition

Figure 4: Effect of steam flow rate on syngas composition

Figure 5: Effect of operating pressure on gasification products

### 3.2. Energy and Exergy analysis of the power generation system

In this study, to ensure maximum power generation, the power generation system is simulated at the optimum gasifier operating temperature of 805°C and the optimum steam to PE mass ratio of 0.5. The Sankey diagram of the process shown in Figure 6 demonstrates the energy flow for evaluating the plant's performance. In the figure, the widths of the different colored bars represent the quantity of energy in kilowatts. Using this system, plastic waste input equivalent to 2269 kW of higher heating value (HHV) results in an electrical power output of 721 kW. The electricity output from SOFC is 582 kW (for details please see Suther *et al.*, 2007) and the gas turbine can generate 139 kW. The energy efficiency is calculated to be 31.4% and the exergy efficiency of the process is 34.2%. These compare favorably to many gasification CHP systems studied in previous literature where the exergy ranged from 30-45% (Colpan *et al.*, 2010; Jia *et al.*, 2015; Mojaver *et al.*, 2019; Karimi *et al.*, 2020).

Figure 6: Sankey Diagram of the process

## 4. Conclusions

In this paper, a small-scale CHP system based on the concept of gasifying waste plastic to be used as fuel for power generation through solid oxide fuel cells (SOFC) has been developed using Aspen Plus. To determine the ideal operating conditions for the gasification system, effects of temperature, pressure, and O<sub>2</sub>-steam flow ratio with the feed PE have been examined. The optimal operating conditions for gasification are determined to be 805 °C and 1 atm. The optimum O<sub>2</sub> to PE mass ratio is nearly 1, and the optimum steam to PE mass ratio is 0.5. In addition, the energy and exergy assessments of the complete power generation system are performed. This power generation system generates 721 kW of electrical power with an overall energy efficiency of 31.4 percent. The overall exergy efficiency is 34.2 percent. The results compare favorably to contemporary works and offer solutions to the prevailing plastic-waste recycling problem and alternative fuel crisis. Even though the results from this work are heavily dependent on the assumptions made, and it was within many limits of the simulation, it would help to establish plastic waste-based CHP system as a viable topic for research.

## Abstract

Climate change scenarios highlight the significance of modifying production patterns in order to transition to a low-carbon economy, as well as the value of recycling innovations in this regard. This study examines the co-hydrothermal treatment (Co-HTC) of coal discard (CD) and sewage sludge (SS) in order to enhance the carbon content of the produced hydrochars for a sustainable circular and low-carbon economy. Using a coal-sewage sludge blend ratio of 5:1, the optimal hydrothermal carbonization (HTC) and Co-HTC parameters for producing hydrochars with the highest fixed carbon (FC) and lowest ash content (A) were 150°C, 27bar, 92.13 minutes and 208°C, 22.5 bar, 331 minutes, respectively. The physicochemical parameters of the optimized hydrochar were evaluated and compared to those of the raw materials. According to the results, HTC and Co-HTC raised the calorific value of CT and CS to 19.33 MJ/kg, 25.79 MJ/kg, and 24.31 MJ/kg, respectively.

**Keywords:** hydrothermal carbonization; coal tailings; coal slurry; sewage sludge, hydrochar, low-carbon economy.

## 1. Introduction

South Africa (SA) is one of the world's greatest coal producers and uses coal as its primary energy source (Bohlmann et al., 2018). According to the 2001 National Coal discard and slurry inventory compiled by the South African Department of Energy, about 65 million tons of coal wastes are produced annually. These coal by-products are disposed of in either tailings heaps or slurry dams (Van de Venter et al., 2021). Due to the solubilization of harmful pollutants from coal discard (CD) and the potential of spontaneous combustion, coal waste disposal is seen as a significant threat to the country's environmental waste management (Onifade and Genc 2020). Beneficiation procedures, such as physico-chemical processes and regeneration techniques, have evolved over time,

however they are regarded as inefficient, not ecologically friendly, difficult, and costly (Petlovanyi et al., 2018). While the mining industry contributes to global CO<sub>2</sub> emissions, it may also be critical to lowering global CO<sub>2</sub> emissions, particularly in developing economies, not only by supporting responsible mineral extraction and processing, but also by ensuring the adoption of a circular economy approach based on mineral waste reuse and beneficiation as shown in Figure 1 for the cases of coal discards and sewage sludge. Conversely, South African wastewater treatment plants produce a substantial amount of sewage sludge (SS) (Grobelak et al., 2019). Current SS management procedures, including on-site land disposal and waste piling, are deemed unsustainable (Shaddel et al., 2019). Therefore, creative approaches to managing the CD and SS are thought essential. Hydrothermal carbonization technology (HTC) was used in this study to improve the physicochemical properties of CT, CS, and a blend of the two in order to develop suitable precursors for activated carbon, and other carbonaceous materials (value added products). The Co-HTC treatment of CD-SS mixture has the potential to enhance the carbon life cycle in coal waste while also offering an ecologically closed loop for WWTP effluent treatment, which is the cornerstone of this work (Figure 1).

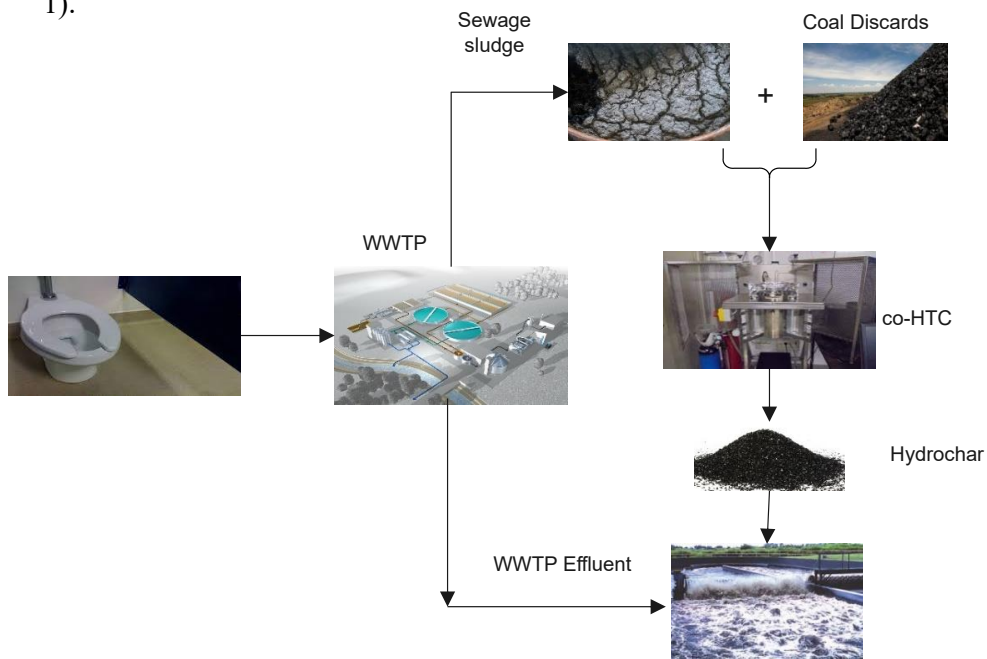

Figure 1: Co-treatment of coal waste and sewage sludge to improve the carbon life cycle in coal waste while providing an ecologically closed loop for WWTP effluent treatment.

## **2. Materials and methods**

### **2.1. Materials**

The coal samples utilized in this study are coal tailing (CT) and coal slurry (CS) obtained from a coal beneficiation plant in Mpumalanga, South Africa. The sewage sludge (SS) obtained from a wastewater treatment plant (Ekurhuleni Water Care Company (ERWAT)).

### **2.2. Experimental Methods**

The HTC and Co-HTC tests were conducted in the high-pressure tubular reactor using –1mm coal samples. HTC were performed, individually, on coal tailing (CT) and coal slurry (CS), while Co-HTC were performed on the coal-sewage sludge mixtures. 25g of the feedstock (coals, mixtures of coal and sewage sludge) was mixed with water as input solvent in a solid to liquid ratio of 1:4 in the reactor. The HTC and Co-HTC process parameters (temperature, pressure, residence time and CT+CS:SS ratio) were varied according to the design expert matrix. For experimental designs, the central composite design (CCD) and the custom design (CD) were utilized to know the number of runs that will be required to optimize the HTC and Co-HTC process respectively. Based on the CCD, 20 experimental runs were performed for the HTC of CT and CS, six center points, height factorial points and six axial points and was repeated five times to ensure reproducibility of the responses and to determine accurate experimental error. However, 40 experimental runs were performed according to the CD matrix of the Co-HTC process. The CD matrix predicted 20 edge\* interior points and 20 vertex\* interior points to accurately determine the process optimum conditions. The obtained solid products are identified as hydrochar coal tailing (HCT), hydrochar coal slurry (HCS) and hydrochar blended coal and sewage sludge (HCB).

## **3. Results and discussions**

The impact of operating conditions on the FC of the produced hydrochars (HC) is illustrated by the 3D plot of the response surface (Fig 2-3). The slopes observed on the surface plots of responses indicate the impact of reaction temperature on the FC of the produced hydrochars. The increase of temperature above 150°C decreases the FC of the produced HCT and HCS. However, the increase of temperature up to 208°C and (CT+CS): SS ratio up to 3:1 increases the FC of the produced HCB.

Figure 2: Surface plot showing the influence of temperature and pressure on the Fixed Carbon of Coal tailing's HC (left) and Coal slurry's HC (right).

The results indicate that 150°C, 27bar and 92.13 minutes were the optimum HTC conditions, while 208°C, 22.5 bar, 331 minutes and 20.02:4.98(CT+CS: SS) were optimum Co-HTC conditions. The process water (PW) analysis during the HTC and Co-HTC processes identified several chemical components that were dissolved in the liquid phase. For economic and environmental reasons, the PW generated by the HTC and Co-HTC processes was recycled back into the processes in this work.

Figure 3: Surface plot showing the influence of temperature, pressure, time and the (CT+CS): SS ratio on the Fixed Carbon of produced hydrochar.

Additionally, the HTC and Co-HTC processes have shown the ability to upgrade the fixed carbon (FC) contents of coal discards and/or sewage sludge by releasing mineral matter (ash content), oxygen, and sulphur content from their molecular structures, which improved their porosity characteristics (Aliakbari *et al.*, 2018; Saba *et al.*, 2020). The data obtained further show that the optimal HTC and Co-HTC conditions favored the

hydrolysis of aliphatic components, the dissolution of mineral materials, and the prevention of carboxylate gas release. Table 1 shows the effect of the HTC and co-HTC processes under optimum settings on the physicochemical properties of the raw materials. Additionally, the HTC and Co-HTC processes raised the calorific value of raw CT, CS, and CB from 16.59MJ/kg, 24.40MJ/kg, and 17.68MJ/kg to 19.33MJ/kg, 25.79MJ/kg, and 24.99MJ/kg, respectively. Due to comparable interactions (acidic environment caused by the decomposition of SS) occurring between the feedstocks during the Co-HTC process, the CV increase of produced HCB (41.34%) was greater than that of HCT and HCS (16.51% and 5.69%). Table 2 compares the properties of the produced hydrochars to various previous study findings. The data confirmed that the optimal HTC and co-HTC conditions established in this study could be efficient for prospective carbonization of comparable feedstocks.

#### 4. Conclusion

The conversion of carbon-based wastes into energy and chemical products is a potential approach for waste treatment. In order to improve the hydrothermal carbonization (HTC) of coal discards from coal beneficiation operations and/or sewage sludge, this work optimized a range of process parameters to enable the synthesis of hydrochar with improved physicochemical properties. The best hydrothermal carbonization (HTC) and Co-HTC parameters for synthesizing hydrochars with the highest fixed carbon (FC) and lowest ash content (A) using a coal-sewage sludge blend ratio of 5:1 were 150°C, 27bar, 92.13 minutes and 208°C, 22.5 bar, 331 minutes, respectively. The enhanced hydrochar's physicochemical properties were assessed and compared to those of the raw materials. HTC and Co-HTC increased the calorific value of CT and CS to 19.33 MJ/kg, 25.79 MJ/kg, and 24.31 MJ/kg, respectively.

## Abstract

A new process design for plastic waste gasification and conversion to methanol is described in its main elements. An electrification approach is used to maximize the CO<sub>2</sub> credit generation of the plant. The overall process yields are described for three different feedstocks made of HDPE, PP, and PS. Electrical consumption is broken down by unit contributions to identify process bottlenecks. Preliminary profitability analysis is done with and without accounting for the possibility of selling credits CO<sub>2</sub> showing that the process is unprofitable unless CO<sub>2</sub> credits are accounted for. Depending on the feedstock, CO<sub>2</sub> credits between 89.5 and 103.2 €/t are shown estimated to reach a payback time of 3.5 years without accounting for labor and taxes.

**Keywords:** process simulation, circular economy, electrification, plastic waste, sustainable development, chemical recycling

## 1. Introduction

The issue of developing a fully circular supply chain for plastic materials is a crucial topic for waste management and the carbon economy (Pacheco-López et al., 2021). Chemical recycling of plastic waste has become a hot topic in recent years with pyrolysis being the main focus (Qureshi et al., 2020). Mechanical recycling has reached commercial maturity with the current bottleneck being feedstock purity and property degradation over multiple cycles (Schyns and Shaver, 2021). Gasification is a supplementary route for contaminated feedstocks that have become unsuitable for mechanical recycling and are available in large amounts. Continuous gasification processes are derived from biomass and asphalts treatment technologies to manufacture syngas which could be used to synthesize polymer monomeric precursors. The circular vision seeks to reach polymeric precursors that can be used to make polymers of virgin quality, which in turn can be recycled over multiple loops after usage, thus drastically extending the lifespan of the raw material in the market. This work develops and analyses a plant configuration that converts plastic waste through mild gasification (Kristiano Prifti et al., 2021) and fully electrifies the downstream of the gasification unit to make methanol with no CO<sub>2</sub> emissions assuming enough renewable electrical energy is available. The process was designed with the intent of maximizing CO<sub>2</sub> credit generation and carbon emission abatement. The boundaries are a mix of PE,

PS, PP waste, demi-water, and renewable electricity as an input to reach methanol of commercial purity as a final product. The process is divided into five conceptual blocks: gasification, light hydrocarbon bi-reforming, syngas conditioning, methanol synthesis, and methanol purification. The model was developed in Aspen HYSYS V11 using a thermodynamic equilibrium approach for the gasification and reforming reactors and kinetic models in methanol synthesis (Bisotti et al., 2021). Syngas conditioning is carried out with a commercial PEM electrolyzer (Carmo et al., 2013) which generates the hydrogen for CO<sub>2</sub> hydrogenation to methanol and the oxygen necessary for the gasification consuming 55 kWh/kg hydrogen. The environmental impact is evaluated with a simple CO<sub>2</sub> equivalent method while the economic performance was estimated using the CORO framework (Prifti et al., 2022) to compute both capital and operative expenditures. A sensitivity analysis on feed composition is carried out to create a surrogate model (Galeazzi et al., 2022). Which is intended to be introduced in the ontological framework developed by Pacheco-López et al (2021) to further expand such ontology in both applicability and flexibility, as well as evaluate the role this process might have in the value chain of plastic waste in the future.

## 2. Methods

The process was designed to start with a feedstock specification of 1000 kg/h of plastic waste mixtures of different compositions. Three feedstocks were analyzed:

- 48% HDPE, 32% PP, 20% PS: H/C ratio of 1.55, Mass Fraction of C: 88.59%
- 54% HDPE, 36% PP, 10% PS: H/C ratio of 1.73, Mass Fraction of C: 87.40%
- 60% HDPE, 40% PP: H/C ratio of 2, Mass Fraction of C: 85.71%

Changing the overall mass fraction of carbon greatly impacts the performance of the gasification and oxygen demand of the system. The PEM electrolyzer is assumed to have a consumption of 55 kWh/kg of hydrogen, and the specification of the module is given on hydrogen demand. The PEM produces all the hydrogen necessary for the plant to fully hydrogenate CO<sub>2</sub>. Oxygen, if produced in excess is sold as a secondary product, while, if not produced in sufficient amount, is supplemented with an outside source (cylinders or Air Separation Unit). The PEM electrolyzer is a bottleneck for pressure in the upstream of the methanol loop. Pressure is set at 20 bar, which corresponds with the highest pressure supported by commercial solutions for a PEM electrolyzer considered in this study.

The steam methane reformer is electrified and follows the design commercialized by Topsoe A/S (Wismann et al., 2019). Thermal losses toward the environment are neglected and the outlet temperature of the syngas can reach 950°C due to the compact design and direct catalyst heating. Moreover, the unit uses Ni-CeO<sub>x</sub>-MgAl<sub>2</sub>O<sub>4</sub> catalyst instead of the conventional Nickel catalyst, which is active also for dry reforming reactions and to further help with the conversion of CO<sub>2</sub> (Ye et al., 2019).

The gasification unit is an entrained flow gasification reactor (Bader et al., 2018) working with pure oxygen coming from the electrolyzer and steam. A controller keeps the temperature at the outlet of the gasification at 850±1°C by regulating the oxygen demand and thus, adjusting the equivalence ratio. The dynamic variation of the equivalence ratio is made to keep the level of tars in the gasification chamber as constant as possible (the assumption is that tar degradation depends more on temperature than the composition of the feedstock, even if the higher aromatic content in PS affects tar concentration to some extent).

The methanol synthesis loop is done with two shell and tube reactors cooled with boiling feed water and with intermediate sequestration of the product. The kinetics model used

for the reactor is based on Graaf kinetics (Bisotti et al., 2021) which was chosen due to its reliable performance at pressures close to 60 bar (Bisotti et al., 2022).

The distillation section works with a triple-column scheme. The scheme could be simplified since the kinetic scheme does not account for the formation of Dimethyl Ether, higher alcohols, and formaldehyde, but it was intentionally kept like the industrial designs to allow for a more accurate CapEx estimation.

The resulting process layout is a more detailed and improved design with regard to the conventional process layout as previously implemented in Prifti et al. (2021).

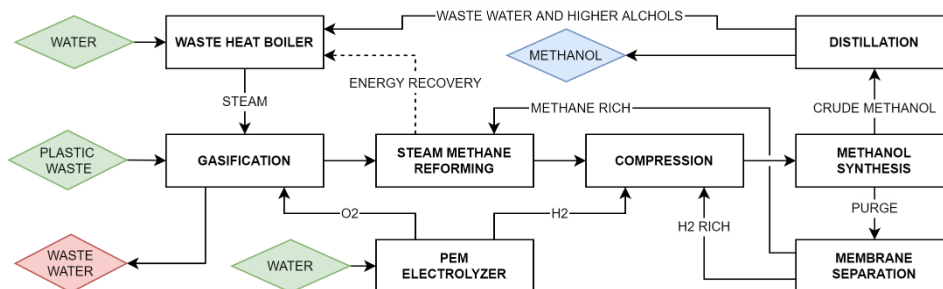

Figure 1: Block flow diagram of the process layout

### 3. Results

The overall input-output plant performance is reported in Table 1. As can be seen from the mass flow rates, the bottleneck of this process is the carbon content in the feedstock. This causes methanol production to rise as the H/C ratio of the feedstock decreases. This behavior can be explained by considering that, from the point of view of the process, there is an unlimited supply of hydrogen thanks to the electrolyzer's presence.

Table 1: Process input and output streams

		48PE32PP20PS	54PE36PP10PS	60PE40PP
		Hydrogen/Carbon ratio		
		1.55	1.73	2
INPUT	Electricity [kWh]	9650	9110	8349
	Plastic Waste [kg/h]	1000	1000	1000
	Demi water [kg/h]	1607	1468	1268
OUTPUT	Oxygen [kg/h]	249	139	-18
	Off gasses [kg/h]	26	26	28
	Wastewater [kg/h]	19	19	19
	Methanol [kg/h]	2316	2285	2238

Electricity shows the highest variability when changing the feedstock composition. Looking at the detailed breakdown of electricity consumption in Figure 2, the PEM electrolyzer is the main consumer of electricity as well as the most sensitive to feed changes. The PEM consumption from the most hydrogenated feedstock to the least hydrogenated one increases by 20%, while compression duty increases by 8% and the reformer one decreases by 8%. The resulting overall electricity consumption is 15.6% higher for the process with the most hydrogenated feedstock.

While the additional electricity consumption translates to higher operative costs, the plant has higher methanol and oxygen production, which could compensate for these higher operative costs. To understand the relative profitability of each feedstock an analysis of the operative margin was made and is reported in Table 2. First, the more hydrogenated the feedstock, the more profitable the process, even with lower methanol yield; second, assuming 8000 hours of operation a year, the plant can generate earnings between 940 k€/y in the best-case scenario, and 260 k€/y in the worst-case scenario, before taxes and without accounting for labor and maintenance. Using the framework described in Prifti et al. (2022) the plant CapEx was estimated at 15.7 M€. With these assumptions, the payback time would range from 16.7 to 60.4 years, being unfeasible in both cases.

Table 2: Process operative margin sensitivity made with EU October 2022 price assumptions.

	€/unit	[(€/h) 48PE32PP20PS]	[(€/h) 54PE36PP10PS]	[(€/h) 60PE40PP]
Methanol [kg/h]	0.58	1343.3	1325.3	1298.0
Electricity [kWh]	0.14	-1351.0	-1275.4	-1168.9
Oxygen [kg/h]	0.2	49.9	27.9	-3.6
Off gasses [kg/h]	0	0	0	0
Waste Water [kg/h]	0	0	0	0
Demi Water [kg/h]	0.006	-9.6	-8.8	-7.6
Net		32.5	68.9	117.9

Figure 2: Electrical consumption breakdown by unit operation

Among the revenues, CO<sub>2</sub> credits have been neglected until now. Currently, methanol production has an average footprint of 110 gCO<sub>2</sub>/MJ or converted in mass, 2.21 gCO<sub>2</sub>/gCH<sub>3</sub>OH (Hamelinck and Bunse, 2022). Since the plant does not emit CO<sub>2</sub> and is assumed to consume only renewable energy, for each kg of methanol, 2.21 kg of CO<sub>2</sub> credits are generated which translates into revenues.

As reported in Table 3, including CO<sub>2</sub> credits value at 67 €/t (Europe, October 2022), it considerably increases the process profitability but does not change the trend seen in the sensitivity analysis with the more hydrogenated feedstock still being the most profitable. In conclusion, the process feasibility relies heavily on CO<sub>2</sub> credits and thus the business model depends on subsidies, either local or regional. Therefore, the identification of an appropriate location with political stability and willingness to address the climate challenge is of key importance for the feasibility of the process.

Table 3: Process economics accounting for the CO<sub>2</sub> footprint

	48PE 32PP 20PS	54PE 36PP 10PS	60PE 40PP
CO <sub>2</sub> Credits from Methanol [kg/h]	5118.36	5049.85	4945.98
CO <sub>2</sub> credit revenues [€/h]	342.93	338.34	331.38
October 2022 CO <sub>2</sub> credit value of 67 €/ton			
Annual revenues from CO <sub>2</sub> credits sales [€/y]	2,743,440.96	2,706,719.60	2,651,045.28
Annual revenues by process sales [€/y]	259,984.00	551,616.00	943,744.00
<b>Total revenues [€/y]</b>	<b>3,003,424.96</b>	<b>3,258,335.60</b>	<b>3,594,789.28</b>
<b>Payback time [y]</b>	<b>5.23</b>	<b>4.82</b>	<b>4.37</b>
CO <sub>2</sub> credit value to have PBT of 3.5y [€/t]	103.2	97.4	89.5

Two other aspects that might come into play in the future are the revenues from plastic waste treatment that are intentionally underestimated to account for pre-treatment costs not discussed in the paper, and further subsidies on methanol produced from non-fossil sources. However, both terms require a legislative push towards chemical recycling against incineration and landfill, as well as economic commitments to the circular economy development model from governments.

#### 4. Conclusions

The paper described a possible pathway to methanol synthesis from plastic waste through gasification, maximizing the generation of carbon credits by electrifying key unit operations and exploiting a PEM electrolyzer that generates hydrogen and oxygen to use on site. A sensitivity study on the process feed was carried out and used to obtain mass and energy balances using a detailed simulation. The results of the preliminary economic analysis show the process as unfeasible unless CO<sub>2</sub> credit sales are accounted for. The process becomes economically appealing for the highest price of CO<sub>2</sub> credits. To reach a payback time of 3.5 years, carbon credit values between 89.5 and 103.2 €/t are necessary, even though at current CO<sub>2</sub> credit values of 67 €/t, acceptable payback times lower than 6 years are achieved for every feedstock analyzed.

## Abstract

In the pulp and paper industry, the external energy and pulping chemical consumption have been reduced by recovering the lignocellulosic biomass (LB) produced during the pulping process. However, this involves the inevitable emission of thermal NO<sub>x</sub> owing to the high pyrolysis reaction temperature. Therefore, it is necessary to simultaneously optimize energy and pulping chemical recovery and minimize NO<sub>x</sub> emissions. Hence, this study focuses on the multi-objective optimization of maximizing the net profit from energy and pulping chemical recovery while minimizing NO<sub>x</sub> emissions in recovering LB. For multi-objective optimization, a deep neural network (DNN)-based optimization model for the net profit and NO<sub>x</sub> emissions was developed with the 1,071 simulation data points according to the operating conditions. Consequently, Pareto-optimal solutions with profits between 5,241,520 and 1,329,558 \$/y and NO<sub>x</sub> emissions between 87.95 and 78.27 ppm were obtained. The proposed Pareto-optimal front can offer comprehensive solutions to decision-makers.

**Keywords:** Lignocellulosic biomass, Profit, NO<sub>x</sub> emission, Multi-objective optimization, Deep neural network

## 1. Introduction

The pulp and paper industry is energy-intensive, involving high operating costs because of the large amounts of chemicals used during the pulping process. Therefore, lignocellulosic biomass (LB) is recovered to reduce energy and pulping chemical consumption. LB is produced during the pulping process and is composed of lignin, inorganic compounds, and 80–85% water. The energy consumption in the pulp and paper industry is reduced by reusing lignin in LB as a primary energy source. Further, the consumption of pulping chemicals is reduced by recovering the pulping chemicals converted from the inorganic components in the LB via pyrolysis.

The recovery of energy and pulping chemicals is increased by decreasing the moisture content in LB via evaporation, followed by efficient combustion with multi-level injected air through the biomass boiler. Currently, to increase energy and pulping chemical recovery with LB reuse, research is actively conducted to reduce energy consumption by modifying the configuration of the evaporation process (Kim et al., 2021), or increase

energy and chemical recovery by retrofitting the internal structure of the biomass boiler to improve combustion performance (Pérez et al., 2016).

However, increasing the efficiency of LB combustion leads to higher emission of thermal NO<sub>x</sub> owing to the high temperature during the pyrolysis reaction. Therefore, research has been conducted on reducing thermal NO<sub>x</sub> by combining an additional system with a biomass boiler (Tu et al., 2018).

Despite the considerable contributions of previous studies, some challenges remain to be solved. First, previous studies have focused on retrofitting the conventional evaporation process and biomass boiler (Kim et al., 2021; Pérez et al., 2016; Tu et al., 2018). The presented solutions have limitations in that on-site application to the existing pulp and paper industry is difficult due to structural changes or additional equipment installation. Second, previous studies have not simultaneously considered minimizing the energy consumption of the evaporation process, maximizing energy and pulping chemical recovery, and minimizing NO<sub>x</sub> emissions in the biomass boiler (Kim et al., 2021; Pérez et al., 2016; Tu et al., 2018). Removal of higher amounts of moisture in LB during evaporation leads to increased energy recovery through LB reuse; however, it also results in increased energy consumption during evaporation. In addition, more efficient LB combustion in a biomass boiler results in increased energy and pulping chemical recovery; however, it also leads to higher thermal NO<sub>x</sub> emissions. Therefore, it is necessary to simultaneously focus on minimizing the energy consumption during the evaporation process, maximizing energy and pulping chemical recovery, and minimizing NO<sub>x</sub> emissions in the biomass boiler.

To overcome these challenges, this study focused on the deep neural network (DNN)-based multi-objective optimization of NO<sub>x</sub> emission, and net profit from energy and pulping chemicals recovery by reusing LB. This study aimed to maximize net profit and minimize NO<sub>x</sub> emissions in an applicable on-site way by simultaneously considering the evaporation process and biomass boiler operating conditions. To this end, simulation models of the evaporation process and biomass boiler were developed to derive NO<sub>x</sub> emissions and net profit according to the operating conditions. Then, a DNN-based optimization model for the net profit and NO<sub>x</sub> emissions was developed with the 1,071 simulation data points to derive the optimal operating conditions.

## **2. Methodology**

### *2.1. Model development*

#### *2.1.1. Process model*

The simulation conducted in this study involved an evaporation process, followed by a biomass boiler. The evaporation process was simulated using Aspen Plus V11.0, ELECNRTL method, and industrial data. Lignocellulosic biomass (LB) with a concentration of 17% entered an intermediate evaporator and flowed partially forward and backward. Using this configuration, LB was efficiently concentrated to 69–85%. The higher the target LB concentration, the more energy sources are required for the evaporation process to remove more moisture. A schematic of the evaporation process is shown in Fig. 1.

The biomass boiler was simulated using Aspen Plus V11.0, Peng Robinson–Boston Mathias method, and industrial data. Tertiary-level air and concentrated LB were directed into the biomass boiler. Subsequently, dehydration, pyrolysis, gasification, reduction, reoxidation, and combustion reactions occurred. First, the concentrated LB was sprayed in the furnace in the biomass boiler, and the moisture in the LB was completely evaporated via dehydration. Second, the dried LB in the solid state dropped toward the bottom of the furnace and was combusted with secondary air. Lignin in the dried LB was

decomposed into fixed carbon and volatiles via pyrolysis. Thermal NO<sub>x</sub> was also produced owing to the high pyrolysis reaction temperature. The volatiles (including thermal NO<sub>x</sub>) moved to the upper part of the furnace, and the fixed carbon and remaining inorganics in the LB were stacked in the form of a char bed at the furnace bottom. Third, the fixed carbon in the char bed was combusted with primary air and the energy required for the reduction reaction was produced. In the char bed, Na<sub>2</sub>SO<sub>4</sub> in the inorganic components was converted to Na<sub>2</sub>S via gasification with the remaining fixed carbon. Partial Na<sub>2</sub>S was converted to Na<sub>2</sub>SO<sub>4</sub> via reoxidation with the O<sub>2</sub> present in the primary air. Furthermore, a part of the fixed carbon was converted to CO<sub>2</sub> via gasification, and the converted CO<sub>2</sub> reacted with Na (the inorganic component in LB), forming Na<sub>2</sub>CO<sub>3</sub>. After the reaction, inert components such as Na<sub>2</sub>S, Na<sub>2</sub>SO<sub>4</sub>, and Na<sub>2</sub>CO<sub>3</sub> exited the furnace bottom in the form of smelt. Subsequently, Na<sub>2</sub>CO<sub>3</sub> in the smelt was converted to NaOH by additional treatment, and Na<sub>2</sub>S from the smelt and NaOH were recovered as pulping chemicals. Finally, all the volatiles moved to the upper part of the furnace and combusted with the tertiary air. In this combustion reaction, polluting gases such as H<sub>2</sub>S, SO<sub>2</sub>, CO, and NO<sub>2</sub> were reduced. The final flue gas exited the furnace, and steam was produced in the upper region (economizer, boiler bank, and superheaters) of the biomass boiler. A schematic of the biomass boiler is shown in Fig. 2.

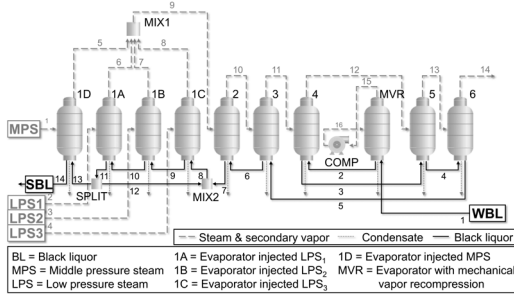

Fig. 1. Schematic of the evaporation process

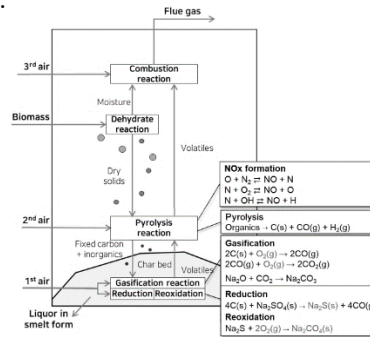

Fig. 2. Schematic of the biomass boiler

The main operating parameters that affect the energy, pulping chemical recovery, and NO<sub>x</sub> emissions are the LB concentration and tertiary-level injected air distribution. The net profit by reusing the LB according to the operating conditions was calculated using Eqs. (1)–(4). The net profit was calculated by subtracting the energy consumption cost from the sum of the profit by recovering the energy (e.g., steam) and pulping chemicals, as shown in Eq. (1). The profit from steam recovery was calculated by multiplying the mass flow and specific enthalpy of the flue gas with the steam price, as shown in Eq. (2). The profit obtained by recovering pulping chemicals was calculated by multiplying the mass flow with the prices of Na<sub>2</sub>S and NaOH, the main components of the pulping chemical, as shown in Eq. (3). Here, NaOH could be recovered only through additional treatment of Na<sub>2</sub>CO<sub>3</sub>; therefore, the NaOH profit was additionally considered in terms of Na<sub>2</sub>CO<sub>3</sub> conversion and NaOH yield during the treatment. The steam consumption cost was calculated by multiplying the price of each type of steam consumed in the evaporation process with the consumed steam mass flow, as shown in Eq. (4).

$$Net\ profit = P^S + P^{PC} - C^S, \quad (1)$$

$$P^S = M^{flue\ gas} \times E^{flue\ gas} \times Price^S, \quad (2)$$

$$P^{PC} = Price^{Na_2S} \times M^{Na_2S} + Price^{NaOH} \times \alpha \times M^{Na_2CO_3}, \quad (3)$$

$$C^S = \sum_{i=1} C_i^S \times M_i^S. \quad (4)$$

### 2.1.2. DNN-based optimization model

Using the limited datasets derived from the process model makes it easy to fall into the local optimum problem. However, the DNN model enables global optimization by efficiently generating numerous datasets. Therefore, this study developed a DNN model for robust multi-objective optimization to maximize net profit while minimizing NO<sub>x</sub> emissions. First, the initial net profit and NO<sub>x</sub> emission datasets were generated through the process model. Subsequently, the DNN model was trained using these datasets. Among these datasets, 60% were used for training, 20% for validation, and 20% for testing. The input variables of the developed DNN model were the concentration of the LB exiting the evaporation process and tertiary-level injected air distribution ratio. The output variables of the model were net profit and NO<sub>x</sub> emissions, and the model consisted of 3 hidden layers and 20 hidden nodes. ReLu and R<sup>2</sup> were used as the activation function and evaluation index of the developed DNN model, respectively.

### 2.2. Multi-objective optimization

This section describes the multi-objective optimization methodology. There were several constraints in solving the multi-objective optimization problem of minimizing NO<sub>x</sub> while maximizing the net profit. First, the NO<sub>x</sub> emissions should not be higher than those of the existing operation. Second, the net profit should not be lower than the existing values. Third, the concentration of LB exiting the evaporation process was 69–85%. Finally, the sum of the distributed air was 100%. Multi-objective optimization was conducted using the datasets from the process and DNN models. Finally, this study proposed Pareto-optimal solutions that satisfy the specified constraints.

## 3. Results and discussions

### 3.1. Model validation

Conventionally, LB is concentrated to 70% during evaporation, and combusted with the distributed tertiary-level air at ratios of 24.89%, 49.06%, and 26.04% in the biomass boiler. The simulation results for the evaporation process and biomass boiler were validated using industrial data. The performance of the models showed little error compared to the industrial data ( $\leq 0.24\%$  and  $\leq 4.55\%$ , respectively). Consequently, the operating conditions of the evaporation process consumed 368,157 t/y of steam, 1,629,187 t/y of steam and 591,542 and 1,789,136 t/y of Na<sub>2</sub>CO<sub>3</sub> and Na<sub>2</sub>S, respectively, for converting to pulping chemicals were recovered by the existing biomass boiler. Therefore, the net profit was 1,329,641 \$/y in the existing operation condition: 1,521,825 \$/y of energy consumption cost, and 5,518,458 and 6,635,017 \$/y by recovering energy and pulping chemicals, respectively. Furthermore, the NO<sub>x</sub> emissions from the existing operation were 87.95 ppm. The DNN model was trained using 1,091 data samples for profit and NO<sub>x</sub> emissions according to the operating conditions obtained by the process model. Consequently, the developed DNN model was confirmed to have high accuracy, with an R<sup>2</sup> of 0.982 for profit and 0.981 for NO<sub>x</sub> emission.

### 3.2. Optimization of NO<sub>x</sub> emissions and net profit

This section first describes the changes in energy consumption, energy and pulping chemical recovery, and NO<sub>x</sub> emissions according to the operating conditions: the concentration of LB exiting the evaporator and tertiary-level injected air distribution ratio. Then, representative solutions are presented along with the results of multi-objective optimization for maximizing the net profit while minimizing NO<sub>x</sub> emissions.

The concentration of LB exiting the evaporator was changed to 69–85%, and the resulting steam consumption is shown in Fig. 3. The evaporation process consumed steam of 367,462 t/y at 69%, 368,157 t/y at 70%, and 387,810 t/y at 85%. The steam consumption

of the evaporation process increased as the LB concentration increased, because the higher the target LB concentration, the more energy sources were required to remove the higher amount of moisture.

The effects of the LB concentration and tertiary-level injected air distribution ratio on steam, pulping chemical recovery, and  $NO_x$  emissions are shown in Fig. 4 (a). The flue gas enthalpy, which is directly related to steam recovery, increased when the LB concentration and secondary air flow ratio increased. The higher the LB concentration, the less energy that is lost to remove moisture from the LB. In addition, as the secondary air flow ratio increases, more volatiles can be introduced into the flue gas by the activated pyrolysis reaction.

The  $Na_2S$  recovery for pulping chemicals increases as the secondary air flow ratio increases, and the primary air flow rate approaches 14.74%, as shown in Fig. 4 (b). As the secondary air flow ratio increases, the pyrolysis reaction actively occurs so that more substances for  $Na_2S$  conversion (C, CO) are decomposed from the LB. As the primary air flow ratio increases, more energy can be generated during gasification. However, it has an optimum point of 14.74% because it also promotes the reoxidation reaction of  $Na_2S$ .

Fig. 3. Steam consumption according to LB concentration

Fig. 4. Steam and pulping chemical recovery according to operating conditions: (a) steam; (b)  $Na_2S$

The  $Na_2CO_3$  recovery for the pulping chemicals increases as the primary air flow ratio and biomass concentration increases, as shown in Fig. 5 (a). As the primary air flow ratio increases,  $CO_2$  generation increases because of the activated gasification reaction. The  $Na_2CO_3$  conversion is promoted by increased  $CO_2$  generation. In addition, as the biomass concentration increases, the energy used for the  $Na_2CO_3$  reaction increases by decreasing the energy lost to moisture removal from LB.

Finally, the  $NO_x$  emissions decrease as the secondary air flow ratio decreases and the tertiary air flow ratio increases, as shown in Fig. 5 (b). As the secondary air flow ratio increases, the pyrolysis reaction becomes more active; accordingly, the amount of thermal  $NO_x$  production increases with increasing temperature of the pyrolysis reaction. As the tertiary air flow ratio increases,  $NO_x$  emissions decrease owing to the activated  $NO_x$ -reducing combustion reactions.

Fig. 5. Pulping chemical recovery and  $NO_x$  emissions according to operating conditions: (a)  $Na_2CO_3$ ; (b)  $NO_x$  emissions

$NO_x$  emissions were derived. Fig. 6 shows the Pareto-optimal front with representative solutions. Representative solution 1 has  $NO_x$  emissions equal to the existing operating conditions but can increase profits by up to 294.23%. Representative solution 3 has the

same net profit as before but can reduce NOx emissions by up to 11.01%. Finally, Solution 2 is the average of Solutions 1 and 3, which can increase the net profit by 147.41% and reduce NOx emissions by 5.50%. In addition to these three solutions, decision-makers can select solutions that fit the situation from the proposed Pareto-optimal front.

Fig. 6. Pareto-optimal front with representative solutions

#### 4. Conclusions

This study focuses on multi-objective optimization of maximizing net profit and minimizing NOx emissions while recovering LB. This study makes two major contributions to the existing literature. First, the solutions proposed in this study do not include any retrofitting of the conventional evaporation process and the biomass boiler, and are thus applicable on-site. Second, robust multi-objective optimization was realized by simultaneously considering the net profit and NOx emissions in the overall processes in the pulp and paper industry using the DNN model. The derived representative solutions increased the net profit by up to 294.23% and decreased the NOx emissions by up to 11.01%. In addition to representative solutions, decision-makers can select solutions that fit the situation from the proposed Pareto-optimal front. Therefore, we believe this study can offer comprehensive solutions to on-site decision-makers.

## Abstract

Ammonia is one of the leading products of the chemical industry worldwide. In addition, its manufacturing is significantly both energy- and emissions-intensive. As ammonia production is heavily based on fossil fuels, its synthesis integration with the Allam power cycle is a promising technology that can lead to substantial decarbonization of the whole process and an important abatement of the electrical energy costs (and indirect emissions). The Allam cycle is a system for high-efficiency power generation with supercritical CO<sub>2</sub> working fluid. Its integration into conventional ammonia plants allows for simultaneously producing electricity, water, and pipeline-ready carbon dioxide. An original, improved layout of a gray ammonia plant combined with the Allam power cycle is simulated to run a techno-economic assessment of the process and detect the optimal operating conditions that improve its economic and environmental sustainability.

**Keywords:** Haber-Bosch; carbon dioxide; sustainability; climate change mitigation.

## 1. Introduction

The rising energy transition era calls for the decarbonization of hard-to-abate sectors, with the chemical industry at the forefront. Specifically, in 2020 only, ammonia synthesis totaled more than 440 Mt<sub>CO<sub>2</sub>eq</sub>/y, being the most carbon-intensive process of the whole sector (Isella and Manca, 2022). Considering a conventional ammonia plant, the core of its direct CO<sub>2</sub> emissions is the so-called “front-end”. Such a term, which refers to the reforming, shift, and syngas purification sections as a whole, is opposed to the “back-end”, which refers to the ammonia converters and the separation section that allows the final product recovery. This is because conventional front-ends heavily rely on fossil fuels (primarily natural gas) to meet both the hydrogen and energy demands of the process. In answer to this, the integration of a recently introduced power cycle known as the “Allam cycle” in the front-end of a conventional (“gray”) ammonia plant is here proposed and performed through process simulations and techno-economic evaluations. Indeed, since the main peculiarity of the Allam cycle lies in exploiting supercritical carbon dioxide as a working fluid for electricity production (Allam *et al.*, 2015), the present work investigates how ammonia production may be decarbonized by diverting the whole CO<sub>2</sub> produced in the front-end of the production site to the Allam cycle. Such a strategy would lead to producing a sort of “blue” ammonia (to borrow the hydrogen color codes) and

generating electric power (which would fulfill first the electricity demand of the whole plant and then export the surplus).

## 2. Process simulation

The simulations of this study were performed by UniSim® Design R491. Specifically, three distinct sections constitute the plant: the Front-end, the Air separation unit, and the Allam cycle. First, these sections were singularly modeled and finally joined into the whole process flow diagram reported in Figure 1.

Figure 1: Block flow diagram of the simulated ammonia plant with the Allam cycle integration.

As evident from Figure 1, the main goal of the proposed integration is to fully abate the gaseous  $\text{CO}_2$  emissions generated in the Front-end by routing all the tail gases (separated in the purification section from the hydrogen product) to the Allam cycle power plant. Such a  $\text{CO}_2$ -rich stream feeds the combustor of the Allam cycle. Specifically, this unit burns natural gas and oxygen to increase further the temperature above  $1100\text{ }^\circ\text{C}$  and produce even more  $\text{CO}_2$  that feeds a turbine for electricity production. Next, a series of heat exchangers cool the exhaust stream and recover a significant amount of heat. One of them, the recuperator, has the crucial function of pre-heating the recycle stream before it returns to the combustor. After water removal, the  $\text{CO}_2$  mass flow is compressed through a train of centrifugal compressors that make the expanded  $\text{CO}_2$  supercritical again: a minor fraction is removed as pipeline-ready carbon dioxide, and the remaining part is recycled back to the combustor. It is worth noting that the Allam cycle contributes to an increase in the total amount of carbon dioxide produced by the whole process. However, unlike the gaseous emissions from the ammonia plant, the  $\text{CO}_2$  product is collected in such a state that easily allows exporting it for industrial uses (e.g., urea synthesis, enhanced oil recovery, food market). Indeed, the usage of carbon dioxide in the industrial sector records remarkable extents: around  $230\text{ Mt}_{\text{CO}_2}/\text{y}$  are currently used for the said purposes (IEA, 2022). Even water is among the products of the Allam cycle. Concerning the current integration layout, it can be used in the ammonia section either as a utility for the on-site steam generation required by the reformers or as cooling water. Finally, an air

separation unit (ASU) that concurrently produces the nitrogen required for ammonia synthesis meets the oxygen demand of the Allam cycle combustor. Indeed, a nitrogen-to-hydrogen ratio equal to 3 is mandatory at the inlet of the ammonia converters. The following subsections show each simulated section of the integrated plant.

### 2.1. Front-end

The Front-end model primarily comes from Soltani *et al.* (2014). It is a simplified model of a typical steam methane reforming (SMR) process, comprehensive of the furnace, the reformer and shift reactors, and the purification section.

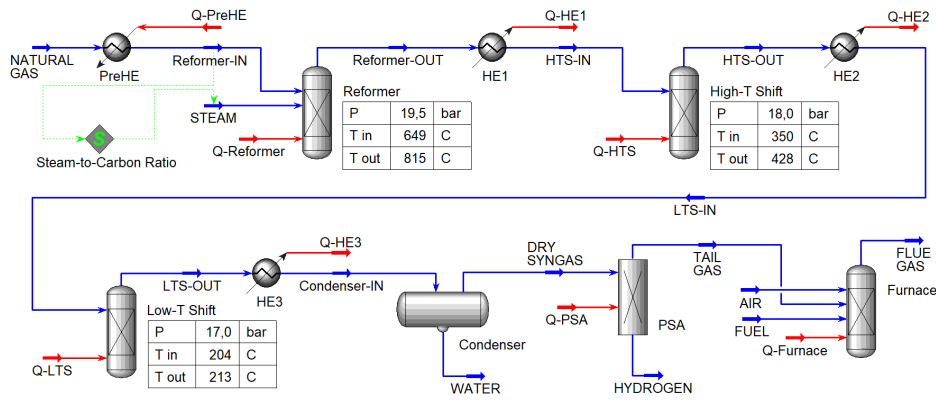

Figure 2: The simulated Front-end process flow diagram.

Precisely, all the reactors were simulated as “Equilibrium reactors” (*i.e.* reactors whose outlet streams achieve both chemical and physical equilibria according to the specified reaction set). In contrast, the furnace was modeled as a “Gibbs reactor” (*i.e.* a reactor that simply minimizes the Gibbs free energy of its products, suited to avoid complicated and inadequately accurate stoichiometric reactor models). Note that the furnace appears at the end of the flowsheet because it downstream evaluates the amount of fuel it needs. In this respect, the flue gases from the furnace virtually enter the reformer to exchange their enthalpy with the reacting flow.

### 2.2. Air separation unit

The Air separation model comes from Ebrahimi *et al.* (2015). Expressly, it consists of a conventional double-column cryogenic distillation process.

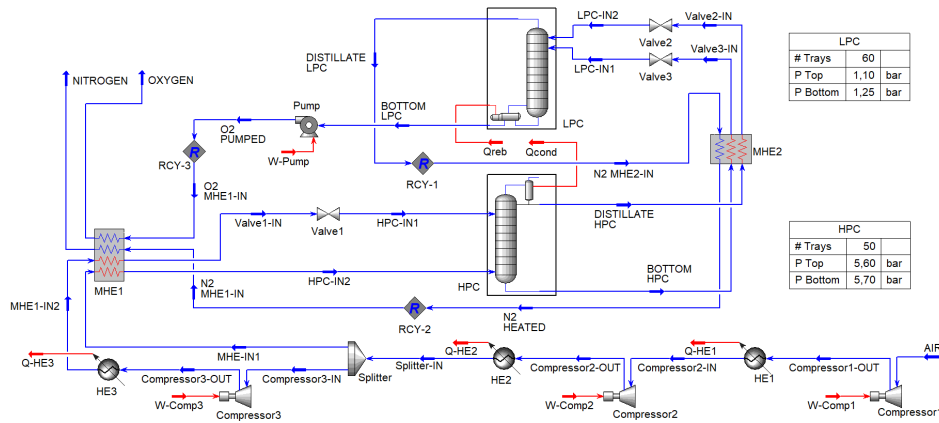

Figure 3: The simulated Air separation process flow diagram.

Concerning product purities, the nitrogen stream should preferably have purity above 99 mol% to avoid oxygen poisoning the catalyst of the ammonia synthesis loop. In contrast, the oxygen stream headed to the Allam cycle should be over 95 mol%, *i.e.* the near-optimal oxygen purity value for oxy-fuel combustion (Ye *et al.*, 2019).

### 2.3. Allam cycle

The Allam cycle model mainly relies on Allam *et al.* (2015) and Wang *et al.* (2021). The inlet tail gas and oxygen streams come from the Front-end and the Air separation unit sections, respectively.

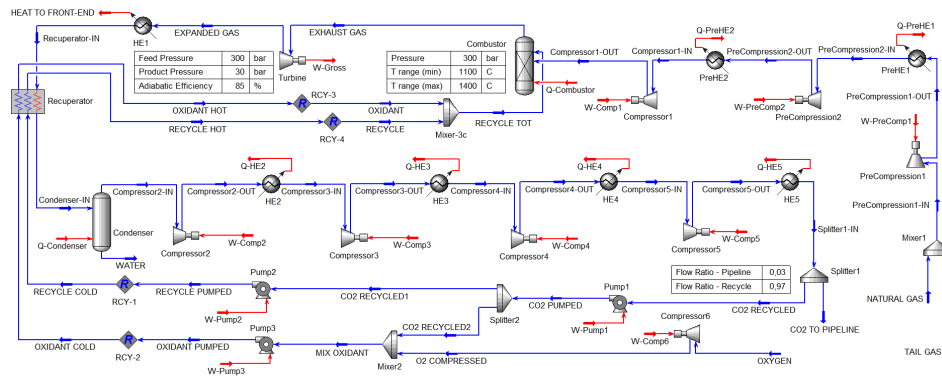

Figure 4: The simulated Allam cycle process flow diagram.

As happened for the furnace of the Front-end, even the combustor was modeled as a Gibbs reactor. Specifically, its temperature operability range spans from 1100 to 1400 °C. Also, note that an additional heat exchanger (missing in the original layout of the Allam cycle patent) was added to recover heat beneficial to the Front-end reforming section, as proposed by Wang *et al.* (2021). The CO<sub>2</sub> purge, ready for the pipeline, equals 3% of the processed flow, while the remaining 97% is recycled back to the combustor.

All the simulations implement the Peng-Robinson equation of state for thermodynamic computations. Finally, the three sections were combined in a single flowsheet to assess the performance of the retrofitted ammonia synthesis plant.

### 3. Results and discussion

Both CapEx (Capital Expenditure) and OpEx (Operational Expenditure) were evaluated for the economic assessment of the whole plant. The main hypotheses for such calculations consist in considering 8000 working hours in a year and a 10-year depreciation time for the equipment in each section of the plant. Regarding the Front-end, according to the rather simplified model, the CapEx and the OpEx terms rely on the indicative values of 390 USD/t<sub>H2</sub> and 970 USD/t<sub>H2</sub> (IEA, 2019), respectively. Conversely, concerning the Air separation unit, the CapEx estimation mainly derives from Guthrie’s formulae (for columns and compressors) and the equipment costs reported by Young *et al.* (2021) for the two multi-pass heat exchangers provided in the process flow diagram. Finally, the costs of the Allam cycle originate from an indicative value of 685.7 USD/kW<sub>e,output</sub> (IEAGHG, 2015) for the CapEx, while market values of utilities (*i.e.* natural gas, 0.08 USD/kWh in the 1<sup>st</sup> semester of 2022) and products (*i.e.* electricity, 0.25 USD/kWh in the 1<sup>st</sup> semester of 2022, and ready-to-pipeline carbon dioxide, 10 USD/t<sub>CO2</sub>) for the OpEx. Four ammonia plant capacities were considered: 750, 1000, 2000, and 3000 t<sub>NH3</sub>/d. In this regard, a “0.8 power law” replaced the conventional “0.6 power law” for the economies of scale to run a conservatively safer economic assessment. Indeed, both the combustor and the turbine of the Allam cycle are rather peculiar units (especially as they have to deal with CO<sub>2</sub>-rich streams), thus likely less liable to such a typical behavior of the conventional units of chemical plants.

Table 1: Main results of the techno-economic assessment. Key process variables, CapEx and OpEx, and the percentage cost increases ( $\Delta\%$ ) of the performed Allam cycle integration as a function of the ammonia plant capacity. A combustor temperature equal to 1100 °C is considered.

Plant capacity [t <sub>NH3</sub> /d]	CO <sub>2</sub> to pipeline [t <sub>CO2</sub> /d]	Water output [t <sub>H2O</sub> /d]	Net power [MWe]	Max pipe diameter [m]	CapEx [MUSD]	OpEx [MUSD/y]	$\Delta\%$ CapEx [-]	$\Delta\%$ OpEx [-]
750	1426	664	147	0.58	510	82.6	+82.4%	-34.5%
1000	1902	885	205	0.67	627	100.5	+85.9%	-28.4%
2000	3803	1770	438	0.95	1073	208.7	+88.8%	+5.4%
3000	5704	2655	670	1.16	1497	351.8	+87.4%	+37.7%

Table 1 shows the main process variables and the results of the CapEx and OpEx assessment performed on the integrated facilities. Specifically, increasing the operative temperature of the combustor does not show any beneficial effect on both the investment and operative costs of the plant. Thus, the table reports only the results corresponding to the simulated lowest feasible operative temperature at the combustor (*i.e.* 1100 °C). Nevertheless, as evident from Table 1, the integration of the Allam cycle to gray ammonia plants becomes increasingly unprofitable as the ammonia plant capacity increases. Indeed, although higher ammonia plant capacities allow producing considerable amounts of electric power, they also lead to extremely high flowrates in the Allam cycle loop (note that the CO<sub>2</sub>-to-pipeline stream is just 3% of the total processed flow). In other words, this means the power cycle needs high piping diameters to process all the flowing mass within the loop. The maximum internal diameter of a standard stainless-steel tube (material needed to resist the corrosivity of the CO<sub>2</sub>-rich stream: indeed, in presence of water, severe corrosion of the infrastructure may result due to the formation of carbonic

acid) is around 0.8 m: thus, both 2000 and 3000  $t_{\text{NH}_3}/\text{d}$  plants would inevitably require at least a parallel configuration. As previously mentioned, the water produced by the Allam cycle could be exploited to generate steam as required by the reforming section: specifically, at each ammonia plant capacity scenario, it would reduce about 40 wt% of its demand. Finally, the oxygen demand of the Allam cycle is another crucial factor making the integration disadvantageous at high capacities. Indeed, an air separation unit producing about 1900  $t_{\text{O}_2}/\text{d}$  was simulated to deal with the nitrogen demand of the 750 and 1000  $t_{\text{NH}_3}/\text{d}$  ammonia plants but, in the case of 2000 and 3000  $t_{\text{NH}_3}/\text{d}$  facilities, such oxygen productivity just covers 25% and 50% of the final demand of the power cycle, respectively.

#### 4. Conclusions

The integration of the Allam power plant into an ammonia synthesis process proved to be a feasible strategy to decarbonize ammonia production. The results of the presented techno-economic assessment showed that such a solution primarily suits low/medium-capacity ammonia plants. Indeed, concerning the 750 and 1000  $t_{\text{NH}_3}/\text{d}$  capacities, substantial reductions in OpEx complement the inevitable increases in CapEx. On the other hand, medium/high-capacities would suffer greatly from the extremely high flowrates circulating in the Allam cycle, although this would make it capable to export much more electricity. In addition, such higher capacities would call for further measures such as parallel configurations and additional raw materials and utilities entering the system. However, if one disregards any economic considerations, it is rather important to observe that every integrated layout was able to simultaneously prevent all the gaseous emissions originating from the front-end section of the ammonia plant and cover the electricity demand of the whole facility. Therefore, although occasionally proving less profitable than the original configurations, the retrofitting of conventional ammonia plants with the Allam cycle turned out to be an available-to-date strategy capable of fully abating both direct (*i.e.*  $\text{CO}_2$  released on-site by the front-end) and indirect (*i.e.*  $\text{CO}_2$  generated by the power stations for the production of electricity) emissions at all plant capacities. Finally, the significant amount of ready-to-pipeline  $\text{CO}_2$  produced by the shown configurations may represent an attractive feed for several industrial applications. Indeed, although over 35  $\text{Gt}_{\text{CO}_2}/\text{y}$  are currently emitted into the atmosphere every year since the last decade (Our World in Data, 2022), shortages in industrial-grade carbon dioxide have been particularly recurrent in the past few months in several European countries, including Italy, Germany, and the United Kingdom (The Guardian, 2022). Moreover, by doing so, completely abating carbon dioxide emissions in the atmosphere allows to avoid paying any “carbon tax”, which are expected to substantially raise in the next years.

## Abstract

Although the concept of Valley of Death (VoD) has been widely documented, also in the context of the slow uptake of the Green Transition (GT), the available literature rarely provides any contemplations from more than one point of view. By reviewing works from different viewpoints like economics, policies, research, and industries, this contribution discusses the phenomenon of VoD in the GT more comprehensively and outlines the extent of the issues at hand. The study argues that VoDs of individual biorefinery technologies are not solved independently but only by overcoming the systemic barriers that stranded the GT in its overarching VoD. In fact, the GT efforts may be the first venture that has to address such a multitude of technological, economic, social, political, and market aspects on its way to maturity and commercialization.

**Keywords:** biorefinery, assessment, sustainability, policy, industry

## 1. Motivation

Despite the interest and support for sustainable process industries, shared by many actors from the public, politics, industries and research, being higher than ever, the Green Transition (GT) is leaping behind considerably. With most biorefinery concepts still being stuck between the experimental and demonstration phases, unable to cross this so-called Valley of Death (VoD), the deployment of sustainable technologies on a full-industrial scale has been slow at best. The concept of VoD refers to a point in process or technology development where the sum of available research grants and existing commercialization funding is at its minimum. This is usually experienced after the technology readiness level (TRL) 4 has been achieved - the lab-scale validation, and before TRL 7 can be met, that is, the technology's prototype implementation in a relevant, operational environment. As depicted in Figure 1, research activities push new concepts until TRL 4, mainly aided by public funding. From TRL 6 on, those concepts have to be pulled by the industries since private investments become the predominant funding. TRL 5–7 are therefore the bridge between basic knowledge generation and industrial application. If, before this phase, the technology has not reached

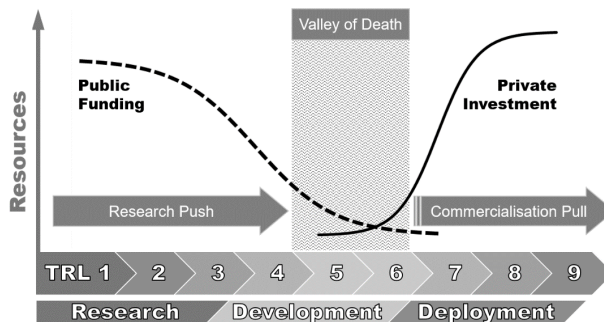

Figure 1: The Valley of Death in technology development

sufficient legitimacy and reliability for commercialization pulls, it strands in a calm belt of next to no push or pull; the VoD.

Since development processes are not linear and often even require the major scientific, technological and social disruptions of so-called paradigm shifts (Kuhn, 1970), the existence of VoDs is nothing new. Accordingly, the barriers involved are not only technical ones; those of economic, sustainable and socio-political nature continue to exist, although many technical issues may be long resolved. Identifying and understanding these barriers and how they can be overcome is thus essential for supporting the GT.

In an unfortunate plot twist concerning the GT, most of the VoDs observed with individual technologies can not be resolved independently - they are mere projections of the much larger, overarching VoD that the GT is currently stranded in. Analogously, the aforementioned barriers are rooted in significantly larger and systemic causalities, thereby necessitating the discussions on them to be lifted to a broader scale as well. The GT is probably the first genuinely global technical transformation humankind has ever aimed for; a new Industrial Revolution and an absolute at that. It is thus of no surprise, that the GT faces such a multitude of interrelated, global-scale barriers of scientific, technological, economic, social and political natures. However, the available literature on the concept of VoD and barriers of the GT rarely addresses more than one discipline and point of view. This contribution, therefore, bases its discussion on reviewing prior work from different sources like economics, policies, research and industries, thereby painting a comprehensive picture of the root causes and the extent of the issue at hand.

## **2. The Green Valley of Death**

During the Industrial Revolution in the 18<sup>th</sup> and 19<sup>th</sup> centuries, hand-production workshops have largely been replaced with mechanized factories, thereby prompting such an unprecedented, radical technological shift that society was fundamentally altered. Considering the GT's scope and expected global impact, disruptive industrial shifts similar to those aforementioned are more likely than the comparably confined societal impacts of recent technological innovations. However, the GT is still often handled as a slow, iterative process of incremental changes and regime reconfigurations, which may hinder renewal and profound structural change if left unchallenged in policies and governance (Bauer, 2018). This notion is fortified by the current policies' emphasis on primarily supporting new technologies' developments, which seem to implicitly assume default commercialization of them as soon as sufficiently developed (Hansen & Coenen, 2017). Apparently, many actors still try to enforce traditional transformation measures on the GT instead of enabling much-needed paradigm shifts. Meanwhile, the private sector proves those notions wrong by being unwilling to finance biorefineries alone due to residual GT-associated risks (Philip, 2018). Even after over 20 years of research and development (R&D), the GT still struggles to move from a formative R&D phase towards one of commercial growth. Interrelated barriers that involve co-evolving changes in technologies, markets, policies and industrial strategies as well as capabilities still limit interests and abilities to mobilise resources around the emerging technologies, thereby embedding the GT in a typical case of systemic lock-in (Hansen & Coenen, 2017).

### *2.1. Industrial Constraints*

Although innovation fosters economic growth, the GT depends on industries entering into uncertain environments, where they may be well advised to proceed and invest cautiously. Correspondingly, Nilsen (2017) describes that despite a few corporative strategy changes in recent years, many mature companies like Statoil ASA (since renamed Equinor ASA) remain highly dependent on the petroleum path as the main competitive advantage in the

years to come. Industrial incumbents have lower incentives to prioritise radical innovations since efficiency and profit come from established, predictable and reliable technologies, and the organizational routines surrounding them. It also implies bureaucratic inertia and resistance to change. The Technology Innovation System (TIS) analyses by Hansen & Coenen (2017) and Frishammar et al. (2019) identified, among others, high capital intensity, a lack of strategic value-chain partnerships and market knowledge, as well as overall system weaknesses rooted in uncertainty, complexity, equivocality and ambiguity as the main limiters in the technological adoption of the GT. A limited industrial interest may also be inferred from present business models certainly having to drastically adapt in the GT. Contrary to traditional industrial characteristics like the economics of scale and competition based on market prices, businesses arising from the GT may be characterized by distributed, small-scale plants, economics dominated by local supply/demand, and competition in terms of sustainability. Growing new sectors like this, however, requires operational support via appropriate policies due to long formative periods in which investments can be substantial with little to no return and new businesses struggling to develop any legitimacy (Peck et al., 2009). Industrial initiatives require investment motivation and assistance by long-term, reliable policies.

### *2.2. Market Barriers*

Instead of achieving the multi-product biorefinery configuration, already implemented biorefineries are mostly working as stand-alone facilities without any integral, well-designed process for the maximum use of an extensive feedstock portfolio or a range of different products (Cardona-Alzate et al., 2020). Consequentially, they are at the mercy of market fluctuations in the absence of operational support. Although renewable, the capitalism-inherent intention of unlimited growth cannot be met within the narrow constraints of biomass. Policies that aim on evolving the GT concurrent to the petroleum industries, increasing the industries' overall size instead of substituting fossil with sustainable resources, will thus fail due to many overlapping resource and market competitions. These competitions are, besides a lack of coordination and policy instruments in niche markets, already today a predominant cause for weak resource mobilization and market formation (Hansen & Coenen, 2017). There is a strong need to support the creation of bio-product markets through, for example, public procurement, price guarantees and biomass/bio-product production incentives (Fevolden et al., 2017). The implementation of carbon taxations and fossil fuel subsidy reforms would especially aid the creation of new markets, however, policies explicitly facilitating market adoption and commercialisation are weak or altogether lacking (Hellsmark et al., 2016). As a result, current market structures neither secure a sufficient supply of sustainable feedstocks nor generate ample demand for bio-products, thereby creating one of the conditions that deter investors (Philip, 2018). Supply chain analyses are therefore critical to the success of the entire GT. Their reliability may, however, be questioned: Seidenberger et al. (2010) and Schueler et al. (2016) demonstrate significant variability in published global biomass potentials due to several weaknesses and a lack of short-term estimates (i.e. 2030).

### *2.3. R&D Bottlenecks*

Even though segueing to barriers within R&D may be appropriate at this point, most of the discussion can be found in Pujan & Preisig (2022), therefore keeping this paper's considerations on the topic to a minimum.

The conservative notion of forcing bio-products into the shapes of fossil products seems to be a predominant factor that is hindering innovations in R&D. However, despite early propositions by, for example, Marquardt et al. (2010) to use the GT as a unique opportunity for redesigning industrial value chains, current literature shows the majority

of R&D trends still aiming at bio-feedstock conversions to products very similar to their fossil counterparts. In this regard, knowledge of biorefinery integrations into existing technical systems may remain critical for further developments, however, Bauer et al. (2017) reported a consensus in the literature that R&D may be necessary but investing more resources in it would certainly not enable biorefineries to cross the VoD.

#### *2.4. Erratic Policies*

Since the Industrial Revolution has been a century-long effort, one may conclude that the GT's slow uptake is par for the course. However, scientific innovation methods have tremendously improved since the 18<sup>th</sup> century and are accelerated by the rise of computing. This evolution is, however, barely visible since the GT faces barriers unknown to the Industrial Revolution. The latter was mainly driven by economic growth, disregarding environmental and social ramifications, and did not encounter fierce competition from deprecated industries. Additionally, the early years of the Industrial Revolution were confined to national scales, whereas the GT was always a global venture. Industrial boundaries often do not coincide with national borders and may vary between different industrial sectors. Accordingly, without supra-national policies that are stable in the long term, private investments in disruptive GT technologies remain too risky for consideration. Many EU and national policies still show insufficient levels of coherence and private sector incumbents question the coordination between EU, national and regional policy levels, especially in terms of biomass use (Peck et al., 2009). Due to the rush and hype regarding biofuels and bioenergy in recent years, many supra-/national policies are incentivizing the energetic utilisation of biomass, while almost neglecting material exploitation. Since the private sector must necessarily respond to market forces, a broad uptake of new businesses is generally dependent on significant political support with a consistent future vision. Regional developments, national R&D and global issues necessitate sufficiently flexible policies that are coherent across boundaries and minimum in duplications (Philip, 2018). Policies are of particular importance where significant positive externalities of the new system, like environmental and social benefits, are yet not priced by current market structures (Peck et al., 2009). However, although current political discussions centre on sustainability narratives, the resulting policies remain focused on efficiency, productivity and industrial competition instead of environmental benefits (Bauer, 2018). Standard policies like these do not yield the same effect in the GT as in other sectors, as demonstrated by Maes & Passel (2019). By investigating the policy frameworks for past technological transitions, Verbong et al. (2008) conclude that close adherence to industrial policies is problematic and that the innovation learning effects were not sufficiently guarded by past policy instruments. More than any other sector, the GT requires a combination of technology-push and demand-pull policies to stimulate sufficient levels of innovation and progress (Frishammar et al., 2019). Public-private partnerships, governmental loan guarantees and other innovative funding instruments like Green Bonds are necessary to de-risk private investments in the GT (Philip, 2018). This asks for large capital sums and long-term commitments since any biorefinery would need external support until the industry achieves critical mass and supply-demand stability. Relocating funding from fossil subsidies and introducing carbon taxations can be a huge source for these endeavours. However, their widespread realisations are still due.

#### *2.5. Legitimacy Thresholds*

Conducting the GT calls for eliminating more barriers than mere technological ones. It requires transitions in consumer behaviour and expectations, institutional norms, standards and regulations, as well as technological, economic and organizational innovations throughout supply and value chains – it is such a politically contested

transformation where public perceptions are key (Bauer, 2018). Understanding public perceptions has been shown by Marciano et al. (2014) to be critical for managing the costs of emerging biorefineries. Peck et al. (2009) outlines how an understanding of the processes of building cognitive and socio-political legitimacy is relevant to the GT and how early legitimacy enhancements can reduce the duration and difficulties of formative phases in the evolution of innovative businesses. The socio-economic aspect influences most of the barriers to the critical adoption of the GT, which necessitates policy intervention (Ubando et al., 2020). Unfortunately, the public is largely oblivious to the environmental and social costs of fossil fuel subsidies, as well as the state-of-the-art in the GT. Accordingly, public and political opinions are erratic, and actors may even be confused by the aims and activities of the GT. An informant in the study of Frishammar et al. (2019) reported public backlash to the company when buying palm oil, even though it was certified – strangely, the public is less discerning with regard to crude oil. The impact and pace of climate change are just not obvious enough and too complex to grasp for most of the public. Similarly, the GT's complexity and its multitude of technological pathways are confusing even to scientists working in the field (Peck et al., 2009). Researchers still debate whether the bioeconomy is itself inherently sustainable or rather some weak ecological modernization and thus a threat to sustainability (Pfau et al., 2014). Truly sustainable solutions require much wider perspectives than presently considered. There are some mainstream claims that the GT's early adopters will mostly be interested in the green image, thus, technologies would not have to be refined or reasonably priced. Although those early adopters may provide initial finances, relying on them would certainly not enable an absolute GT. Furthermore, since the sustainability concept is often not objectively defined in current assessment methods (Cardona-Alzate et al., 2020), reaching public and political legitimacy in terms of sustainability may be a lost game.

Although R&D is proposing several technologies for the GT, hardly any evidence is provided to ensure widespread economic legitimacy. Evidence has to prove the feasibility and reliability of the GT technologies in development that is systematic scale-up studies, extensive simulation runs and reliable assessment analyses. After failed R&D hypes in recent decades, like, for example, microalgae, public funding measurements and investors understandably became very hesitant.

### **3. Concluding Remarks**

As reasoned before by others as well, the GT can be successful in terms of economics, sustainability and society only if developed under certain conditions (Devaney & Henchion, 2018). However, as discussed here, the lack of these conditions as well as a multitude of interrelated, global-scale barriers of scientific, technological, economic, social and political natures keep the GT stranded in a VoD. Conflicting narratives dominate public opinion, policy-makers are acting too reluctant, R&D fails to establish legitimacy for GT technologies, and industries are enclosed in established routines and market constraints. Many barriers are rooted in notions that still try to undertake the GT without drastic shifts. Often, outdated measures as well as the profile of traditional fossil industries are enforced on the GT, thereby ignoring the largely different nature of this industrial revolution. More than 20 years of mainstream attention to the GT, yet, the nurture of “monkey see, monkey do” remains a dominating approach, trying to reproduce traditional chemical industries and old societal systems in the GT. It is about time to encourage that old monkey to take more risks and teach it some innovations.

## Abstract

Waste Cooking Oils (WCO) are considered a harmful waste, though also constitute a valuable carbon source if treated correctly. This paper illustrates a novel WCO valorization chemistry to produce added-valued bioplastics. The core process is based on bio-based catalysis, in which *E.Coli* is fermented to produce oleate hydratase enzyme, which catalyzes FFAs conversion into the key building block of 10-Hydroxystearic-Acid (10-HA). The process is further integrated with upstream saponification-acidification stages for the pre-treatment of mixed WCOs, while downstream chemical processes (hydrogenation, esterification, polymerization) are upgrading the 10-HA building block into bio-based poly-10-HAME polymer. As upstream and downstream stages involve different scales, the paper addresses the scope to scale-up using a systems approach that builds efficiency and optimizes interactions. Overall, 3 tn of WCO yield in 1.5 tn of poly-10-HAME, CAPEX and OPEX are estimated to 141 M€ and 65 M€/yr, while emissions are estimated to 2.4 kg CO<sub>2</sub><sub>eq</sub>/kg biopolymer.

**Keywords:** WCO, FFA, Bio-catalysis, Fermentation, *E.Coli*.

## 1. Scope of work

Waste Cooking Oils (WCO) constitute a valuable carbon source composed of unsaturated triglycerides (TGs) collected as wastes after frying with vegetable oils. They are usually disposed in landfills and/or along with wastewater resulting in huge environmental impacts; nevertheless, there are still options for recycling. The traditional solutions include the well-known transesterification chemistry that returns 1G biodiesel. Biofuel production is questioned in terms of social (edible sources), economic and environmental aspects (Lopes et al, 2019). Other emerging technologies use alternative renewable feedstocks (Pateromichelakis et al, 2022), or target to other bio-based products, like alcohols for vehicle and/or shipping fuels (Pyrgakis et al, 2016). Instead, a novel green solution based on a biocatalytic chemistry is proposed enabling the valorization of WCOs towards high-value bioplastics. The chemistry has been validated at laboratory scale (TRL4) and, in this work, it has been studied at modelling level to build knowledge and efficiencies for scaling up purposes.

The chemistry is based on the catalysis of the transformation of FFAs into 10-HA by means of oleate hydratase enzyme, which is produced by *Escherichia Coli*. The unsaturated fats of WCO are processed to prepare the required FFAs feedstock for the parallel enzymatic conversion to 10-HA, while, finally, 10-HA is upgraded to prepare the

Figure 1 Reactions of FFAs transformation to biopolymer building blocks

10-HAME monomer for biopolymer production. Specifically, saponification is decomposing triglycerides (WCOs) into soaps, while acidification of soaps returns the exploitable FFAs co-substrate. *E. Coli* is fermented using glucose substrate and nutrients as cultivation media for growth and the production of oleate hydratase enzyme. The latter catalyzes the transformation of oleic and linoleic acids (FFAs) into 10-Hydroxyl-stearic acid and 10-Hydroxy-linoleic acid (10-HAs) following the reaction paths of Figure 1. Next, both 10-HAs and unconverted FFAs are hydrogenated generating their saturated fractions, which are next esterified forming the 10-HAME precursor and biodiesel (FAME). The latter closes the gap of carbon losses of the organic feedstock, which are not catalyzed to 10-HAs. The two fractions (10-HAME and FAME) are split by distillation returning drop in biodiesel and pure 10-HAME for polymerization purposes.

Based on experimental data for the core and surrounding chemistries, an integrated biorefinery flowsheet was developed from scratch in ASPEN Plus for analysis and simulation purposes.

## 2. Challenges in WCO valorisation

The studied chemistry was never addressed before at a modeling level, or as a complete biorefinery flow diagram. Experimental data concerning the biocatalysis cultivation media and its substrates and conversion efficiencies of FFAs are available for analysis. In this scope, challenges rise in terms of transferring the new-to-nature chemistry into a complete biorefinery flowsheet from raw (WCOs) and auxiliary (i.e., glucose) substrates to end-biopolymer products. Moreover, this plant utilizes 5 different chemical paths (saponification, acidification, fermentation, hydrogenation, polymerization) and challenging separation unit operations (e.g., spray drying). As far as concerns biocatalysis, the chemistry brings new challenges in modelling hybrid systems utilizing a fermentation-driven pathway and enzymatic conversion across the same system. Biocatalysis combines growth with glucose and production of primary metabolites (enzyme), which are exploited as catalyzing means of other reactions converting the FFAs co-substrate into desired products. These conditions increase the size and complexity of coupling different kinetic models that essentially require Monod-based kinetics for the *E. Coli* fermentation, and Michaelis-Menden-based kinetics for the enzymatic reactions. In addition, fermentation is affected by  $O_2$  inhibition and temperature bounds that define fermentation and enzymatic efficiencies. Finally, the modeling procedure was challenged by lack of properties for special nutrients/auxiliaries, like the biochemical inducer IPTG.

## 3. Methodological steps

This work followed a 6-step approach to transfer chemistries at laboratory scale into a complete process biorefinery flowsheet for simulation, scaling up and analysis purposes of new-to-nature biotechnology concepts. The approach includes (1) estimation of biocatalysis kinetics; (2) process flowsheeting from scratch; (3) simulation and scaling up; (4) energy integration; (5) LCA for estimation of environmental impacts; and (6) techno-economic analysis of bio-based polymers.

### 3.1. Development of biocatalysis kinetics

An engineered strain of *E.coli* is incubated to achieve desirable growth rates for target scales. In parallel, the raw feedstock is prepared by means of saponification (KOH) and acidification (H<sub>2</sub>SO<sub>4</sub>) resulting treated FFAs; the conventional reaction systems are modeled by RSTOIC in ASPEN. Centrifuges are employed to remove water from organic phases. Next, experimental data including biocatalysis yields were used for kinetics modeling. Conditions such as growth, temperature and O<sub>2</sub> inhibition are considered resulting in an extended version of Monod kinetic model, which integrates the following terms for each limiting condition (Wang et al, 2014; Cruz et al, 2018):

$$\text{Growth: } r_c = k^{cell} \cdot \frac{C_c \cdot C_S}{C_S + C_M^{Mon}} \Leftrightarrow \frac{dC_R}{dt} = k^{cell} \cdot \frac{C_c \cdot C_S}{C_S + C_M^{Mon}} \cdot \frac{C_R - C_{R0}}{C_c - C_{c0}} \quad (1)$$

$$\text{Temperature: } r_c = r_c^{max} \cdot \frac{T_{max} - T}{T_{max} - T_{opt}} \cdot \left( \frac{T}{T_{opt}} \right)^{\frac{T_{opt}}{T_{max} - T_{opt}}} \quad (2)$$

$$\text{O}_2 \text{ inhibition: } k_{obs} = k^{cell} \cdot \left( 1 - \frac{C_{O_2}}{C_{O_2}^*} \right)^n \quad (3)$$

$$\text{Enzymatic conversion: } r_{10HA} = k^{enz} \cdot \frac{C_{E0} \cdot C_{FFA}}{C_{FFA} + C_M^{enz}} \quad (4)$$

where  $C_i$  and  $C_{i0}$  are the concentrations of component  $i$  at the end of each batch experiment and the beginning, respectively;  $C_{O_2}^*$  the limiting concentration of inhibition;  $r_c$  the reaction rate of cells growth;  $k$  the maximum growth rate;  $C_M$  the Monod constant;  $k_{obs}$  the observed growth rate;  $n$  the exponential factor of inhibition; and  $T_{max}$ ,  $T_{opt}$  and  $T$  the maximum, the optimum and the actual temperatures in cultivation medium. The indexes C, S, R and O<sub>2</sub> account for cells, Substrate (glucose), product (enzymes) and oxygen components that participate and affect the biocatalysis system.

### 3.2. Process flowsheeting of biocatalysis chemistry

The overall biorefinery diagram is represented in Figure 2. At preliminary steps of the plant, the WCOs feedstock is chemically pre-treated. The cell factories and the processed feedstock are mixed in conventional reactor systems generating 10-HAs (with and without hydroxyl groups) that are saturated by hydrogenation. The saturated FFAs are esterified with methanol yielding in the 10-HAME biopolymer precursor and FAME. Finally, 10-HAME is polymerized resulting in the end-product of poly-10-HAME.

The above process diagram of Figure 2 was designed in detail from scratch including all process operations. The flowsheeting procedure was followed to deliver all pre-treatment, bioconversion and formulation chemistries; including intermediate separation stages for cost-effective removal of by-products, co-products and water-organic streams resulting high purity poly-10-HAME. In Aspen, the ‘‘General’’ type and the ‘‘LHHW’’ class of reactions have been used to integrate the complex kinetics. Based on the calculated Monod parameters, the optimal cells and glucose concentrations that result in maximum production rate and conversion have been defined. Accordingly, based on the tuned fermentation and enzyme production rates, the optimal feed rate of FFAs and the retention time for maximum production of 10-HA are estimated. Accordingly, the reactor volume is specified and the RCSTR model (Aspen plus) was used for the biocatalysis system.

Figure 2 Biorefining stages

Based on the finalized process flowsheet, techno-economic and LCA analyses have been conducted to address the economic and environmental sustainability of biopolymers production in front of competitive synthetic and fossil-based polymers.

### 3.2.1. Scaling up and analysis

The developed process flowsheet was modeled in Aspen for the simulation of mass and energy balances at higher scales (3 tn/hr). Thereafter, energy integration has been performed to identify the maximum feasible energy savings at higher scales. Moreover, the biorefinery input-outputs (energy, materials and wastes) fed the LCA analysis for the estimation of mid- and end-point indicators; including the global warming potential (CO<sub>2</sub> equivalent) for biopolymers production. Finally, a techno-economic analysis focusing on capital and operating expenses was performed to identify profitability margins and potentials for market entry of alternative biopolymers.

## 4. Results

The process flowsheet that is presented in Figure 3 consists of 4 sections for (i) WCO pre-treatment, (ii) biocatalysis, (iii) FFAs upgrade and (iv) biopolymers production.

### 4.1. Saponification-Acidification stage (WCO pre-treatment)

Saponification (RSTOIC model) takes place at 80 °C using KOH (5 M) to break the bonds of triglycerides of WCO resulting in glycerol and potassium oleic, linoleic, palmitic and stearic acid at conversion rates of 78.3%. In the basis of 3 tn of WCO, 2349.7 kg of potassium-FFAs are produced, which are then acidified at 80 °C in presence of H<sub>2</sub>SO<sub>4</sub> returning the treated FFAs for biocatalysis. A vapor-liquid separation stage is employed to recover volatile compounds in acidification effluents, while a downstream decanter is implemented to remove the water-glycerol content finalizing the biocatalysis feedstock.

### 4.2. Biocatalysis stage

The biocatalyst was prepared by inoculation to reach 3 tn of biomass ready for use in fermentation (37 °C). The biocatalysis step results in 1827.1 kg (77.7% conversion) of 10-Hydroxystearic-Acid. Based on experimental data, the kinetic parameters are accordingly estimated as follows:  $k^{cell} = 0.022388 h^{-1}$ ,  $C_M^{Mon} = 74.6269 mmol/L$ ,  $T_{max} = 315.2 K$ ,  $T_{opt} = 311.9 K$ ,  $C_{O_2}^* = 0.12 mg/L$ ,  $n = 1$ ,  $k^{enz} = 1.0288 mol/L$ ,  $C_M^{enz} = 0.025 mol/L$ . The fermentation exit stream is treated with ethyl-acetate solvent (5% v/v) to facilitate mixing and extraction of the biocatalysis phase (desired products) and removal of the excess water content by centrifugation. Next, spray drying was implemented to recover an ethyl-acetate rich phase (43%), the unsaturated FFAs (47%), and the remaining water (10%).

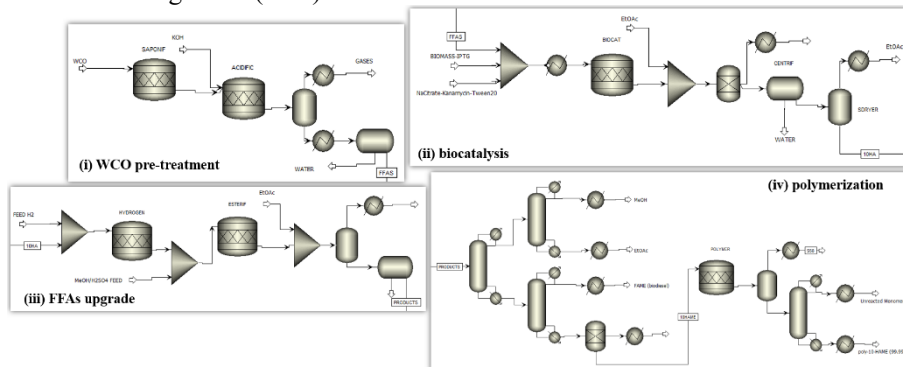

Figure 3 Biorefinery process flowsheet for biocatalysis implementation

#### 4.3. Hydrogeneration and Esterification stage (FFAs upgrade)

The recovered organic phase was hydrogenated (fixed bed reactor) with the use of a nickel-based catalyst to saturate double carbon bonds with hydrogen reaching nearly 99.9% saturation. The esterification stage is next implemented to treat the saturated acids with methanol. The key component, 10-Hydroxystearic-Acid, is esterified into 10-Hydroxystearic-Acid-Methyl-Ester (10-HAME) by 99.4% (1816.72 kg), while the methyl-esters (FAME) of all remaining FFAs are produced. The effluent methyl-esters stream is mixed with ethyl-acetate solvent to entrain the organic phase from water, which are recovered through a 2 liquid phase separation.

#### 4.4. Polymerization stage

Downstream esterification, a 3-distillation system is employed to recover the 4 key fractions from the ethyl-acetate entrainment: (i) unreacted methanol, (ii) FAME, (iii) 10-HAME and (iv) ethyl-acetate. The distillation separations have been designed to perform sharp splits at high purities ( $\geq 99\%$ ). Methanol and ethyl-acetate can be recovered back to esterification and liquid-liquid separation stages, while FAME (1440.5 kg) constitutes the biodiesel co-product. The 10-HAME (1816.54 kg) is finally driven to the polymerization stage producing the poly-10-Hydroxystearic-Acid-Methyl-Ester (1453.19 kg), that is equivalent to an overall yield of 48.44%.

#### 4.5. Evaluation: Energy, techno-economic and environmental analyses

Energy integration is applied to minimize operating and capital costs; the biorefining concept will fall short to compete with conventional processes or address sustainability targets [Kokossis et al, 2015; Pyrgakis et al, 2019]. Prior to energy integration, hot and cold utilities consumption have been at 7.4 MW and 14.1 MW, respectively. After integration the total utilities ware estimated to 2.24 MW (hot) and 8.9 MW (cold), which is equivalent to 70% and 37% of energy savings in heating and cooling demands. The optimal distribution over the utilities levels was accordingly estimated to 2.05 MW (LP steam), 0.19 (VHP steam) and 8.9 MW cooling water, as presented in the Grand Composite Curve of Figure 4.a.

Moreover, an LCA approach was followed using SimaPro to estimate the mid- and end-point indicators to produce biopolymers based on the input-output flows estimated by the biorefinery model. The Ecoinvent databases were used for the environmental indicators, while the ReCiPe methods was followed for the calculations. Accordingly, the contribution of the difference flows to the respective indicators are summarized in Figure 4.b. The emissions of CO<sub>2</sub> equivalent for the production of biopolymer were estimated

Figure 4 Energy Integration (a) and LCA (b) results

to 2.4 kg CO<sub>2</sub><sub>eq</sub>/kg biopolymer, while the emissions for conventional fossil-based polymers range between 2-3.5 kg CO<sub>2</sub><sub>eq</sub>/kg polymer.

Finally, the Aspen Process Economic Analyzer (APEA) was used to approximate the capital and operating expenses for production of 17,600 tn/yr FAME and 11,200 tn/yr biopolymers; accordingly, a mass allocation of 61-39% can be considered. The CAPEX was estimated to 141 M€, while OPEX was 65 M€/yr. As a result, for a depreciation period of 20 years (and the mass allocation), a production cost of 1.5 €/kg of biodiesel and ≈1 €/kg of biopolymer are estimated, while respective market costs are identified to 0.91 €/kg (biodiesel) and 1.8 €/kg (PVC equivalent cost). This is enough to consider that if another cost allocation strategy was accounted (i.e. by 34-64%), then an average price of 1.66 €/kg of biopolymer and 0.84€/kg of biopolymer could be achieved, resulting in improved prices (by 8%) compared to existing ones.

## 5. Conclusions

The work presented a new chemistry driven at industrial scales for production of biopolymers and biodiesel (co-product). The chemistry is attributed by complex kinetics in terms of cellular growth, enzymes production and enzymatic conversion of FFAs into valuable building blocks for biopolymers. Biodiesel was also considered to maximize utilization of residual carbon content of WCOs. The chemistry was presented at biorefining scales and achieved reductions at both costs and environmental impacts compared to existing solutions and products. Future work could include the investigation of alternatives auxiliaries (KOH, H<sub>2</sub>SO<sub>4</sub>) with lower cost and environmental impacts, as well as alternatives for downstream separations (e.g., membranes).

## Abstract

This work follows a systems engineering approach to re-deploy a real-life lignocellulosic biorefinery for lower operating and capital costs, featuring benefits as solvent demands are reduced, and a better scope to integrate with first generation biorefineries. The redeployment focused on hot spots with high materials and energy use that affect cost-effective production of pulp, lignin, and bio-based products. The collaborative work investigates alternative designs for process, feedstocks and products portfolio and combines process-to-process integration to ensure optimal valorization of materials and energy. The reference real-life biorefinery case is modeled in ASPEN and involves high volumes of solvents for delignification, so re-deployment addressed a delignification-free case with parallel integration of downstream ethanol fermentation resulting in 22.5% lignin and 26% ethanol yields. The revised mass and energy balances of alternative scenarios were estimated and new insights for CAPEX (€ 39.6M), OPEX (€ 212M/yr) and energy costs (74% lower hot utilities) are obtained.

**Keywords:** biorefinery, delignification, bioethanol, techno-economic, energy integration.

## 1. Introduction

To date, there are 93 European lignocellulosic biorefineries (BBIC, 2022). Given the extended experience in 2G biorefining and the current social, political, and economic environments, the design contexts need to be revisited to face critical challenges related to cost and production efficiencies and serve replicable solutions for broader commercialization of the biorefining concept. State of the Art 2G biorefineries undertake the fractionation of lignocellulosic biomass into its main ingredients: C5, C6 sugars and lignin. All fractions can be integrated in bioeconomy markets and downstream chemistries for fuels, power, chemicals, and food additives production (Pyrgakis et al., 2016; Kokossis et al., 2015). This work is focusing on a real-life 2G biorefinery (CIMV, 2022), whose operation is based on processing wheat straw and poplar residues with organic acids (organosolv technology) returning C5, C6 sugars fraction and a functional biolignin based on the CIMV technologies (Delmas et al., 2011; Delmas et al., 2013; Nadja et al., 2014). Still, alternative organosolv technologies have been also recently appeared using biobased solvents and new fractions recovery concepts (Pateromichelakis et al., 2022).

Biolignin™ is a phenolic polymer with linear structure and low molecular weight. Moreover, the cellulosic polysaccharide is composed of a linear chain of  $\beta$ -1,4 linked d-glucose units, while the pentose sugar syrup consists of xylose monomers and oligomers (Mesa et al., 2016). The CIMV process takes advantage of the organosolv fractionation

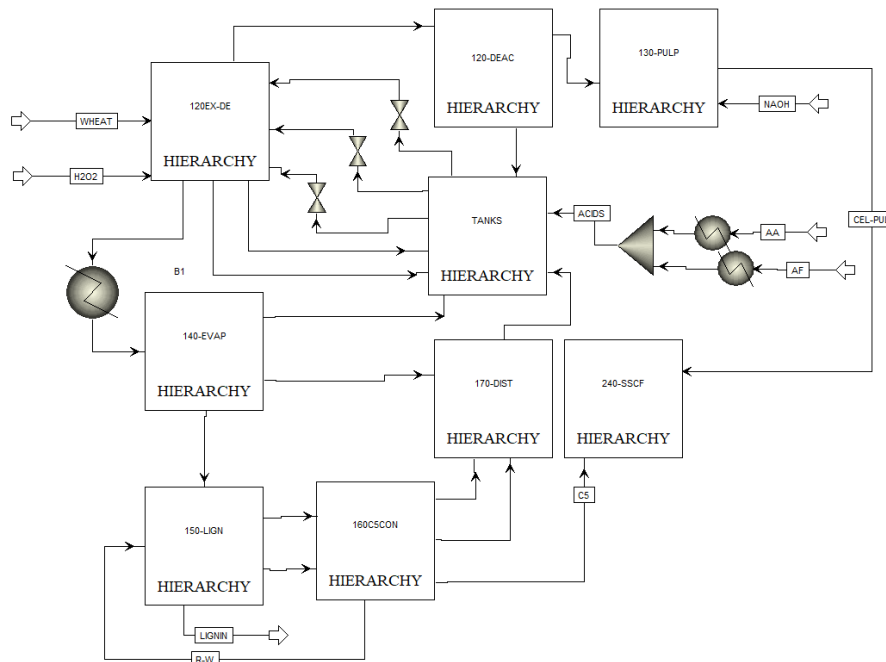

Figure 1 CIMV biorefinery flow diagram

concept utilizing a mix of organic acids as solvents of the three lignocellulosic components. The technology is applicable to both forestry and woody feedstocks and the overall biorefinery flow diagram is presented in Figure 1.

The biorefinery of CIMV consists of the main Biomass fractionation section (120EX-DE, in Figure 1), where C6 sugars and C5-soluble lignin are recovered from the raw lignocellulosic biomass. The C6 sugars are next delignified with a H<sub>2</sub>O<sub>2</sub>-organic acids mixture (Khama et al., 2005). After deacidification of the cellulosic fraction (120-DEAC), that is finally pulped (130-PULP) resulting the C6 sugars of the reference biorefinery. The C5-lignin mixture (from 120EX-DE) is dried through a thin film evaporation system (140-EVAP), while the lignin content is precipitated with water (150-LIGN), driving the residual C5 sugars towards the concentration section (160C5CON) where C5 sugars are collected. Any residual organic acids are recovered by distillation (170-DIST) and stored in the biorefinery acids tanks (TANKS) to be recycled across biorefinery.

Across the reference biorefinery, there are 3 main challenges identified that affect cost-effective valorization of biomass:

- i. the high auxiliaries' costs for delignification (water and H<sub>2</sub>O<sub>2</sub> solvents)
- ii. the co-production of added-value chemicals to face technoeconomic bottlenecks
- iii. the use of alternative feedstocks to face pricing seasonality and build flexibility

## 2. Problem description

As shown in Figure 2, the delignification process uses a 1:1 H<sub>2</sub>O<sub>2</sub>-water mixture to extract 2.6% of lignin trapped within pulp fraction returning 550 kg/hr of soluble Lignin from 21.000 kg/hr of the pulp feedstock. The high water and H<sub>2</sub>O<sub>2</sub> demands ( $\approx 4.500$  kg.hr) in combination with the high energy needs for downstream recovery of auxiliary organic acids and water crucially affect the sustainability of this section and profitability

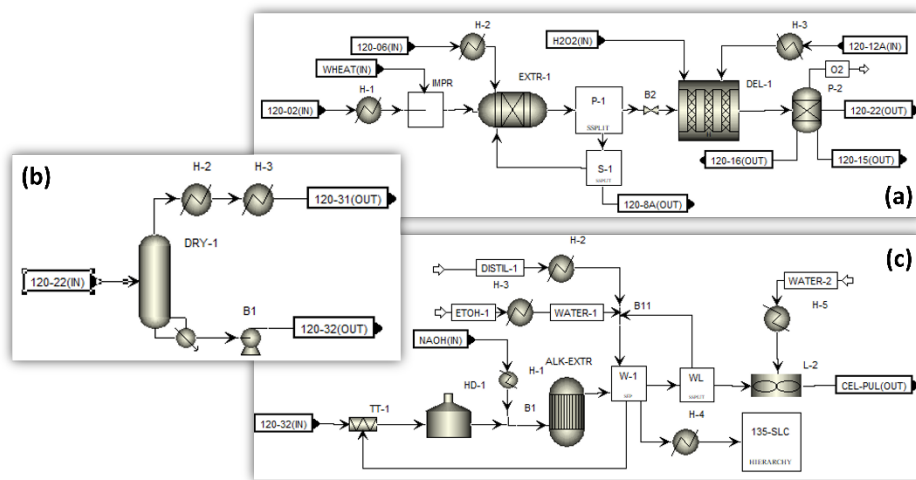

Figure 2 The delignification (a), deacidification (b) and alkaline extraction (c) sections of the whole biorefinery, raising concerns of re-engineering, or even removing, this section. Such decision will incur significant effects on the quality of delivered C6 sugars as end-product and might require its valorisation through alternative, still mature, technologies to other products. Modelling of the design alternatives will reveal vital answers on the trade-offs and redevelopment of the biorefining concept towards the exploitation of the C6 biomass fraction. Under these conditions, the replacement of the delignification section with direct hydrolysis and co-fermentation of C5 and C6 sugars for bioethanol production was addressed; otherwise, pulp could attribute commercial value as lower-grade C6 sugars.

The case of co-producing biofuels is a radical swift on the reference biorefining concept in technological and commercial contexts by changing the products portfolio. Bioethanol production can be provided by regular glucose (C6) fermentation, while simultaneous valorization of the xylan and glucan substrates are also considered to boost ethanol production (Hassan et al., 2019; CIMV, 2022; Pyrgakis and Kokossis, 2019).

The implementation of alternative biomass feedstocks featuring alternative C5-C6 sugars fractions are capable of significantly affecting bioethanol and functional lignin productivities. Changes in feedstocks will infer a series of changes in mass and energy balances of the high complexity biorefinery raising questions about sustainability margins on the different lignocellulosic feedstocks. Biorefining is naturally affected by seasonality of the different woody and forestry feedstocks – with subsequent effects on integration potential and energy savings – thus, flexibility in operation is indispensable to face pricing volatilities and seasonality. As a result, besides wheat straw, corn stover is also examined to investigate new production potentials and sustainability margins. All above challenges map a set of alternative design options for re-designing the reference biorefinery and address trade-offs in terms of capital, operating and integrated energy costs.

### 3. Methodology

Dealing with above challenges, this work employs process systems engineering know-how and tools to identify better solutions than the reference biorefinery scenario. The whole and interconnected sections of the reference biorefinery has been modeled in Aspen in contexts of a previous work (Mountraki et al., 2016). This work elaborates the existing process flowsheet by re-engineering the existing sections of Figure 2 providing a

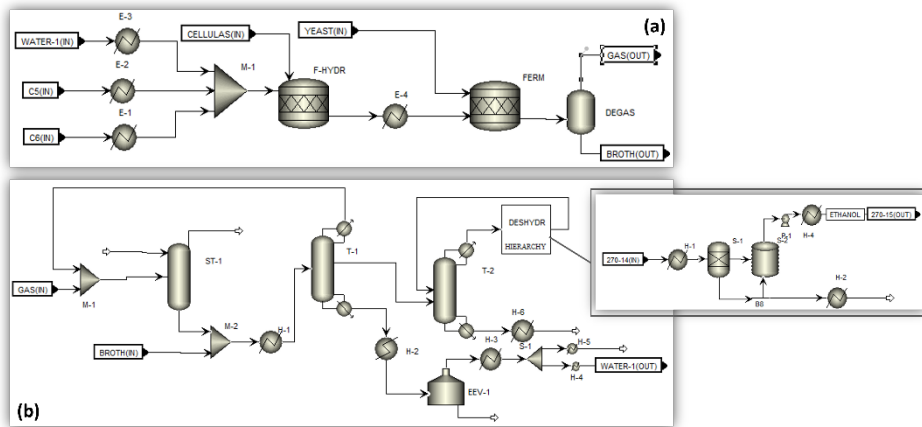

Figure 3 Ethanol production chemistry: Fermentation (a), products recovery (b)

set of alternative biorefining scenarios for analysis.

The case of removing the challenging delignification section, at cost of low-grade C6 sugars production has been examined. Such decision inherently affected mass and energy balances; let alone given the high complexity of the interconnected sections. The reference biorefinery has been appropriately amended and converged to the new balances. As an alternative, bioethanol production has been integrated along with hydrolysis, fermentation and downstream separations systems targeting to the production of high purity ethanol. The biorefinery section simultaneously valorizes the C5 (xylose) and C6 (pulp) fractions and the appropriate chemistry has been integrated (Figure 3). The analysis focused on all alternative combinations of using the delignification and ethanol chemistries resulting in 4 main scenarios with/without delignification, and with/without ethanol production. In addition, the 4 alternative biorefinery designs have been also tested in presence of two alternative feedstocks (corn stover and the reference-wheat straw) to adapt flows, unit operations and productivities to each carbon source. In this scope, 8 alternative biorefinery scenarios, and the corresponding simulations, have been developed and performed establishing a valuable portfolio of test cases for analysis.

The analysis involves energy integration and techno-economics to estimate the new sustainability margins of alternative scenarios. The energy analysis of multiple-process and multiple-product biorefineries is essentially challenged by the complex and variable integration routes (Pyrgakis and Kokossis, 2019). Furthermore, the investigation of alternative chemistries (e.g., bioethanol production) rises questions on the new integration patterns that need to be systematically addressed for all potential biorefinery scenarios. The guidelines of Pyrgakis and Kokossis (2019) have been followed to handle the energy integration alternatives, while the Aspen Process Economic Analyzer was used to estimate the new capital and operating expenses for each case.

#### 4. Results

The process systems engineering analysis of the lignocellulosic biorefinery results a set of 8 alternatives scenarios to compare with the reference biorefinery in terms of capital and operating expenses. To this end, the design options account for (i) the use, or not, of the pulp delignification with sequent costs in the quality and quantity of end-pulp product;

Table 1: Production yields of the 8 scenarios

Scenario	Delignif. section	Ethanol production	Feedstock	Mass flows [tn/hr]			
				C5	C6	lignin	ethanol
Reference	YES	NO	Wheat straw	5.82	15.79	8.96	
2	YES	YES	Wheat straw	0.57	1.48	8.96	9.44
3	NO	NO	Wheat straw	5.67	14.57	8.43	
4	NO	YES	Wheat straw	0.58	1.55	8.43	9.74
5	YES	NO	Corn stover	6.00	8.63	4.13	
6	YES	YES	Corn stover	0.56	0.75	4.13	11.63
7	NO	NO	Corn stover	5.31	7.88	3.75	
8	NO	YES	Corn stover	0.56	0.94	3.75	12.00

Table 2: Energy and economic results of the addressed scenarios

Design strategy	Hot [MW]	Cold [MW]	CAPEX [k€]	OPEX [k€/yr]
Del. (YES) - Eth. (NO)	133 (62%)	148 (54%)	31.8	215.6
Del. (YES) - Eth. (YES)	256 (60%)	64 (55%)	42.4	221.0
Del. (NO) - Eth. (NO)	126 (58%)	141 (50%)	28.9	207.0
Del. (NO) - Eth. (YES)	148 (74%)	57 (53%)	39.6	212.4

(ii) the integration, or not, of bioethanol production replacing profits from biomass C5 and C6 fractions with biofuels, at cost of additional equipment and (iii) the changes in biorefinery economic performance at use of different feedstocks. Accordingly, the production yields of end-products (Table 1) considered in each scenario have been calculated preparing the economic analysis for comparison. The 8 scenarios have been also addressed in terms of alternative energy integration patterns of the revised energy balances across biorefinery resulting in significant savings and cost reductions, as shown in Table 2; the value in parenthesis reflects the savings compared to the non-energy integrated biorefineries justifying advanced economics for all scenarios. In addition, Table 2 also summarizes the capital and operating expenses of each biorefinery scenario.

## 5. Conclusions

As indicated by the presented data, there has been a significant hot utilities reduction (up to 74%), after the successful bypassing of the delignification section and its consequent blocks. In addition, by the design of the downstream ethanol production unit, the insignificant amount of delignified lignin (0.53 tn/hr) and the sugars fractions are replaced by produced ethanol (9.74 tn/hr). With CIMV's starting point referring to a case scenario containing Delignification which was afterward deleted, the "energy needs" reduction was an expected change. Though the ethanol production integration has an apparent increase in CAPEX by 33%, there is a slight effect (3%) on the operating expenses (including the energy integrated costs) favoring payback of the new investment. In this context, the delignification section was observed to have a strong effect of operating costs by € 8.7M/yr, while the also reduces the efficiency of the ethanol production (ethanol production drops by 300kg/hr). As a conclusion, the most promising results are observed in the scenario of replacing the delignification section with ethanol production resulting

in 22.5% lignin and 26% ethanol yields, which are the highest among all cases; CAPEX and OPEX indexes are accordingly estimated to € 39.6M and € 212M/yr. Feedstock seasonality is capable of affecting the biorefinery operations and production capacities by 2-55%, while corn stover appears better productivities and, thus, process economics than wheat straw.

## Abstract

In the near future, tools brought on by digitalization will play a more significant role in technology development and operation for debottlenecking challenges in the biochemical industry. In that regard, a novel vibrating membrane filtration system at pilot scale is currently under investigation to fractionate bio-succinic acid fermentation broth. Remarkably sustained flux has been obtained that is 3.6 times higher than the best results found in literature. Experimental data was used to develop a digital object that combine a robust communication system and hybrid model to predict hydrodynamics and fouling rate. The digital object is used to forecast membrane performance 25 min ahead, predicting the flux with high accuracy (4% error) and the onset of the irreversible fouling formation during step-up experiments. These tools will become the core of a digital twin for the adaptive operation of the ultrafiltration system under uncertainty.

**Keywords:** Digital-twin, Vibrating membrane ultrafiltration, Fractionation fermentation

## 1. Introduction

Extensive research in debottlenecking bioprocesses gains traction as manufacturers commit to more sustainable development practices (Ruales-Salcedo et al. 2022). Digitalization initiatives including advances in process monitoring, data storage, computing power, modelling approaches, and simulation tools join to improve bioprocess development. The concept of integrating digital and physical objects is not revolutionary and has existed for many years in areas such as aeronautics. However, in chemical- and biochemical processes lack of advanced process analytical tools to measure critical compounds and computationally expensive models hindered harnessing digitalization in these fields. Digital shadow and twin have been defined as a system of an interconnected physical process and in-silico/digital replica which have continuous information exchange. In a digital shadow, the virtual plant representation can assess process performance (past and present) to evaluate future scenarios, while the digital twin is capable to determine and implement open or closed loop actions given by an optimal objective function (Gargalo et al. 2021). The heart of a digital-twin is data-driven and hybrid modelling that has a great potential to exploit a priori system understanding

complemented by nonparametric models. This approach is particularly relevant in emerging technologies where there is a lack of understanding of the underlying phenomena, thus, a data-driven or hybrid approaches could provide a more accurate system description (Azevedo et al. 2019).

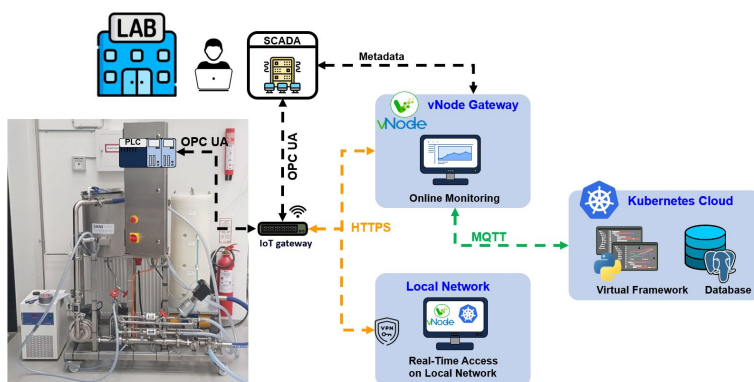

This research is focused on optimizing downstream process for the fractionation of succinic acid fermentation broth. Succinic acid bioproduction is interesting since it is one of the most important building blocks in the biorefinery concept (Ruales-Salcedo et al. 2022). Despite that succinic acid bioproduction is already operated at a commercial scale, there is still has room for improvements to reach an even larger scale. In this context a novel vibrating membrane ultrafiltration system at pilot scale is currently under investigation as the first stage of a possible downstream processing. This step aims to separate cells, cell debris and proteins from the main dissolved organic acids (i.e., succinic, formic, lactic, and acetic). This separation is particularly challenging and conventional technologies like centrifugation reports around 90% recovery of cells and only 50% of proteins (Wang et al. 2013). Membrane ultrafiltration has been proposed as an alternative to obtain better separation performance with the possibility of integrating a membrane bioreactor. Despite the promising components recovery (i.e., 100% cells and 83% proteins), there is up to 75% throughput loss due to membrane fouling. A novel vibrating membrane technology is a possible alternative to conventional membrane ultrafiltration where fouling is mitigated by inducing a relatively high shear rate at the membrane surface (Prochaska et al. 2018). In that way, operation at higher throughput is attempted while reducing energy consumption. However, determining and understanding the maximum membrane throughput (so called critical flux), requires extensive experiments due to time-variant fouling nature plus potential inlet disturbances. Therefore, the design and optimal operation of the system will benefit by developing a digital twin aimed to predict the hydrodynamics and irreversible fouling onset. This research aims to present the challenges on building a digital twin for the vibrating membrane system including communication architecture, experimental campaign, digital object development and evaluation. The main outcome of this research is to build a tool which can estimate the performance of the novel membrane system operation and employ the model to optimize the energy demanding operation improving the sustainability of the process.

## 2. Methodology

### 2.1. Digitalization infrastructure

Last year, the Department of Chemical- and Biochemical Engineering at the Technical University of Denmark (DTU) heavily retrofitted the existing digital infrastructure aiming to centralize data collection, process monitoring and model validation activities across the portfolio of pilot scale laboratory equipment (Jones et al. 2022). A representation of the communication infrastructure is depicted in Figure 1. Process data and logged at-line tags from each unit are now forwarded to an IoT gateway software, vNode that facilitates online bidirectional communication to the process equipment through a secure connection to the DTU network. A Kubernetes cluster has been implemented in parallel to store historical data and contain PSE and modelling tools. Kubernetes is a container management architecture that manages a collection of independent internally connected server entities. One of the entities are designated as the “master” node, while the

remaining entities are categorized as “worker” nodes (Gupta et al. 2021). The master-node orchestrates the available hardware across the collection of entities and designates resources depending on the demand of active applications. Local virtualization makes it possible to simulate several server entities and orchestrations on a local machine to test application deployment dataflow and database schemas before large scale implementation. vNode ensures that the OPC-UA signal received from the units are routed to the Kubernetes cluster during regular operation. Additionally, a relational SQL database standardized data collection for the process units and contextualizes data across different experimental runs. The cluster also acts as a deployment domain for containerized model application that can be used for prediction, control, and monitoring in real-time. Easy access to the process real-time data and historian improves the capabilities of utilizing data-driven methods and real-time optimization for these systems. The vibrating membrane module is being integrated with this new infrastructure.

**Figure 1.** Schematic of the connectivity to the digital infrastructure at DTU Chemical and Biochemical Engineering. The OPC-UA signal from the PLC cabinet is sent to the IoT gateway software to be joint with metadata from offline measurements thus send to Kubernetes cluster where the tag values are stored and online accessible for monitoring or modelling tasks.

## 2.2. Experimental campaign

The equipment is a 7.5 m<sup>2</sup> Vibro Pilot membrane separation unit from SANI Membranes. For the separation, a polyethersulfone membrane (PES) is employed with a Molecular Weight Cut-Off of 30 KDa, which is enough to retain cells and most of the expected protein. Due to the experiment’s scale, a considerable amount of fermentation broth is required. To circumvent this limitation, a simulated fermentation broth is used for tuning purposes. The simulated fermentation broth composition is extracted from literature for continuous operation including biomass (8 g/l yeast cells), proteins (0.25 g/L BSA) and organic acids (25 g/l succinic, 0.5 g/l acetic, 0.5 g/l formic acids). The experimental strategy to find the operating point is the well-known step-up method at constant transmembrane pressure. The feed channel pressure is increased stepwise, while the system pressures, flowrates and temperatures are monitored every 15 s. Because of the fouling, the membrane flux is expected to decline with time. According to the resistance in series model, the flux decline with time corresponds to the fouling rate which determine when the membrane should be cleaned. The influence of the crossflow velocity and fermentation broth composition are currently under investigation.

### 2.3. Developing the digital object

A multipurpose digital twin for design and control, consists of multiple digital objects that can combine different modelling approaches (i.e., first principles, data-driven and hybrid)(Grisales Díaz and Prado-Rubio 2022; Prado-Rubio, Grisales Diaz, and Kjøbsted Huusom 2022). Herein, a hybrid model is proposed with the potential to incorporate forthcoming process understanding provided by a more dedicated first principles models (e.g., CFD) and experiments. As initial step, the digital object approach uses a parallel implementation of a hydrodynamic and fouling rate models. The system hydrodynamics is modelled using the unsteady laminar flow model near an oscillating plate. This model is used to predict velocity profiles and shear rate in the zone adjacent to the membrane surface. This information is relevant to compare model prediction with literature. A MIMO ARX model with forgetting factor is then tuned using the online recursive least squared method, where the model structure and forgetting factors are defined by a sensitivity analysis using MAPE, FIT and NRMSE as performance indexes. This model is calibrated to predict the membrane flux and transmembrane pressure based on the pressure and recovery setpoints plus the crossflow rate. Thus, the model is used to forecast 25 min in the future the flux decline and its trend which represent the dynamic fouling rate.

## 3. Results

To date, five campaigns have been conducted including 10-15 experiments each. The results of the experimental campaigns showed remarkable performance where the vibrating membrane module achieved a maximum sustainable operation of around 53 LMH at TMP of 2 bars, and up to 100%, 89.4% and ~25% rejection of yeast, BSA and organic acids, respectively. Previous research has shown that ultrafiltration membrane with analogous properties and operating conditions achieved 14.74 LMH at laboratory scale (Wang et al. 2013), which represent a 3.6 fold improvement at a more larger scale with the potential to be further optimized. The best result from the campaigns is herein used for the modelling tuning and forecasting analysis. The hydrodynamic modelling results for the conventional operation show that the velocity profile decreases, as expected, linearly towards the membrane surface where the shear rate is zero.

**Figure 2.** Velocity profiles for the conventional crossflow ultrafiltration and vibrating membrane operation at 20 Hz and an oscillation amplitude of 2.5 mm.

Figure 2 shows the velocity profiles at the boundary layer. The oscillating membrane at 20 Hz and with 2.5 mm amplitude generates a relative velocity at the membrane surface up to 0.31 m/s, which is 1.5 to 3 times higher than the crossflow. This corresponds to an average surface shear rate of 2239.5 1/s to mitigate fouling. Previous research with vibrating microfiltration of yeast and BSA at 20 Hz and 1.375 mm amplitude, generated a shear rate of 1230 1/s (Prip Beier & Jonsson, 2009). Under those conditions, a sustained flux of 30 LMH was obtained. The current results show how almost doubling shear rate has substantially enhanced flux.

The increased shear rate appeared to be more efficient in removing the pore blocking and cake-controlled fouling expected from fermentation broths.

The adaptive online system identification model was able to capture the time variant flux nature with high accuracy (Model quality: NRMSE = 0.0092, MAPE = 0.57% and FIT = 97.7%). Experimental data and model predictions are shown in Figure 3, where 97% of data have relative error lower than 1%.

**Figure 3.** Online system identification predictive power during 14 experiments. Flux prediction and histogram of the relative model error

The model is also used in real time to forecast 100 samples into the future (25 min) and estimate the flux decline and fouling rate. A zoom-in is depicted in Figure 4. Note that there is a small deviation of ~4% in the flux forecast. Despite that the step-up disturbances during the experiment are mild (i.e., 0.2 bar at the time), there is a tremendous effect on the fouling rate which tends to stabilize after 10 min. This result is important since it defines that the experimental tuning should last at least 20 min to stabilize the fouling when vibration is on. Now, defining an affordable fouling rate of -0.05 LMH/min (corresponding to a 50% of max flux decline in 8 h operation), it can be predicted that experiments beyond 190 min (exp 10) the system consistently overcomes the threshold. Every step further leads to a higher fouling rate where the last represent 2.4 times the desired target. All these points then represent super-critical operation and should be avoided. This tool can then predict the onset of the irreversible fouling formation during experiments which will be tested in the near future when the full digitalization infrastructure is implemented.

**Figure 4.** Moving horizon flux and fouling rate forecasting 25 min ahead using the last estimated ARX model

## Conclusions

The department of Chemical and Biochemical Engineering at DTU is designing a robust pilot plant infrastructure capable of coping with the current and forthcoming challenges of biomanufacturing using a digitalization strategy. Herein, the development of a digital twin for a novel vibrating membrane is elaborated upon, discussing communication, experimental campaigns, and modelling approaches. This technology has shown remarkable performance during the fractionation of succinic acid fermentation broth by increasing the membrane flux 3.6 times compared to the best reported conventional ultrafiltration. Employing an online system identification, it is possible to predict the flux behaviour with high accuracy (MAPE = 0.57%). This was used to forecast the onset of irreversible fouling formation and detecting 4 super-critical experiments. The developed digital object plus the digitalization infrastructure will become the core of the implementation of digital twin for process optimization and adaptive system operation under uncertainty.

## Abstract

The increasing amounts of CO<sub>2</sub> in the atmosphere, which is caused by the burning of fossil fuels, contribute greatly to global warming. In a standard post-combustion carbon capture (PCC) process, the energy penalty attributes to regenerate the CO<sub>2</sub> lean solvents. Microalgae have been established as the most promising candidate to the CO<sub>2</sub> capture and utilization (CCU) technology due to a high growth rate, oil productivity, and photosynthetic efficiency. However, the gaseous form of CO<sub>2</sub> is utilized by microalgae only to a very limited degree due to its low water solubility and high outgassing rate. In addition, the flue gases from a coal-fired power plant, which contains 10% to 16% of CO<sub>2</sub>, cannot be supplied as the carbon source for the microalgae, directly. The bicarbonate-based microalgae cultivation may offer a promising alternative that relieves the burden of regeneration energy and improves the low carbon utilization efficiency of the gaseous form of CO<sub>2</sub> cultivation. In the present work, the rate-based model of Aspen Plus is adopted to simulate a flue gas in the flow rate of 1800 m<sup>3</sup>/h with 14% CO<sub>2</sub> that is absorbed by aqueous NaOH solution. The absorbent is recycled from the mother liquor where most of bicarbonate is precipitated, and the fresh makeup with 30 wt% NaOH is applied. The column height to achieve 90% of CO<sub>2</sub> removal rate is investigated by varying the recycle rate of absorbent and the solid fraction in the bicarbonate product. In addition, the carbon utilization efficiency (CUE) by gaseous CO<sub>2</sub> and bicarbonate solution for the microalgae cultivation is compared. The results show that the CUE of the bicarbonate-based cultivation is far superior to that of the counterpart.

**Keywords:** carbon capture and utilization, chemical absorption, rate-based model, bicarbonate-based microalgae cultivation.

## 1. Introduction

In 2015, the United Nations General Assembly (UNGA) set out 17 sustainable development goals (SDGs) to be achieved by 2030. Microalgae have an increasing interest in various sectors in the SDGs, such as SDG-6 “clean water and sanitation”, SDG-7 “affordable and clean energy”, and SDG-13 “climate action”. The microalgae can be cultivated in wastewater or seawater that provides a way for water reclamation (Wang et al., 2015). Moreover, microalgae could complete the entire growth cycle via photosynthesis reactions that convert light energy into renewable energy. The CO<sub>2</sub> emitted from the power generation and heavy industries is the largest contributor to the global warming problem. Vuppaladadiyam et al. (2018) reviewed the technical feasibility

of combined carbon fixation and microalgae cultivation for carbon reuse. They concluded that the rate of carbon fixation by microalgae tends to be too slow to capture CO<sub>2</sub> from flue gases. Unless the rate of CO<sub>2</sub> uptake can be drastically improved, culturing algae may not be suited for the post-combustion carbon capture (PCC) from the power generation and heavy industries.

Amine scrubbing has been used to separate acid gas, such as H<sub>2</sub>S, SO<sub>2</sub>, and CO<sub>2</sub>, from the flue or tail gases since 1930 (Bottoms, 1930). It is a robust technology and is ready to be tested and used on a larger scale for CO<sub>2</sub> capture from coal-fired power plants. However, the high regeneration energy of the amine-based solvents is the most critical challenge for extensively applying the PCC technology to thermal power plants. It is well known that the improvements of process configuration and solvent development may reduce the regeneration energy that is around 4.0 GJ/t-CO<sub>2</sub> for a standard PCC process configuration using 30 wt% monoethanolamine (MEA) aqueous solution (Rochelle, 2009). Solvent development has historically focused on reducing the enthalpy of absorption, increasing the absorption capacity, and enhancing the reaction kinetics by blending and synthesizing new amines. Recently, Benquet et al. (2021) reported that the second generation of amine-based solvent, named CO<sub>2</sub> Enhanced Separation and Recovery (CESAR1), was tested at large scale with a real flue gas at the pilot plants in Technology Centre Mongstad (TCM). The CESAR1 solvent, which is a blend of 27 wt% amino-methyl-propanol (AMP) and 13 wt% piperazine (PZ), that poses the lower regeneration energy (3.0 GJ/t-CO<sub>2</sub>), higher stability, and lower corrosivity compared to those of traditional 30 wt% MEA solvent. The energy reduction of 25% can be achieved by blending amine-based solvents in the standard PCC process configuration. On the other hand, Le Moulec et al. (2014) reviewed available literature as well as the patent database and summarized 20 elementary modifications to save regeneration energy for the PCC. These methods can be categorized into three groups: absorption enhancement, heat integration, and heat pump. According to the survey by Le Moulec et al. (2014), up to 39.0% of energy savings could be achieved by modifying the PCC process configuration.

Recently, Zhu et al. (2022) suggested the integration of the bicarbonate-based microalgae cultivation with the carbon capture that significantly reduces the production costs of cultivation and the regeneration energy in the PCC. The authors estimated that the cost of bubble CO<sub>2</sub> gas for microalgae production ranges from \$1.47 to \$7.33 kg<sup>-1</sup> and the carbon utilization efficiency (CUE) is in the range of 1.0% to 5.0%. In contrast, the carbon cost of bicarbonate-based *Spirulina* production is around \$0.359 kg<sup>-1</sup> due to the high CUE around 90%, particularly. Kim et al. (2017) reported that only 3.59% of the gaseous CO<sub>2</sub> was used for biomass synthesis, bicarbonate was effectively incorporated into the biomass with 91.40% of CUE. The CUE of bicarbonate-based cultivation is significantly superior to that of the gaseous CO<sub>2</sub> because CO<sub>2</sub> supplied in a gaseous form easily escapes from the culture medium, rather than being captured and utilized by the cell.

Wang et al. (2022) developed a PCC process by chemical absorption using aqueous sodium glycinate solutions (SGS) to produce high-value NaHCO<sub>3</sub> nanomaterials. CO<sub>2</sub> was captured from a split flue gas stream emitted from the 600 MWe coal-fired power plant in the Wolverine Clean Energy Venture project. The operating expenditure (OPEX) and capital expenditure (CAPEX) were calculated as \$27.53 and \$7.96 per metric ton of CO<sub>2</sub>, respectively. In this study, aqueous NaOH solvents are applied to capture CO<sub>2</sub> to form the precipitation of NaHCO<sub>3</sub>, which can be diluted for bicarbonate-based microalgae cultivation. Subsequently, the PCC process design is briefed in Section 2. Section 3 compares the experimental results of cultivating a variant strain of *Chlorella vulgaris* by gaseous CO<sub>2</sub> and bicarbonate, respectively. Conclusions are presented in Section 4.

## 2. Process Design for Bicarbonate Precipitation

The rate-based model of Aspen Plus is applied to design an absorber to achieve 90% of CO<sub>2</sub> removal rate from flue gases by sodium hydroxide solutions. The Redlich-Kwong equation of state and the electrolyte-NRTL method were used to compute the properties of the vapor and liquid phases, respectively. In addition, all the ionic reactions and solid dissociation can be assumed in equilibrium reactions, as listed in (R1) – (R5), where the equilibrium constants are calculated from the Gibbs free energy changes. In the rate-based model, the mass transfer rate of CO<sub>2</sub> diffused into the liquid phase needs to be considered; therefore, the rate-controlled reactions of CO<sub>2</sub> with OH<sup>-</sup> are concerned as following (R6) and (R7). The kinetic reaction rate is described by the reduced power law:

$$r = k \exp(-E/RT) \prod_{j=1}^N (C_j)^{a_j}$$

where the concentration basis is Molarity,  $N$  is the number

of components and  $a_j$  is the stoichiometric coefficient of component  $j$ ; the rate constants of  $k$  and  $E$  are listed in Table 1 (Aspen Technology, 2014). The parameter settings for the rate-based model, such as Film resistance and Flow model options can be found in the technical document (Aspen Technology, 2014).

$r$ (kmol·m <sup>-3</sup> ·s <sup>-1</sup> )	$k$	$E$ (J·kmol <sup>-1</sup> )
(R6)	$4.32 \times 10^{13}$	55.4
(R7)	$2.83 \times 10^{17}$	123.2

The flow rate of the flue gas from a coal-fired boiler was 1800 m<sup>3</sup>/h, containing 14% CO<sub>2</sub> and the saturated water vapor at 40 °C. Assuming that SO<sub>x</sub> in the flue gas was removed before entering the CO<sub>2</sub> absorber, the reaction of forming sodium sulfite can be neglected. In this study, the fresh makeup of sodium hydroxide solution was set to 1500 kg/h, which contains 30 wt% NaOH and the balanced water. The column diameter was determined by calculating 80% of the maximum flood capacity, so that the diameter of 0.85 m was applied. The column height was adjusted to fulfill the CO<sub>2</sub> removal rate at 90%. Figure 1(a) shows the process flow diagram for the PCC process where the flue gas and lean solvent enter the absorber from the bottom and top, respectively. The outlet temperatures of the absorber are higher than those of inlets, because the CO<sub>2</sub> absorption is an exothermic reaction. The temperature of the settling tank was maintained at 20 °C for the NaHCO<sub>3</sub> precipitates, in which the recycled flow rate and the weight fraction of NaHCO<sub>3</sub> drawn in the outlet flow are two adjustable variables. Figure 1(b) shows the packed height that needs to maintain the CO<sub>2</sub> removal rate at 90% under varying the recycle-to-outlet ratio (Recycle/Outlet) and the solid fraction (SF) of precipitates in the outlet flow. The results show that the packed height needed is under 2 m once the SF is larger than 0.7, whereas the operating condition of the Recycle/Outlet ranges from 0.5 to 3.0 that is a robust design for operations. In contrast, the feasible operating range of Recycle/Outlet limits from 0.8 to 2, once the SF is operated at 0.5, as shown in Figure 1(b), where the packed height is between 2 to 2.5 m. Figure 1(a) show the simulation results of the ratio of Recycle/Output at 1.8 and the SF operated at 0.7. The outlet flow contains 28 wt% of NaHCO<sub>3</sub>, whereas 6.6 wt% of bicarbonate in the recycle flow can be dissolved after

mixing with the makeup flow, by which the lean temperature after mixing was risen due to the exothermic reactions of mixing the recycle flow and the fresh makeup.

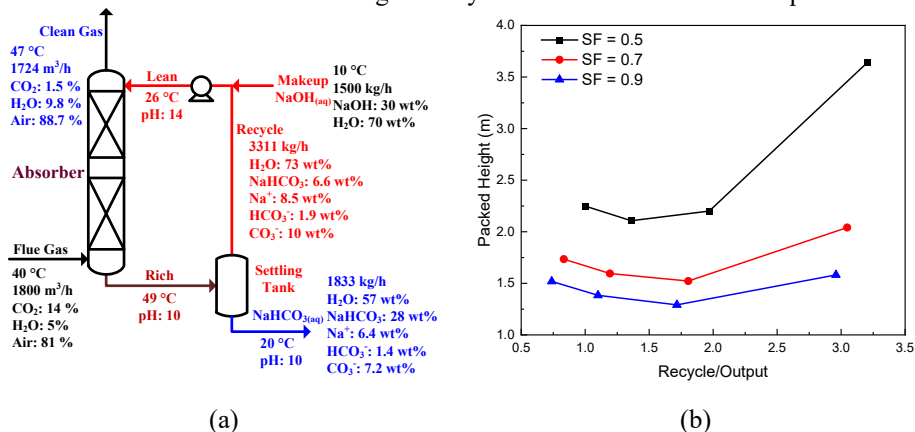

Figure 1. The simulation results of the makeup flowrate being 0.7 times flue gas, (a) process flow diagram and (b) the packed heights under varying the designed parameters. In this study, the makeup-to-feed flow ratio was set as 0.7 (kg/kg) for the proof of concept, which microalgae could be cultivated by captured CO<sub>2</sub> through chemical absorption. The CAPEX, OPEX, and levelized cost of carbon (LCOC) will be investigated under varying the makeup-to-feed ratio, whereas the robust operations are also taken into consideration for designing the PCC process in the future work.

### 3. Carbon fixation by Bicarbonate-Based Microalgae Cultivation

The microalga used in this study (*Chlorella vulgaris* SU-1) is a variant strain of *Chlorella vulgaris*, which is similar to that of the study by Wang et al. (2015). BG-11 medium was used as preculture medium with continuously supplied carbon dioxide (2%) at a flow rate of 0.2 L/min for the baseline cases. On the other hand, 5 g/L NaHCO<sub>3</sub> were supplemented as the carbon source at the beginning of cultivation and the 4<sup>th</sup>, 8<sup>th</sup>, and 12<sup>th</sup> day after sampling. The microalga was cultivated in a 1-L glass photobioreactor illuminated by external light sources (white fluorescent lamps) mounted on both sides of the photobioreactor at a light intensity of 200 W/m<sup>2</sup>, and the room temperature was controlled at 25 ± 2 °C. A volume of 10 mL microalgae suspension was collected every day from each photobioreactor for nutrient analysis. Meanwhile, the pH value for each photobioreactor was adjusted to 7, 8, and 9, respectively, by adding hydrochloric acid on a daily basis for the bicarbonate-based cultivation. On the other hand, the pH value for cultivating microalgae by gaseous CO<sub>2</sub> was not controlled. The daily samples were centrifuged at 7000 rpm for 2 min. Dry cell concentrations were obtained based on the optical density (OD) values measured at 685 nm with a spectrophotometer (model U-2001, Hitachi, Tokyo, Japan). Figure 2(a) show the calibration curve of OD<sub>685</sub>, in which the R<sup>2</sup> is 0.98, that was used to calculate the biomass concentration by the measured OD values. Figure 2(b) show the measured pH values during the experimental period where the pH values in the culture medium by the gaseous CO<sub>2</sub> were not controlled and the averaged pH value is around 8.5. The pH values of the other counterparts were measured and controlled to the corresponding values on the daily basis.

The growth curves are shown in Figure 3(a) where the biomass concentration ( $X$ , g/L) was calculated by the measured OD<sub>685</sub> values and the calibration curve in Figure 2(a). Figure 3(a) shows that the growth curves of the bicarbonate-based cultivation were

inferior to the gaseous CO<sub>2</sub> cases; the final biomass concentration under the gaseous CO<sub>2</sub> condition was over four times as high as those by the bicarbonate-based cultivation. In addition, the figure shows that the pH values maintained at 8 may favor the bicarbonate-based cultivation for this algae strain by contrasting to pH values controlled at 7 and 9. The biofixation of CO<sub>2</sub> can be calculated through the biomass concentration (Adamczyk et al., 2016):  $CO_2 \text{ fixation} = C \times X \times (M_{CO_2} / M_C)$  where  $C$ ,  $M_{CO_2}$  and  $M_C$  are the carbon content in the biomass and the molecular weights of CO<sub>2</sub> and C, respectively. In this study, the carbon content of 47.1 wt% was applied for the strain of *Chlorella vulgaris* (Silva et al., 2016). Figure 3(b) shows the carbon utilization efficiency for each photobioreactor, in which the efficiency for the gaseous CO<sub>2</sub> cases is not over 6%, because the CO<sub>2</sub> gas was supplied at the steady flow of 0.2 L/min. Over 90% of CO<sub>2</sub> were slipped by directly exposing the gaseous form of carbon source that is impractical on the PCC perspective. On the other hand, the average CUE of the bicarbonate-based cultivation was around 40%, as shown in Figure 3(b); in some cases of the pH controlled at 8, the efficiency could be over 60%. In this study, the CUE of the bicarbonate-based cultivation is not as promising as the work of Kim et al. (2017) reported, which is over 90%, because the final biomass concentration was too low for the cases by bicarbonate cultivation. Kim et al. (2017) reported that the final biomass yields by gaseous CO<sub>2</sub> and bicarbonate were comparable.

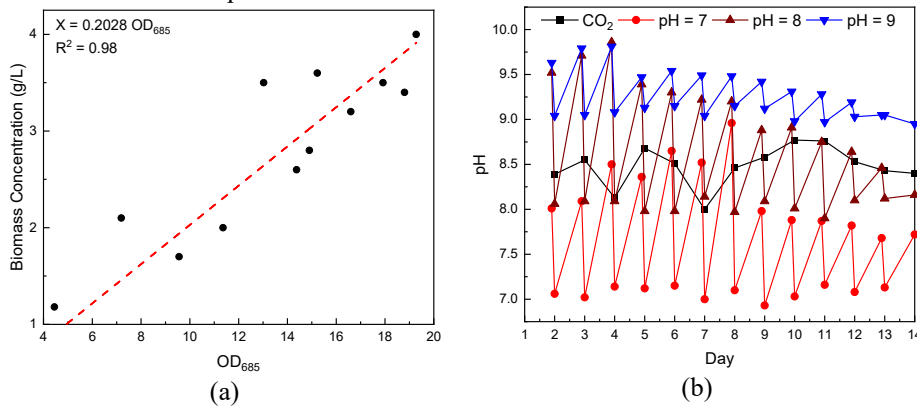

Figure 2. Cultivation of *Chlorella vulgaris* SU-1 with pH controlled, (a) calibration curve of OD<sub>685</sub> to biomass concentration, (b) measured pH values.

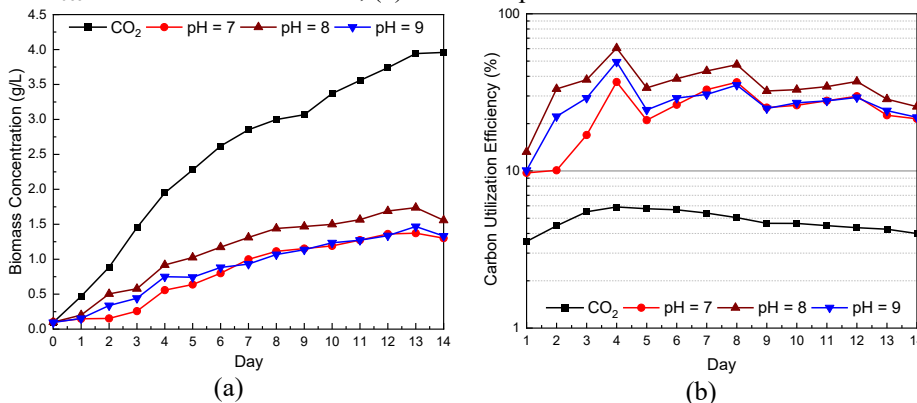

Figure 3. Growth curves of *Chlorella vulgaris* under different carbon sources, (a) biomass concentration (g/L) and (b) carbon utilization efficiency (%).

In this preliminary study, the biomass yield by bicarbonate is inferior to that by the gaseous form of carbon source. The alkaline culture medium may suppress the *Chlorella vulgaris* strain growth, although the pH values of the bicarbonate-based photobioreactors were maintained on a daily basis. However, the CUE of the bicarbonate-based cultivation is still superior to the counterpart. In the future work, the amount and frequency of the supplemented  $\text{NaHCO}_3$  will be adjusted to enhance the productivity. More importantly, adopting a strain of microalgae that is resilient to the alkaline culture medium may improve the final biomass concentration, whereas increases the CUE.

#### 4. Conclusions

Microalgae cultivation to recycle material and energy represents a significant circular economic approach. However, the flue gases from a power plant cannot be directly supplied to cultivate microalgae due to the high concentration of  $\text{CO}_2$  in the flue gases. On the other hand, the energy penalty for regenerating absorbents, which is around 15%–20% reduction in overall electricity, is a major obstacle to implement the PCC for a coal-fired power plant. This study demonstrated that the penalty-free PCC through bicarbonate-based microalgae cultivation is a feasible solution for the circular economy. However, the results show that the biomass yield of bicarbonate-based cultivation is inferior to that of using gaseous  $\text{CO}_2$  as the carbon source. The limitation will be investigated by cultivating the microalgae that can be found in hypersaline environments. In addition, the simulation results show that the robust design for the absorber can be achieved, for which the designed column height is insensitive to the recycle flow rate, by removing sodium bicarbonate from the settling tank as possible.

## Abstract

Modelling strategies in metabolic engineering cover a broad spectrum to simulate microbial cell behaviour and product formation. Understanding differences and limitations of various approaches is key for accurately simulating metabolic network activities and designing high-efficiency strains. One of the main challenges lies within the simulation of dynamic environments, where steady-state assumptions are invalid. However, modelling a dynamic operation is essential for developing batch processes, which are immensely common for fermentation and pharmaceutical industries. This study is to propose and compare different dynamic modelling approaches for metabolic network simulation. The overall aim is to identify the most cost-effective and robust approach to model a metabolic network under non-steady-state conditions.

**Keywords:** Dynamic metabolic flux analysis, kinetic modelling, metabolic network simulation, parameter estimation, dynamic modelling.

## 1. Introduction

Microbial fermentation modelling lies at the epicenter of biochemical engineering, as such systems can produce renewable biofuels, bioplastics, and many other high value bioproducts, and mammalian cell lines account for a large proportion of therapeutic recombinant proteins. The UK bioeconomy alone is worth around £220 billion (as of 2018), and is expected to double by 2030, making this a lucrative research field (Harrington, 2018). Such growth requires overcoming many challenges, including low yields in reactor scale-up, deficient metabolic and secretory phenotype for protein production, accumulation of by-products ( increasing separation costs and product loss), and finally significant variation between batches, leading to quality-control challenges.

Understanding the metabolic pathways is essential to conquering such challenges for two reasons: 1) to develop industrially desired microbial strains for large scale fermentation; and 2) modify mammalian cells to overexpress recombinant proteins and improve process performance. Several modelling techniques can be employed to infer the behaviour of the metabolic network. These include two main approaches: 1) flux-based methods, which can be applied to both large or small-scale networks to either steady-state or dynamic systems; and 2) mechanistic kinetic models, which try to establish a mechanistic understanding of the behaviour of each reaction pathway. However, there are challenges associated with the various modelling approaches. For example, flux-based

methodologies often utilize a fundamental steady-state assumption, as reviewed by Ahn et al. (2012), that is invalid for batch and fed-batch operation and cannot account for intracellular metabolite accumulation. Although existing dynamic MFA approaches can encapsulate the changing extracellular environment, most methodologies do not account for any intracellular accumulation, constant or dynamic (Antoniewicz, 2013). Regarding kinetic modelling, finding an appropriate model structure can be time-consuming and challenging – many structures also exhibit stiffness, causing trouble with parameter estimation. This study aims to propose a new dynamic metabolic flux analysis framework and then compare with other existing methods to determine the most reliable and robust (least susceptible to simulation deviations for a given input deviation) modelling approach, while considering minimal computational expense.

## 2. Methodology

### 2.1. Kinetic modelling

The first approach to be considered is the kinetic modelling, in which each reaction flux obeys the Michaelis-Menten model structure as shown in Eq. 1, as described in the study by (Goffaux et al., 2017):

$$v = v_{f,max} \prod_f \alpha_f \frac{R_f}{K_{R,f} + R_f} - v_{r,max} \prod_r \beta_r \frac{P_r}{K_{P,r} + P_r} \quad (1)$$

where  $\alpha_f$  and  $\beta_r$  represent stoichiometric coefficients associated with the forward and reverse reactions, respectively, which have their corresponding maximum rates,  $v_{f,max}$  and  $v_{r,max}$ , respectively. Equilibrium constants,  $K_{R,f}$  and  $K_{P,r}$ , are associated with every reactant,  $R_f$ , and product,  $P_r$ , respectively. Although this structure follows basic assumptions, it is utilized to avoid high computational expense to remain competitive with other modelling approaches. Using a mass balance across each metabolite, the reaction fluxes determine the rate of change of each metabolite – integrating this generates concentration profiles that can be compared to recorded data. A sum of least squares objective function can be used to minimise the difference between the actual and simulated concentrations,  $C_{j,meas_t}$  and  $C(t)_j$ , respectively, at the times measurements were taken, as shown in Eq. 2:

$$\min \sum_{t,meas} \sum_{j,meas} \left( \frac{C_{j,meas_t} - C_j(t)}{C_{j,meas_t}} \right)^2 \quad (2)$$

Parameters of the Michaelis-Menten model structure,  $v_{f,max}$ ,  $v_{r,max}$ ,  $K_{R,f}$ , and  $K_{P,r}$ , are constant with time, but vary for each reaction.

### 2.2. Dynamic metabolic flux analysis (DMFA)

For the first DMFA methodology, a traditional approach is undertaken in which it is assumed no changes in intracellular metabolite concentrations occur, unless proven otherwise by measurements. 2<sup>nd</sup> degree polynomial expressions can be used to fit measured intracellular and extracellular metabolite concentrations:  $C_j(t) = a \cdot t^2 + b \cdot t + c$ , where  $a$ ,  $b$ , and  $c$  are parameters to be fitted. No higher order polynomials were utilized to avoid overfitting. Such polynomials construct mass balances, as shown in Eq. 3; an equality constraint. For extracellular metabolites, a similar concept is used to minimise the difference between the simulated and predicted rates of concentration at each timestep  $t$ , shown as Eq. 4. In this case, the reaction fluxes are the problem variables.

$$\frac{dC_{j,int}(t)}{dt} = \sum_i \alpha_i v_i \quad (3)$$

$$\min \left( \frac{X(t) \cdot \mu_t - \frac{dX(t)}{dt}}{\frac{dX}{dt}} \right)^2 + \sum_{j, meas, ex} \left( \frac{10^3 \cdot X(t) \cdot \sum_i \alpha_{i,j} \cdot v_{i,t} - \frac{dC_{j,ex}(t)}{dt}}{\frac{dC_{j,ex}}{dt}} \right)^2 \quad (4)$$

For the second DMFA methodology, the cell is assumed to behave as efficiently as possible. This is done by minimising the magnitude of each reaction flux at each timestep  $t$ , shown by Eq. 5, where  $\omega_i$  is the weight associated with flux  $v_i$ . As with the previous MFA approach, the same polynomials are utilized to determine the intracellular concentration profiles. For extracellular metabolites, the mass balance forms equality constraints to avoid over-complication of the objective function, presented via Eq. 6.

$$\min \sum_i \omega_i v_{i,t}^2 \quad (5)$$

$$\frac{dC_{j,ex}(t)}{dt} = 10^3 \cdot X(t) \cdot \sum_i \alpha_{i,j} \cdot v_{i,t} \quad (6)$$

Finally, we proposed a novel approach to DMFA where accumulation is considered. The accumulation is captured by an accumulation variable  $A$ . This coincides with the mass balance of each intracellular metabolite,  $\frac{dC_{j,int,t}}{dt} = \sum_i \alpha_{i,j} v_{i,t} = A_{j,t}$ . The aim is to recognize that the dynamic system is unlikely to be at complete steady-state but that the cell will ideally not excessively produce or consume any metabolites. Hence, it is appropriate to penalise accumulation in the objective function Eq. 7.

$$\min \left( \frac{X(t) \cdot \mu_t - \frac{dX(t)}{dt}}{\frac{dX}{dt}} \right)^2 + \sum_{j, ex} \left( \frac{10^3 \cdot X(t) \cdot \sum_i \alpha_{i,j} \cdot v_{i,t} - \frac{dC_{j,ex}(t)}{dt}}{\frac{dC_{j,ex}}{dt}} \right)^2 + w_{acc} \sum_{j, in} \left( \frac{A_{j,t}}{\max(|A_{j,t-1}|, 10^{-20})} \right)^2 \quad (7)$$

Metabolite concentrations are updated linearly, which is valid given a small time increment,  $\Delta t$ , between MFA calculations,  $C_{j,in,t} = C_{j,in,t-1} + A_{j,t-1} \cdot \Delta t$ .

### 2.3. Regularizing flux inconsistency

In the DMFA methodologies discussed, there is potential for consecutive fluxes to display severe inconsistency, which is unlikely to be a true representation of the system. To avoid such behaviour, a penalty function is implemented to penalise deviations from the flux at the previous timestep. This penalty has a corresponding weight, which is determined iteratively, to ensure it does not overrule the main objective function.

## 3. Case Study

A metabolic network of Myeloid-Derived Suppressor Cells (MDSCs) studied in a previous paper (Goffaux et al., 2017) was used as a case study given the availability of essential metabolites data. The metabolic network consists of 46 reactions, including biomass generation, and 44 metabolites. The data available contains measurements, taken every 8 hours for 96 hours, of 7 extracellular metabolites, biomass concentration, and 12 intracellular metabolites. The remaining 25 metabolites have an initial concentration measurement only. The metabolic reaction network is shown as Fig. 1. More details about the case study can be found in (Goffaux et al., 2017). Four modelling methodologies are

to be considered and compared: a class kinetic modelling approach and three variations of dynamic metabolic flux analysis (DMFA).

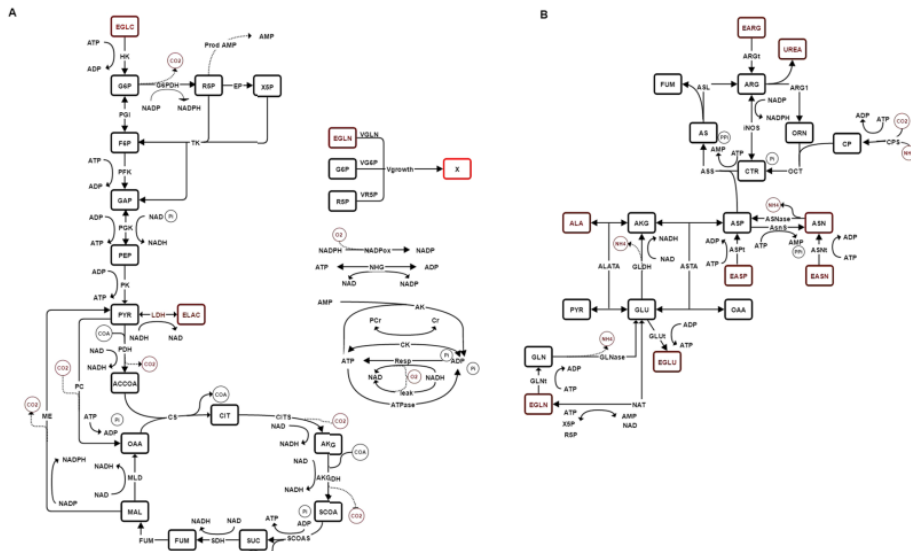

Figure 1: Metabolic network to be simulated (Goffaux et al., 2017), consisting of: (A) Central carbon metabolism and bioenergetics; (B) Urea cycle and amino acid catabolism.

#### 4. Results and Discussion

When comparing the fitting results of the four approaches, the kinetic model is found to performed far worse (mean error 37.8%) than the other methodologies and the three DMFA approaches were almost inseparable (mean error 16.6%), due to the added flexibility provided by the data-driven elements.

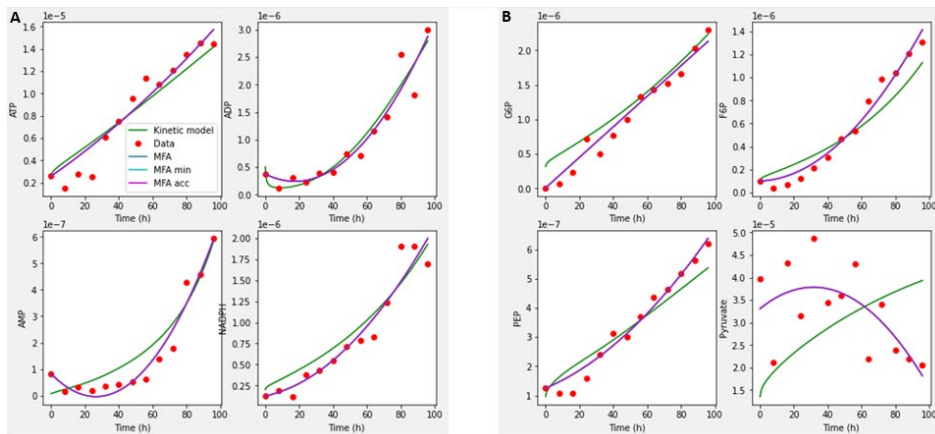

Figure 2: Comparison of experimental data (red) against the simulations of various modelling methodologies, DMFA (blue), DMFA with minimisation (cyan), and DMFA with accumulation (magenta), for both extracellular (A) and intracellular (B) metabolites.

For much of the extracellular metabolites, good fits were obtained – especially in instances of low-level noise in the data. For intracellular metabolites, much of the same was generally observed. However, some datasets were extremely noisy, such as pyruvate, which led to poor fitting – especially for the kinetic model, as shown in Fig. 2B. The excessive noise causes great uncertainty in the initial pyruvate concentration. This is a potential cause of the stiff region simulated by the kinetic model across the initial timesteps (up to a time of 0.3 hours). The stiffness was alleviated by allowing the initial concentration of pyruvate to vary within a sensible region. In addition, the penalty function was successfully implemented, greatly reducing the inconsistency in several reaction fluxes without hindering the performance of the main objective function. When comparing the different methodologies, the DMFA and DMFA with flux minimisation showed the most agreement between any two methodologies. A few cases in which the kinetic modelling and DMFA with accumulation showed better agreement than the traditional DMFA approaches could highlight a metabolite that is in fact violating steady-state or a reaction that requires some form of accumulation to stabilise it. When comparing to DMFA studies and flux observations of similar networks (Tang et al., 2009 and Chan et al., 2003), it is apparent that DMFA and DMFA with flux minimisation simulate more realistic fluxes for both central carbon metabolism, and the urea cycle with amino acid catabolism. DMFA with accumulation and kinetic modelling have a tendency to allow large accumulation of some metabolites as opposed to a larger flux consuming said compound. Since the DMFA approaches used the maximum flux parameters found in the kinetic modelling approach for the flux constraints, it can be concluded that is likely that these parameters were not well estimated since the DMFA and DMFA with minimisation were unable to converge to a feasible solution with such tight constraints. Several constraints, especially in the cyclical structures, had to be relaxed, and literature agrees that the kinetic model and DMFA with accumulation did in fact underestimate said fluxes (Tang et al., 2009) (Chan et al., 2003). DMFA with accumulation was able to overcome these tight constraints by allowing excessive accumulation, despite being unrealistic. Literature containing intracellular metabolite concentrations were immensely scarce, but studies on mammalian cells (Yishitoshi et al., 2017) indicate that the kinetic model was generally predicting sensible concentrations, where data was available.

Finally, the correlation matrix of the kinetic parameters in the kinetic model is also estimated and presented in Fig. 3. About 5% of the correlation values exceed 0.7 and the parameter pairs involved include 25% of the model parameters, meaning the kinetic model has an appropriate structure in most cases, but could benefit from fine-tuning. A high concentration of excessive correlation is observed in parameters associated with biomass growth, indicating it either does not obey the mechanism suggested, or the mechanism involves less relevant metabolites.

Figure 3: Correlation matrix of the kinetic model parameters as a heat-map.

## 5. Conclusion

Kinetic modelling can account for intracellular metabolite accumulation and is able to generate reasonable fits, although less accurate than DMFA. If such fits are improved, it could show a good understanding of the mechanisms within the metabolic pathway. However, it is time-consuming to construct a model and computationally expensive to solve. High stiffness meant that gradient-based optimisation failed, and stochastic search optimisation (Particle-Swarm) was utilized, thus not guaranteeing a local optimum being found. Literature also indicates that the fluxes are being underestimated, and this, along with the high stiffness, cases of high parameter correlation and highest average error, indicates that the correct structure was not found, which is a great challenge in kinetic modelling. The DMFA approaches yielded excellent fits to the experimental data and had a much lower computational cost due to the convex nature of each optimisation approach; allowing a global optimum to be found with gradient-based optimisation. However, there is always a high risk of overfitting when using purely data-oriented models for the measured metabolites and so it is essential to not over-complicate the model structure.

Penalizing inconsistent fluxes was effective for DMFA and DMFA with flux minimization. For DMFA with accumulation, the weights of the penalty functions were more sensitive and challenging to determine due to the presence of three terms in the objective function: 1) the main objective; 2) the accumulation penalty; and 3) the flux inconsistency penalty. All approaches can yield good results to simulate experimental data, but it is essential to study the metabolic network prior to experimental work and identify potential bottleneck metabolites (those leading into a cyclical structure) and try to measure these metabolites to help conclude the appropriate flux within these cycles. Traditional DMFA approaches appear to give more realistic flux simulations, which is intuitive as cells aspire to maintain a balance and not over-consume/produce any metabolites. DMFA with accumulation is the most robust approach due to its ability to overcome changes to the input via its allowance for accumulation.

As a result, based on the current research, an overall approach to modelling metabolic networks is suggested; begin with DMFA or DMFA with flux minimisation. If good results are unattainable, add accumulation terms as required. Apply kinetic modelling last; use the DMFA results to inform the kinetic model to reduce computational expense.

## Abstract

Hybrid modelling combines data-driven and mechanistic modelling, providing a cost effective solution to modelling complex (bio)chemical processes when the underlying mechanisms are not fully understood. While more data-efficient than pure data-driven methods, sufficient experimental data must still be collected through time-consuming experiments for hybrid model construction when applied to simulate a newly investigated process. To address this challenge and accelerate design of new systems, transfer learning has been recently implemented to transfer knowledge from a well-understood source domain to a less-studied target domain. Therefore, in this study, hybrid modelling and transfer learning are integrated for the first time to predict a novel dynamic process for microalgal lutein synthesis through photo-production. Specifically, a hybrid model was built to extract primary knowledge about a well-known lutein production strain, *Desmodesmus* sp., for which considerable process data and a high-fidelity kinetic model are available from the literature. Then transfer learning was used to update the hybrid model using limited process data for a recently isolated microalgal strain, *Chlorella sorokiniana*. Once built, the hybrid transfer model was tested by predicting biomass growth and lutein production of the new strain under various operating conditions. Furthermore, bootstrapping was adopted to estimate and propagate the uncertainty of the hybrid transfer models when predicting each batch process. The performance and efficiency of the hybrid transfer learning model were thoroughly demonstrated through experimental verification. It was found that hybrid transfer learning more efficiently modularised primary knowledge than previous pure data-driven transfer learning techniques, enabling more selective updates of source-specific knowledge to preserve generalisable knowledge. This study, therefore, provides a novel contribution to the predictive modelling and knowledge transfer of complex bioprocesses.

**Keywords:** Machine learning, hybrid modelling, transfer learning, microalgae photo production, small data problems.

## 1. Introduction

Small data problems are prevalent throughout bioprocess industries, where collecting samples of experimental data is both time consuming and resource intensive. Datasets classified as small data lack sufficient data points, so the system domain is sparsely explored hence, it is not possible to parameterise a model which fully represents the process. Recently, the limitations of small data have been discussed in the literature, and several techniques have been proposed to tackle this such as artificial data generation (Abdul Lateh et al., 2017). Another such approach is transfer learning, where modelling knowledge of another system can be applied to the new system in a controlled manner. Literature reports significant advantages in data efficiency using transfer learning to

impart knowledge from a previously studied (larger) dataset to another (similar) system characterised by a lack of data (Barman et al., 2019).

Traditionally, modelling is categorised into data driven and mechanistic approaches (i.e., models derived from statistics and those derived from first principles), however, in recent years there has been a rise in the use of hybrid modelling throughout the literature (Hodgson, 2005). Hybrid modelling combines the two traditional approaches, supplementing the current mechanistic knowledge with a surrogate statistics-based model able to capture additional complex non-linearities within the system. The inclusion of physical knowledge reduces the data required to construct an accurate model which, for systems where data is scarce, can present large benefits. In the bioprocess industries, it is common for first-principle models to be restricted in complexity due to limited mechanistic knowledge of an organisms metabolic reactions and the difficulties in deriving models that represent the immense number of possible metabolic pathways present within the biological system (Hodgson, 2005). Hybrid models, therefore, offer a unique solution to overcome the challenge of limited mechanistic knowledge and small data by integrating data driven techniques to represent the extremely non-linear system complexities that may be left unaccounted for in current first-principle models.

## 2. Problem statement

The focus of this study is directed at determining the possible effectiveness of combining hybrid modelling of a well understood biological system and transfer learning of the learned knowledge to a less studied target domain. The aim is to develop a framework for accelerating the design of new systems from scarce data, typical of that experienced in laboratory conditions for such newly researched systems. The source model is built for the microalgal strain, *Desmodesmus* sp., and the target model is constructed for a recently isolated strain, *Chlorella sorokiniana*. Sufficient data is available for the prior whereas little data is available for the latter. The biomass concentration in each case is recorded alongside the substrate concentration (nitrate) and the concentration of product (lutein) is monitored through the full experiment timespan. In the source domain (*Desmodesmus* sp.), a nitrate feed stream is introduced at the same hour for every experiment, the concentration of which is altered between experiments. This substrate feed stream is not present in the target domain. Furthermore, for both strains, light intensity is a controlled variable modified between experiments. More detailed introduction to the experimental setup and data collection of the case study can be found in (Rogers et al., 2022).

For a successful transfer of knowledge, the two systems under study must share similar underlying mechanisms such that information extracted from one system can be relevant to the other (Weiss et al., 2016). In this study, it is believed that the two microalgal strains share similar kinetics and metabolic pathways such that some level of mechanistic and statistical knowledge can be used to inform the target strain, reducing the data requirements of the hybrid model. The greatest advantages of transfer learning are observed when the target domain is severely lacking in data, which, in this study manifests itself as a lack of experiments available for model construction. The prerequisite to designing a successful transfer model is first to develop a robust, accurate source model from which information can be shared. Without a solid foundation, any information transferred to the target domain will be non-generalisable and will likely limit the performance of the target model.

Although the use of transfer learning and hybrid modelling has been well explored in recent studies, the combination of the two has not been explored. In this work, the data

driven component of the hybrid models will be managed by an artificial neural network (ANN). Bootstrapping techniques are used to estimate the uncertainty associated with the batch predictions. Once a robust source model is designed, the optimised kinetic parameters and ANN parameters (weights and bias') are implemented in their respective objective functions to provide guidance to the target model during its construction.

### 3. Methodology

First, the kinetic model structure will be introduced. For the production of lutein from the *Desmodesmus* sp. strain, (del Rio-Chanona et al., 2017) proposes an informed kinetic model using modified Monod kinetics. The equations proposed are used in this study to represent the source domain and are as follows:

$$\frac{dX}{dt} = u_0(X, N, I) \cdot \frac{N}{N + K_N} \cdot X - \mu_d \cdot X \quad (1a)$$

$$\frac{dN}{dt} = -Y_N \cdot u_0(X, N, I) \cdot \frac{N}{N + K_N} \cdot X + F_{N0} \quad (1b)$$

$$\frac{dP}{dt} = k_0(X, N, I) \cdot \frac{N}{N + K_P} \cdot X - k_d \cdot P \cdot X \quad (1c)$$

Where  $\frac{dX}{dt}$ ,  $\frac{dN}{dt}$  and  $\frac{dP}{dt}$  represent the rate of change of biomass, substrate (nitrate) and product (lutein) concentrations respectively. In equation 1a,  $u_0$  is the specific growth rate,  $I$  is incident light intensity,  $K_N$  is the nitrate half velocity constant and  $\mu_d$  is the specific decay rate. In equation 1b,  $Y_N$  is the nitrate yield coefficient and  $F_{N0}$  is the mass flow rate of nitrate influent. In equation 1c,  $k_0$  is the product synthesis rate parameter,  $K_P$  is the nitrate half velocity constant for synthesis of lutein and  $k_d$  is the product consumption rate constant. Derivation and justification of the model composition is explained thoroughly in (del Rio-Chanona et al., 2017).

For this methodology,  $K_N$ ,  $\mu_d$ ,  $Y_N$ ,  $K_P$  and  $k_d$  are estimated as time constant parameters where as  $u_0$  and  $k_0$  are assumed time varying. Using experimental data for the *Desmodesmus* sp. system, the model parameters are estimated with finite element discretisation and optimised using interior point algorithms in python. In the parameter estimation problem, a least squares error function is implemented to optimise the constant and time-varying terms; for an input of  $n$  experiments and  $N$  timesteps,

$$obj = \operatorname{argmin} \left( \frac{1}{n} \sum_{j=1}^n \sum_{i=1}^N (\theta_{j,i} - \theta'_{j,i})^2 \right); \theta_{j,i} = \{X, N, P\} \quad (2)$$

where,  $\theta$  and  $\theta'$  are the set containing the measured and estimated states respectively. Similarly, a least squares approach is employed in the ANN loss function.  $u_0$  and  $k_0$  are complex functions of  $X$ ,  $N$  and  $I$  so, to reduce the non-linearity of the parameter optimisation problem,  $u_0$  and  $k_0$  are solved as independent parameters at each timestep by minimising the fitting error, then an ANN is implemented to alter the terms achieving a better model fit by better approximating the inherent complexities in the system. Let us address the structure and intent behind the ANN component of the hybrid model. The objective of the ANN is to perform alterations to the time varying parameters ( $u_0$  and  $k_0$ ) to the aim of providing accurate estimations of biomass, nitrate, and lutein concentrations. In addition to this, the uncertainty of the predictions must be determined to ensure confidence in the models' performance hence, bootstrapping is employed to this effect. Two-fold validation was employed to assess the predictive abilities of the model and optimisation of the model hyperparameters was carried out. The structure of the ANN is shown in Figure 1.

Figure 1: ANN component of the hybrid source and transfer models, detailing the structures, inputs and outputs.

To provide a meaningful comparison of results, the following metrics are defined for the mean relative percentage error (MRPE) and mean relative percentage uncertainty (MRPU) respectively:

$$MRPE\% = \frac{x' - x}{\frac{1}{2}(x' + x)} \cdot 100 \quad (3a)$$

$$MRPU\% = \frac{\sigma'}{\frac{1}{2}(x' + x)} \cdot 100 \quad (3b)$$

Where  $x'$  and  $x$  represent the prediction and experimental datapoint respectively, and  $\sigma'$  represents the uncertainty estimate obtained from bootstrapping. It is important to consider the relative error and uncertainty due to the proximity of some datapoints to zero values. If simply the mean average percentage error was taken, when the substrate concentration decreased close to zero, the denominator would then tend to zero yielding unrealistic percentage errors and uncertainties.

Herein, we will shift focus to the transfer of knowledge from the source domain to the target domain and the methodology that entails. It is known that the advantages offered by transfer learning are at their greatest when data is severely limited so, in this study only two experiments are used for estimation of model parameters and training of the target ANN. The target domain mechanistic structure is held almost identical to equations 1a, 1b and 1c, differing only by the  $F_{N0}$  term in equation 1b which is absent for the *Chlorella sorokiniana* strain due to no addition of nitrate solution in the experimental datasets. The transfer of information between mechanistic structures is achieved via implementation of penalty terms for specific constant and time varying parameters estimated by the transfer model which penalises deviation from the source model values. The exchange of statistical knowledge was executed via the direct implementation of the ANN architecture and optimal hyperparameters determined for the source model. Furthermore, an additional penalty was enforced in the ANN loss function to discourage divergence between the weights and bias' calculated through backpropagation in the transfer ANN and the parameters of the finalised source ANN.

#### 4. Results and Discussion

The source kinetic model was fitted using all available datasets. Single-fold cross validation on all 8 experiments of the *Desmodesmus* sp. dataset was used to determine the optimal hyperparameters of the source model ANN. This was achieved using the average MRPE per experiment alongside the determined training loss values to inform this optimisation procedure. Once the parameters were obtained, the source model was tested on the entire dataset to evaluate its performance with respect to both predictive

accuracy and uncertainty estimation. The results in Figure 2 detail the model predictions of biomass concentrations (g/L), nitrate concentration (g/L) and lutein concentration (mg/L) for experiments 6 and 8.

Figure 2 - Hybrid model predictions and corresponding uncertainty limits for test batches 6 and 8. From Figure 2, it can be seen that the hybrid model captures the underlying mechanisms to a considerable extent for the evolution of biomass, substrate and product concentration through time, providing reasonable uncertainty estimations which cover the residuals between the predictions and experimental datapoints. It was therefore determined that the source model was robust in its construction and, due to its success in capturing the fundamental physics driving the system, it is deemed appropriate for use as the foundation to support knowledge transfer to the novel *Chlorella sorokiniana*. system. The transfer model was constructed using only two experiments, severely limiting the information available to the model for informed predictions. The kinetic model for the transfer domain was parameterised using experiments 3 and 6 however a modified objective function was implemented such that the constant parameters  $K_N$  and  $K_P$  were penalised the further they deviated from the source domain values. A similar approach was taken for the time varying parameter,  $u_0$  however, the source model values were averaged at each timestep to obtain a single vector of values which the transfer kinetic model parameters could be compared against. Similarly, the ANN component of the hybrid model was then trained on experiments 3 and 6 and optimised using a MSE loss function adjusted to discourage significant variation of the weights and bias from the source model parameters. The predictions of the transfer model on testing experiments 5 and 7 are shown in Figure 3.

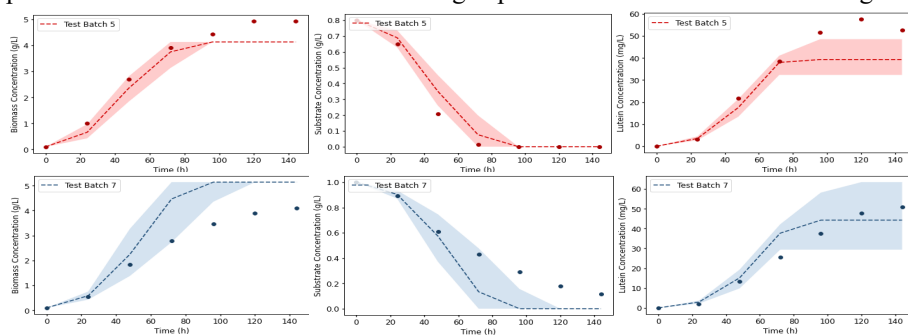

Figure 3: Transfer model predictions and corresponding uncertainty limits for test batches 5 and 7.

Figure 4: Benchmark predictions and corresponding uncertainty limits for test batch 7.

From Figure 3, it is observed that, with very small data, the transfer model successfully reproduced the trends within the process, while offering adequate estimations of state parameters as well as representative uncertainty bounds. To assess the potential of the transfer model, it is necessary to construct a benchmark model built under the same conditions of extreme data scarcity. The mechanistic structure of the benchmark and its corresponding ANN were once again parameterised however, no external influence from the source model was introduced. The results from this analysis are shown in Figure 4.

From Figure 4, it can be observed that the trends captured by the benchmark are generic and lacking in knowledge specific to the provided dataset. When compared to the transfer model, it is clear that the introduction of prior knowledge from the source domain provides notable advantages. It is also evident that the information held within the small training set is insubstantial and is not representative of the *Chlorella sorokiniana*. domain and, as such, knowledge transfer provides a surrogate for this missing information.

## 5. Conclusion

In conclusion, transfer learning offers a unique solution when used in conjunction with hybrid modelling to overcome the necessity of large datasets to achieve satisfactory model performances. The controlled introduction of prior mechanistic and statistical knowledge into a novel, less studied domain establishes a robust framework from which accelerated design can be accomplished. The combination of both data-driven and kinetic modelling simultaneously reduces the data intensity of the transfer learning process while extracting primary knowledge from which some degree of transferable information is contained. Furthermore, the use of hybrid modeling allows for the extension of the framework to systems in which mechanistic understanding is bounded, as increased reliance on the data-driven component can be used to account for this. Overall, this work demonstrates the novel combination of hybrid modelling and transfer learning and exhibits the potential entailed within the use of this framework for situations in which data availability is limited.

## Abstract

Synthetic microbial communities are promising production strategies that can circumvent, via division of labor, many challenges associated with monocultures in biotechnology. Here, we consider microbial communities as lumped metabolic pathways where their members catalyze different metabolic submodules. We outline a machine learning-supported cybergenetic strategy for manipulating the reaction rates of microbial consortia via dynamic regulation of key biomass population levels. To do so, we show a quasi-unstructured modeling approach for synthetic microbial communities with external regulation of intracellular growth regulatory components. Then, we formulate an optimal control problem to find the optimal initial conditions and dynamic input trajectories. We use model predictive control to address system uncertainty, which can be coupled to an observer based on moving horizon estimation. Using a two-member community with optogenetic control as a simulation example, we found the optimal initial biomass concentrations and light intensity trajectories to maximize naringenin production.

**Keywords:** synthetic microbial communities, machine learning-supported optimization, model predictive control, estimation, optogenetics.

## 1. Introduction

Monocultures dominate biotechnological production, i.e., processes catalyzed by single-cell types. While metabolic engineering may increase the production efficiency of cells, it often involves intense genetic modifications. As a result, the engineered cells may suffer from resource burden and disturbances in the energy and redox balances, thus portraying poor growth and low volumetric productivity rates. Synthetic microbial communities (SMCs) are possible solutions to these challenges as metabolic tasks are distributed among a designed consortium of microorganisms, hence division of labor is achieved (Roell et al., 2019). In this work, we outline a (machine-learning supported) modeling, optimization and control framework for maximizing the production efficiency of SMCs.

We visualize SMCs as lumped metabolic pathways consisting of several metabolic submodules, each catalyzed by a different member population. We consider that the

reaction rates of the submodules in the SMCs can be dynamically adjusted by online modulation of the biomass population levels. Being able to do this in a structured and flexible manner can unlock a powerful optimization degree of freedom in biotechnology. To enable online modulation of the population levels, we propose to introduce tunable genetic systems into (some of) the community members for regulating the gene expression of key intracellular growth regulatory elements via external inputs.

The remainder of this paper is structured as follows. In Section 2, we describe a general modeling approach for SMCs in batch processes. We lump up most of the intracellular bioprocesses and focus on the dynamics of the external species and the externally manipulated intracellular growth regulatory components. With this, we aim to decrease the model complexity as much as possible, while still capturing the most relevant process dynamics. We outline the use of machine learning for improving the prediction capacity of the derived models by learning uncertain or unknown parts of the dynamic equations. In Section 3, we formulate a model-based optimal control problem to find the optimal initial conditions and dynamic input trajectories. In Section 4, system uncertainty is addressed via model predictive control (MPC), optionally coupled to a state observer based on moving horizon estimation (MHE) (Findeisen and Allgöwer, 2002; Rawlings et al., 2020). Finally, in Section 5, a two-member consortium for naringenin production (Lalwani et al., 2021) is used as a simulation example.

## 2. Modeling of synthetic microbial communities with cybergeneic inputs

Let  $B \in \mathbb{R}^{n_B}$  refer to the biomass concentrations of the community members. We comprise in  $p \in \mathbb{R}^{n_p}$  all the intracellular concentrations of growth regulatory components present in the SMC and in  $z \in \mathbb{R}^{n_z}$  the concentrations of extracellular metabolites. The reaction rates of the model  $V \in \mathbb{R}^{n_V}$  are divided into rates of production  $V_p \in \mathbb{R}^{n_p}$  and degradation/dilution  $V_d \in \mathbb{R}^{n_p}$  of intracellular growth regulatory components, rates of biomass growth  $V_B \in \mathbb{R}^{n_B}$  and rates of metabolic conversion of extracellular metabolites  $V_z \in \mathbb{R}^{n_z}$ . Hence,  $V := [V_p^T, V_d^T, V_B^T, V_z^T]^T$ . Without loss of generality, we focus on batch processes, thus the dynamics of the SMC follows

$$\dot{p}(t) = S_p V(t), \quad p(t_0) = p_0, \quad (1)$$

$$\dot{B}(t) = S_B V(t), \quad B(t_0) = B_0, \quad (2)$$

$$\dot{z}(t) = S_z V(t), \quad z(t_0) = z_0, \quad (3)$$

where  $S_p \in \mathbb{R}^{n_p \times n_V}$ ,  $S_B \in \mathbb{R}^{n_B \times n_V}$  and  $S_z \in \mathbb{R}^{n_z \times n_V}$  are matrices that map the reaction rates to the corresponding differential equations.

The control inputs are collected in  $u \in \mathbb{R}^{n_u}$  and the model parameters in  $\theta \in \mathbb{R}^{n_\theta}$ . For simplicity, we assume that a given control input can affect the expression of at most one growth regulatory component. In addition, we consider that there is no more than one tunable growth regulatory element per community member. Hence,

$$V_{B_i} = \begin{cases} B_i \mu_{\text{reg}_i}(p_i, z, \theta) & \text{for regulation via } p_i, \forall i \in \mathbb{B} \\ B_i \mu_{\text{unr}_i}(z, \theta) & \text{otherwise,} \end{cases} \quad (4)$$

$$V_{p_i} = \eta_i(u_i, \mu_{\text{reg}_i}, \theta), \quad \forall i \in \mathbb{P}, \quad (5)$$

$$V_{d_i} = d_i(\mu_{\text{reg}_i}, p_i, \theta), \quad \forall i \in \mathbb{P}. \quad (6)$$

$$V_{z_i} = B_j q_i(\mu_j, \theta), \quad \forall i \in \mathbb{Q}(j). \quad (7)$$

where  $\mathbb{B}$  is the set of community members,  $\mathbb{P}$  be the set of growth regulatory elements and  $\mathbb{Q}(j)$  is the set of conversion rates catalyzed by a member  $B_j$ . Furthermore,  $\mu_{\text{reg}_i}: \mathbb{R} \times \mathbb{R}^{n_z} \times \mathbb{R}^{n_\theta} \rightarrow \mathbb{R}$ ,  $\mu_{\text{unr}_i}: \mathbb{R}^{n_z} \times \mathbb{R}^{n_\theta} \rightarrow \mathbb{R}$ ,  $\eta_i: \mathbb{R} \times \mathbb{R} \times \mathbb{R}^{n_\theta} \rightarrow \mathbb{R}$ ,  $d_i: \mathbb{R} \times \mathbb{R} \times \mathbb{R}^{n_\theta} \rightarrow \mathbb{R}$  and  $q_i: \mathbb{R} \times \mathbb{R}^{n_\theta} \rightarrow \mathbb{R}$  are appropriate kinetic functions.

Given the quasi-unstructured nature of the model, the kinetic functions in Eqs. (4)-(7) are often phenomenological relations. Although the latter generally offer good fitting properties, they usually lack good predictability (Zhang et al., 2019). In some cases, one might not even have a mechanistic or phenomenological relation at hand due to the complexity of a given bioprocess. Therefore, *if necessary*, we can learn the uncertain parts of the model using machine learning. In Section 5 we show an example of a *hybrid* model.

### 3. Optimal cybergenetic control of synthetic microbial communities

Let us define  $x := [p^T, B^T, z^T]^T$ ,  $x \in \mathbb{R}^{n_x}$ . We formulate a model-based optimal control problem to maximize the production efficiency of a SMC (e.g., productivity, profit, etc.)

$$\max_{u(\cdot), x_0} \int_{t_0}^{t_f} l(x(t), u(t)) dt + e(x(t_f)), \quad (8)$$

$$\begin{aligned} \text{s. t.} \quad & \text{Eqs. (1) - (7),} \\ & x(t_0) = x_0, \quad (9) \\ & 0 \leq g(x(t), u(t)). \quad (10) \end{aligned}$$

In the previous formulation,  $u(\cdot)$  is the input function,  $l: \mathbb{R}^{n_x} \times \mathbb{R}^{n_u} \rightarrow \mathbb{R}$  is the stage cost and  $e: \mathbb{R}^{n_x} \rightarrow \mathbb{R}$  is the terminal cost. The system state and input constraints are captured by  $g: \mathbb{R}^{n_x} \times \mathbb{R}^{n_u} \rightarrow \mathbb{R}^{n_g}$ . The process time spans from the initial time  $t_0$  to the final time  $t_f$ . Note that we consider both  $u(\cdot)$  and the initial state concentration  $x_0$  as degrees of freedom (DOF). We also refer to this formulation as the *open-loop* optimization as no online corrective actions are taken if the system is out of “specs” or if disturbances occur.

### 4. Predictive cybergenetic control of microbial communities with estimation

We compensate for possible system uncertainty such as model-plant mismatch and disturbances using online feedback or closed-loop control in the form of MPC (Findeisen and Allgöwer, 2002; Rawlings et al., 2020). For the batch case we use a shrinking horizon, i.e., the control problem is solved iteratively over a time horizon  $[t_k, t_f]$ , where  $t_{k+1} = t_k + \Delta t$  and  $\Delta t$  is the sampling time size. Considering that  $\tilde{x}_k$  is the measured state at the sampling time  $t_k$ , the MPC problem reads

$$\max_{u(\cdot)} \int_{t_k}^{t_f} l(x(t), u(t)) dt + e(x(t_f)), \quad (11)$$

$$\begin{aligned} \text{s. t.} \quad & \text{Eqs. (1) - (7), (10),} \\ & x(t_k) = \tilde{x}_k. \quad (12) \end{aligned}$$

When not all the states can be measured, we can *reconstruct* them via MHE. We collect the measurements in  $y \in \mathbb{R}^{n_y}$  and Eqs. (1)-(3) in the vector function  $f(x, u, \theta)$ . Also, let  $h: \mathbb{R}^{n_x} \times \mathbb{R}^{n_u} \times \mathbb{R}^{n_\theta} \rightarrow \mathbb{R}^{n_y}$  be the measurement equations and  $w \in \mathbb{R}^{n_x}$  the state noise. We denote with  $(\cdot)_i$  and  $(\tilde{\cdot})_i$  the optimization and measured variables at time  $t_i$ , respectively. We indicate with  $(\bar{\cdot})$  the prior information of a variable. We assume that the input signal is piecewise constant over the sampling times. Given a time-discrete model, the MHE problem at time  $t_k$  reads (Rawlings et al., 2020)

$$\min_{x_{k-N}, \theta_k, w_{k-N}, \dots, w_k} \left\| \begin{bmatrix} x_{k-N} - \bar{x}_{k-N} \\ \theta_k - \bar{\theta} \end{bmatrix} \right\|_P^2 + \sum_{i=k-N}^k \|y_i - \bar{y}_i\|_R^2 + \|w_i\|_W^2 \quad (13)$$

$$\text{s. t.} \quad x_{i+1} = x_i + \int_{t_i}^{t_i + \Delta t} f(x, u, \theta_k) dt + w_i, \quad (14)$$

$$\begin{aligned} & \text{Eqs. (4) - (7), (10)} \\ & y(t_i) = h(x_i, u_i, \theta_k), \quad (15) \\ & i \in [k - N, k], k, N \in \mathbb{N}, \end{aligned}$$

where  $\|a\|_A^2 := a^T A a$ ,  $N$  is the length of the estimation window and  $P \in \mathbb{R}^{n_x + n_\theta, n_x + n_\theta}$ ,

$R \in \mathbb{R}^{n_y \times n_y}$  and  $W \in \mathbb{R}^{n_x \times n_x}$  are weighting matrices. In general, the decision variables of the MHE are the states at the beginning of the estimation window  $x_{k-N}$ , the parameters and the state noise; with these we can reconstruct the states via Eq. (14). The estimated state vector  $\hat{x}$  can be used to update the MPC. Parameters are assumed to be constant in the MHE horizon, but they can be updated at each iteration to enable an *adaptive* MPC.

## 5. Microbial community with optogenetic control: naringenin biosynthesis

A summary of the application example is presented in Fig. 1. The SMC consists of an engineered *Escherichia coli* that produces tyrosine, and an engineered *Saccharomyces cerevisiae* that consumes tyrosine to synthesize naringenin. *E. coli* expresses a toxin constitutively, while it expresses an antitoxin, MazE, in an inducible manner using blue light intensity  $I_b$  as control input. MazE counteracts the effect and halts the expression of the toxin, thereby enabling different growth levels (Lalwani et al., 2021). This prevents *E. coli* from outgrowing *S. cerevisiae* and turning the SMC into a monoculture.

Figure 1. Cybergnetic strategy for naringenin production by a two-member SMC.

We consider that the dynamics of the SMC follows

$$\dot{p}_{ME} = V_{p_{ME}} - (k_d + \mu_{Ec})p_{ME}, V_{p_{ME}} = \left( \eta_{ME0} + \eta_{ME,m} \frac{I_b^{n_1}}{I_b^{n_1} + k_{ME}^{n_1}} \right) \mu_{Ec}, \quad (16)$$

$$\dot{B}_{Ec} = \mu_{Ec} B_{Ec}, \mu_{Ec} = \mu_{m,Ec} \left( \frac{z_{Gl}}{z_{Gl} + k_{Gl,Ec}} \right) \left( \frac{p_{ME}^{n_2}}{p_{ME}^{n_2} + k_p^{n_2}} \right), \quad (17)$$

$$\dot{B}_{Sc} = \mu_{Sc} B_{Sc}, \mu_{Sc} = \mu_{m,Sc} \left( \frac{z_{Gl}}{z_{Gl} + k_{Gl,Sc}} \right), \quad (18)$$

$$\dot{z}_{Gl} = -(Y_{Gl/Ec} \mu_{Ec}) B_{Ec} - (Y_{Gl/Sc} \mu_{Sc}) B_{Sc}, \quad (19)$$

$$\dot{z}_{Tyr} = (Y_{Tyr/Ec} \mu_{Ec}) B_{Ec} - \left( Y_{Tyr/Sc} \mu_{Sc} \frac{z_{Tyr}}{z_{Tyr} + k_{Tyr}} \right) B_{Sc}, \quad (20)$$

$$\dot{z}_{Nar} = \left( Y_{Nar/Tyr} Y_{Tyr/Sc} \mu_{Sc} \frac{z_{Tyr}}{z_{Tyr} + k_{Tyr}} \right) B_{Sc}, \quad (21)$$

with  $x = [B_{Ec}, B_{Sc}, z_{Gl}, p_{ME}, z_{Tyr}, z_{Nar}]^T$ ,  $x(t_0) = x_0$ . We refer to this model as the *nominal* or *real plant* model. All the optimizations and the machine learning-related methods presented hereafter were performed with HILO-MPC (Pohlodek et al., 2022).

The open-loop optimization results are presented in Fig. 2. We maximized  $z_{Nar}(t_f)$  using the optimal control problem in Section 3 based on the nominal model. We selected the parameter values of the nominal model such that biologically sound process dynamics under aerobic conditions could be simulated. Considering three DOF,  $B_{Ec}(t_0)$ ,  $B_{Sc}(t_0)$  and  $I_b(\cdot)$ , we obtained 12.0 mg/L naringenin. We also analyzed the case where *E. coli* does not possess the toxin/antitoxin system, i.e.,  $\dot{p}_{ME} = 0$  and  $\mu_{Ec} = \mu_{m,Ec} (z_{Gl}/(z_{Gl} + k_{Gl,Ec}))$ . In this second scenario, with  $B_{Ec}(t_0)$  and  $B_{Sc}(t_0)$  as DOF, we obtained 9.3 mg/L naringenin, 23 % less than with the previous optimization. Furthermore, the optimizer predicts a very low  $B_{Ec}(t_0)/B_{Sc}(t_0)$  to reduce the risk of *E. coli* outgrowing *S. cerevisiae*.

In contrast, with dynamic growth regulation of *E. coli*, one can *safely* start the process at a higher *E. coli* concentration, which increases the tyrosine available for conversion to naringenin by *S. cerevisiae*, hence the better performance.

In the previous cases, the predictions of the optimization matched the plant simulations as we did not consider model-plant mismatch. However, often we do not know the exact plant model. In a third open-loop scenario, we assumed that  $V_{p_{ME}}$  in Eq. (17) and the  $p_{ME}$ -dependent factor in the  $\mu_{EC}$ -kinetics (Eq. (18)) were unknown. A feedforward fully connected neural network was trained to learn these unknowns. We simulated eight batches with the nominal model subject to randomized input values and added 2.5 % Gaussian white noise to the *measurements*. We considered  $p_{ME}$  and  $I_b$  as features and the two unknown parts of the model as labels. From the eight batches, 20 % of the data was used for validation. Three additional independent batches were used to test the quality of the hybrid model (Fig. 3). Despite some model-plant mismatch, the hybrid model was able to predict overall trends. Nevertheless, using the hybrid model in the open-loop optimization with  $B_{EC}(t_0)$ ,  $B_{Sc}(t_0)$  and  $I_b(\cdot)$  as DOF rendered 8.5 mg/L naringenin (cf. Fig. 2), 29 % less than with the open-loop optimization based on the nominal model. The hybrid model-based optimization overestimated *E. coli* growth and tyrosine synthesis, thus negatively impacting on naringenin production.

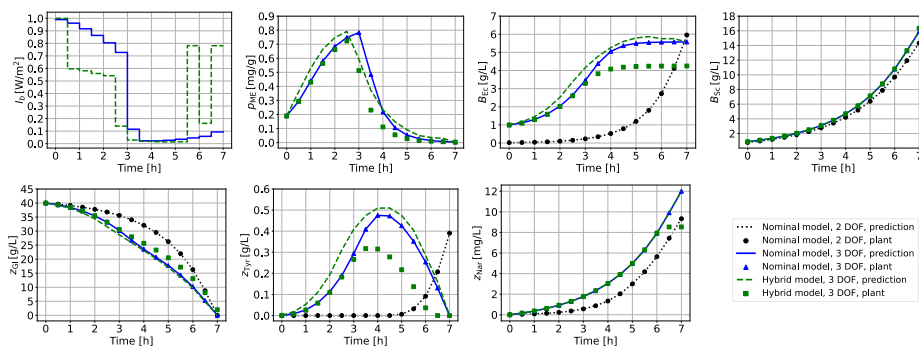

Figure 2. Open-loop optimization results of the SMC for naringenin production. Nominal model:  $\mu_{m,EC} = 0.825 \text{ h}^{-1}$ ,  $\mu_{m,Sc} = 0.418 \text{ h}^{-1}$ ,  $\eta_{ME_0} = 5.71 \times 10^{-5} \text{ g/g}$ ,  $\eta_{ME,m} = 2.86 \times 10^{-3} \text{ g/g}$ ,  $n_1 = 2.49$ ,  $n_2 = 1.5$ ,  $k_d = 1.39 \text{ h}^{-1}$ ,  $k_{GI,EC} = 6.8 \times 10^{-5} \text{ g/L}$ ,  $k_{GI,Sc} = 0.06 \text{ g/L}$ ,  $k_{ME} = 0.138 \text{ W/m}^2$ ,  $k_p = 5 \times 10^{-4} \text{ g/g}$ ,  $k_{TYr} = 1 \times 10^{-6} \text{ g/L}$ ,  $Y_{GI/EC} = 2.2 \text{ g/g}$ ,  $Y_{GI/Sc} = 2.0 \text{ g/g}$ ,  $Y_{Nar/TYr} = 0.016 \text{ g/g}$ ,  $Y_{TYr/EC} = 0.164 \text{ g/g}$ ,  $Y_{TYr/Sc} = 0.05 \text{ g/g}$ . The relevant product yields were inferred *at our best* from Lalwani et al. (2021). Similarly, *realistic* optogenetic-related parameters were inferred from Olson et al. (2014).

Figure 3. Testing of the hybrid model. We only show the dynamics of  $p_{ME}$  and  $B_{EC}$ . Artificial neural network configuration: two hidden layers with ten neurons each, sigmoid activation function.

The hybrid model could be improved by increasing the amount of data used for training. However, experiments in biotechnology are generally expensive and time-consuming, which limits the available data. Therefore, in Fig. 4 we use MPC to address the model uncertainty of the hybrid model. First, we assumed that all the states can be measured online. This led to 11.5 mg/L naringenin, significantly compensating for the uncertainty

of the hybrid model by adjusting the dynamic input trajectory. Despite the good results, online monitoring of intracellular components is challenging. Therefore, we also analyzed the case where  $p_{ME}$  cannot be measured online. A special case of MHE is when all the measurements from  $t_0$  are considered; this is called full information estimation (FIE). We estimated  $p_{ME}$  via FIE, where we minimized the first two terms in Eq. (13) and did not consider the parameters as decision variables. Note that from the estimated state vector, we only passed  $\hat{p}_{ME}$  to the MPC as we *trusted* the measurements. This resulted in 10.8 mg/L naringenin, representing a 21 % enhancement compared to the open-loop scenario with the hybrid model and only 6 % less efficient than the MPC with full state measurement. As expected, the FIE estimates improved as the estimation window grew due to its *memory* effect, i.e., more historical measurements available for the estimation.

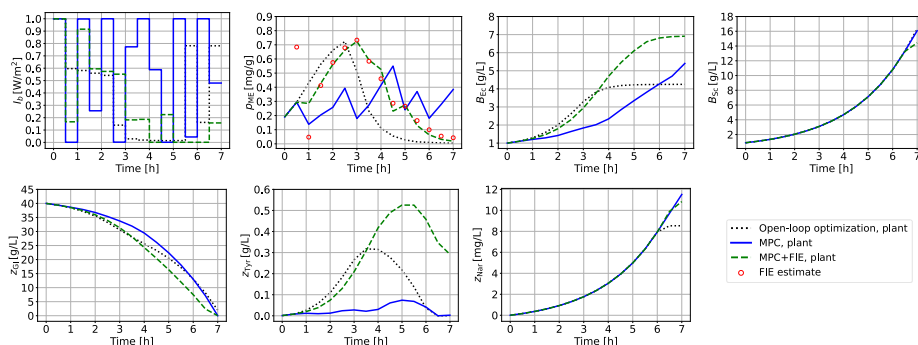

Figure 4. Machine learning-supported feedback control of the SMC for naringenin production.  $B_{EC}(t_0)$ ,  $B_{SC}(t_0)$  and the first step of  $I_b$  were found at the first MPC iteration, then the MPC only had  $I_b$  as a DOF. All the measurements had 2.5 % Gaussian white noise.

## 6. Conclusion

We outlined a (machine learning-supported) cybergenetic modeling, optimization and control strategy for exploiting biotechnological production by SMCs. We also presented a state observer for inferring unmeasured states. We demonstrated the potential of our framework with a two-member SMC for naringenin production with optogenetic control as a simulation example. Although we focused on batch setups, the framework can in principle be extrapolated to other modes of operation. Future work deals with the experimental implementation of the framework and additional hybrid modeling and control approaches, e.g., based on Gaussian processes, Bayesian neural networks, physics-informed machine learning and reinforcement learning.

## Abstract

Within this contribution we use a mechanistic model to optimize the feed addition and harvest time point of the induction phase of a recombinantly produced protein in *E. coli*. The model includes the metabolic load of the forced product formation and its effects on the production rate as well as the biomass conversion yield. The model was fitted to three experiments with different constant substrate feed rates during the production phase. Under usage of the calibrated model, optimal substrate addition and harvest time points with the objective to improve the time-space yield were determined. In addition, a constant feed rate was compared to an increasing feed rate with the aim to maintain a constant biomass specific substrate uptake. Different optimal combinations were identified and compared considering time and resource efficiency. The work shows how recombinant protein production and the inevitable metabolic load can be incorporated into a simple mechanistic model. Once calibrated to a limited number of experiments the model is suited for the design of a resource and time optimal induction phase. Future experiments and uncertainty analysis will show how well the model predicted the real optimal operating points.

**Keywords:** bioprocessing, optimization, production phase modelling, simulation, recombinant protein production

## 1. Introduction

Fed-batch processes using genetically modified *E. coli* bacteria are widely used to produce high value recombinant proteins (Selas Castineiras et al., 2018). State of the art production processes are divided into three main phases, including a batch and fed-batch phase to produce a high amount of active biomass followed by the production phase (Yee and Blanch, 1992). The cell behavior during the first two phases is well understood and optimized to reach high biomass concentrations within short times (Lee, 1996) and to avoid by product formation (Abadli et al., 2021). Due to the metabolic load of the heterologous production of the target protein, cell metabolism changes in course of the induction phase (Neubauer et al., 2003). Therefore, modelling, optimization and control of the induction phase is a challenging task and harvest time points and feed addition are often static parameters derived from historic experiments, which often leads to suboptimal operation and low time space yields. Models can help to improve the exploration of the design space by simulating all different combinations and identifying optimal operation ranges. Möller et al. (2019) for examples used a model to explore the

design space of a CHO cell process to identify optimal feed addition. Bano et al. (2019) extended this concept and recalculated the design space in real-time as soon novel information was available to the model. For recombinant protein production in *E. coli* strong influences on product formation from the feed rate was reported for different products (Mears et al., 2017; Huang et al., 2012; Chen et al., 2012), but due to the lack of proper, mechanistic models, successful examples for insilico exploration and optimization of the production phase are still missing. Although constant substrate feeds are often used during the production phase, recent works show possibilities and potentials to control the specific substrate uptake rate (Kager et al., 2022b) or even the product formation rate (Kager et al., 2022a) by manipulating the feed rate of the limiting substrate. Although the latter being very promising, the control of the specific substrate uptake is easier realizable and was already shown in different applications (Kager et al., 2020; Spadiut et al., 2013; Picon et al., 2005) and can be therefore regarded as a good alternative to constant substrate addition rates.

Within this contribution we show how a previously developed mechanistic model describing the production phase of a recombinantly produced protein can be used to determine optimal feed addition in combination with harvest time. Optimal constant feed addition will be compared to optimal set-points of the cell specific substrate uptake for their time and resource efficiency. After describing the three calibration experiments, the model and its fitting to the experiments are presented. The results show the design space of the analyzed process and the dynamics of the optimal process followed by the conclusion.

## 2. Methods

### 2.1. Experimental data

A modified K12 *E. coli* strain with a rhamnose-inducible expression system (rhaBAD promoter), producing a single chain antibody fragment with a transporter sequence to be transported into the periplasm was used. Fermentations were conducted in a DASGIP multibioreactor system (Eppendorf, Germany). Composition of the used minimal media was based on Wilms et al. (2001). Temperature was kept at 35°C, stirrer speed at 1400 rpm and aeration at 1.4 vvm for the whole process. The pH was controlled at 7.0 ± 0.2 with addition of 12.5 % NH<sub>4</sub>OH solution and the dissolved oxygen (DO<sub>2</sub>) was kept over 25% by supplementing pure oxygen to the air. The reactors with an initial glycerol concentration were inoculated with 25 mL of an overnight shake flask culture (30°C and 170 rpm). The 20 g/L glycerol in the batch phase was consumed after approx. 12 h and a fed-batch phase with an exponential feed ramp with a  $\mu$  of 0.14 according to the equation given in Lee (1996) was applied to reach high biomass concentrations of 40 gL<sup>-1</sup> after another 12 h runtime. Recombinant protein production was induced by a one-point addition of sterile filtrated rhamnose solution (1.5 g L-rhamnose in 10 mL H<sub>2</sub>O) and the glycerol feed rate was set to different constant values (*high* = 14.5 mLh<sup>-1</sup>; *medium* = 8.5 mLh<sup>-1</sup>; *low* = 2.2 mLh<sup>-1</sup>).

Periodical offline measurements were taken and analyzed. Biomass dry content was determined by centrifugation at 4500 g, 10 min, 4°C including one washing step before drying at 105°C for min. 72h. For product concentration, homogenized, centrifuged and gel filtrated (PD MiniTrap g-25) cell suspension was applied on a protein G affinity column (HiTrap ProtG (GE Healthcare; USA) with a flow rate of 2 mlmin<sup>-1</sup> (20 mM phosphate buffer) at 25°C and elution with a change of the pH from 7.4 to 2.5). Acetate and glycerol concentrations were quantified from the supernatant by enzymatic,

photometric principle in a robotic system (BioHT, Roche, Germany) and were always under the detection limit during the induction phase.

## 2.2. Model equations

The system differential equations for the ideally stirred tank reactor in fed-batch mode are:

$$\begin{aligned}
 \frac{dc_X}{dt} &= \mu c_X - \frac{F_{in}}{V_R} c_X \\
 \frac{dc_S}{dt} &= -q_S c_X + \frac{F_{in}}{V_R} (c_{S,in} - c_S) \\
 \frac{dc_P}{dt} &= q_P c_X - \frac{F_{in}}{V_R} c_P \\
 \frac{dV_R}{dt} &= F_{in}; \quad \frac{dS_{met}}{dt} = q_S
 \end{aligned} \tag{1}$$

describing the concentration changes over time of the: biomass  $c_X$ , glycerol  $c_S$ , product  $c_P$ , metabolized substrate  $S_{met}$  and the reactor volume  $V_R$ . Glycerol is added to the system by the substrate inflow  $F_{in}$  with a concentration  $c_{S,in}$ . The biological conversion rates, namely the growth rate  $\mu$ , the substrate consumption rate  $q_S$  and the product formation rate  $q_P$  are described by the following reaction kinetics:

$$\begin{aligned}
 q_S &= \frac{q_{S,max} c_S}{c_S + K_S} \\
 \mu &= Y_{X/S} (q_S - m_S) \\
 Y_{X/S} &= \frac{Y_{X/S,max} \exp(-S_{met} K_{YX/S})}{S_{met}} \\
 q_P &= q_{P,max} \frac{q_S}{q_S + K_{SqS}} \frac{\frac{S_{met}}{K_{IqP}} + S_{met} + K_{SqP}}{S_{met}}
 \end{aligned} \tag{2}$$

The substrate uptake rate  $q_S$  is described by a Monod kinetic with  $q_{S,max}$  being the maximum uptake rate in function of the glycerol concentration  $c_S$  and the half saturation constant  $K_S$ . Biomass growth  $\mu$  is derived from consumed substrate  $q_S$  by substrate conversion yield  $Y_{X/S}$  reduced by the substrate needed for cell maintenance  $m_S$ . Due to the metabolic load  $Y_{X/S}$  decreases by an asymptotic decay ( $K_{YX/S}$ ) in function of the metabolized substrate ( $S_{met}$ ). The product formation  $q_P$  is composed by a Monod term describing the dependency of  $q_{P,max}$  on the substrate uptake  $q_S$  with the half saturation constant  $K_{SqS}$  and a Haldane term to describe the underlying start up and decline phase with  $S_{met}$  as a trigger,  $K_{SqP}$  as the delay coefficient,  $K_{IqP}$  as the decay coefficient and  $k$  as the Haldane exponent determining the shape of the decay.

Table 1: Model Parameter

Parameter	Value	Unit	Description
$c_{S,in}$	850	$gL^{-1}$	feed concentration
$q_{S,max}^*$	1.0	$gg^{-1}h^{-1}$	max. substrate uptake
$K_S^*$	0.0050	$gL^{-1}$	half saturation constant
$m_S$	0.02	$h^{-1}$	maintenance constant
$Y_{X/S,max}^*$	0.47	$gg^{-1}$	max. growth yield
$K_{YX/S}$	0.34	$gg^{-1}$	growth yield decay
$q_{P,max}$	0.0066	$gg^{-1}h^{-1}$	max. production rate
$K_{SqS}$	0.082	$gg^{-1}h^{-1}$	$q_P$ affinity to $q_S$
$k$	4.6	–	Haldane exponent
$K_{IqP}$	3.8	$(gg^{-1})k^{-1}$	product decay
$K_{SqP}$	0.096	$gg^{-1}$	product formation delay

The model was fitted to three experimental data sets, with three different constant feed rates, displayed in figure 1. The model parameters are given in table 1. As fitting criterion the weighted sum of squared errors between measurements of biomass, product and sugar concentrations and the respective model simulations of all three experiments was minimized by a local optimizer (Fmincon:MATLAB). All calculations were done in MATLAB (R2022b, Mathworks, USA) and the differential equations were solved by ode15s. To keep the substrate uptake constant the following equation was used to derive the corresponding feed rate based on the current biomass concentration and aimed  $q_S$  setpoint ( $q_S \ll q_{S,max}$ ).

$$F_{in} = \frac{q_S c_X V_R}{c_{S,in} - c_S} \quad (3)$$

### 3. Results and Discussion

#### 3.1. Process & Model dynamics

In figure 1 the results of the model simulation of the three calibration experiments are shown in comparison to the measured product concentrations. Overall, with a normalized root mean square error (NRMSE) of 11,5 % the model has an acceptable accuracy considering the big feed rate range ( $2.2 - 14.5 \text{ mLh}^{-1}$ ) of the calibration experiments. From the model and the measurements, it can be seen that higher feed rates lead to a faster product formation but also to a faster stagnation. The lowest feed rate leads to highest product titers. Compared to the other processes it takes however longer to reach those concentrations, with a duration of up to 100 h.

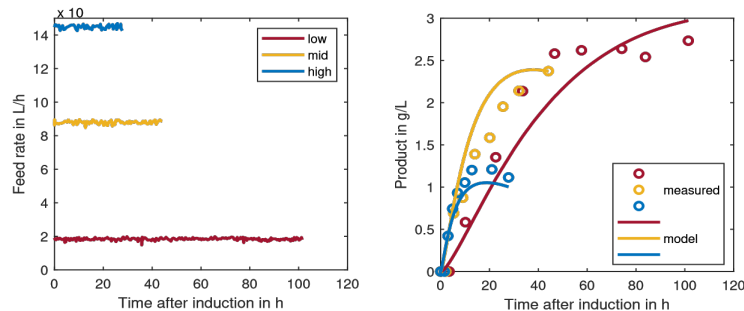

Figure 1: Applied constant feed rates of the three model calibration experiments and alignment of model output to measured product concentrations with NRMSE of 10,7% for low, 12.7 % for mid and 11.2 % for high experiment.

#### 3.2. Design space exploration

Although the fitted model displayed in figure 1, is not perfect it can be used to explore the design space and to determine potentially optimal operating regions. In order to identify optimal combinations of feed rates,  $q_S$  setpoints and harvest time-points the time space yields (TSY) were calculated considering the duration of the induction phase in addition to batch (12 h), fed-batch (12 h) and setup times (7 h). The resulting design spaces for the constant feed rate (a) and the controlled  $q_S$  (b) are displayed in figure 2. According to the model the optimal TSY is reached by applying constant feed rates around 5 mL/h and harvesting after 23 h, which is between the *low* and the *mid* feed rate experiments. It seems that for this process, high constant feed rates are highly unfavorable

with very low TSY's. A similar pattern can be seen for the  $q_S$  controlled induction phases (figure 2 b). Also, here smaller setpoints ( $< 0.1 \text{ g g}^{-1}\text{h}^{-1}$ ) and harvest times between 18 - 40 hours, lead to best TSY's. In contrast to the constant feed rate two optimal regions are identified. A setpoint of  $0.1 \text{ g g}^{-1}\text{h}^{-1}$  in combination with a harvest time of 19.2 h and a smaller setpoint of  $0.055 \text{ g g}^{-1}\text{h}^{-1}$  with a harvest timepoint at 30.2 hours.

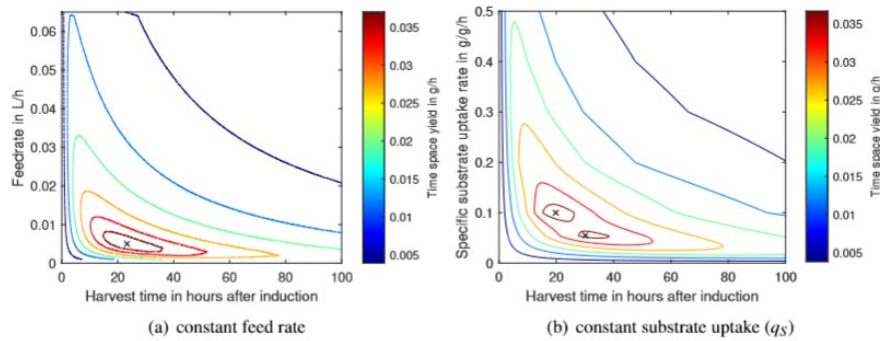

Figure 2: Design spaces for optimal time space yield for induction phases with different constant feed rates (a) and specific substrate uptake ( $q_S$ ) setpoints (b) in dependence on the harvest time-point.

In figure 3 the trajectories of the three potential, optimal conditions are displayed with some performance criteria summarized in table 2. It can be seen that the different optimal conditions differ in their feed profiles, which are all in the lower range (medium feed = 8.5 mL/h). The constant feed rate results in a steadily decreasing  $q_S$  compared to the two optimal constant  $q_S$  setpoints. The product dynamics reveal a similar behavior as seen in the calibration experiments. Hereby, higher feed rates lead to a faster product increase but the lowest setpoint to the overall highest product titer (see also table 2). Although, the constant feed rate and the higher  $q_S$  setpoint have slightly higher TSY's, due to faster product formation dynamics, the low  $q_S$  setpoint reaches the highest product titer with overall lowest consumed glycerol and is therefore the most resource efficient.

Figure 3: Model simulations of identified optimal constant feed and two  $q_S$  setpoints

Table 2: Output of the three potentially good performing processes

Feeding	Harvest (h)	TSY (g/h)	Product (g/L)	Biomass (g/L)	Glycerol (g)
$F_{in} = 0.005 \text{ L/h}$	23.0	0.0389	2.19	58.3	97.8
$q_S = 0.10 \text{ g/g/h}$	19.8	0.0386	2.03	61.0	108.3
$q_S = 0.055 \text{ g/g/h}$	30.2	0.0372	2.47	54.2	91.4

#### 4. Conclusion

In this contribution a mechanistic model was fitted to the production phase of three experiments with different feed addition. Based on the obtained model the design space could be explored and promising regions identified. Based on this methodology potentially optimal experiments can be planned and different control strategies can be bench-marked with only few available experiments. With a proper uncertainty analysis of the preliminary model, a more probability-based approach could be followed in future to predict the most probable design space rather than optima which are highly uncertain due to model-plant mismatches. To show the validity of the obtained results, verification experiments and a proper model uncertainty analysis are necessary. Future verification experiments are also the basis to further improve the underlying model.

## Abstract

To confidently accelerate bioprocess development using high-throughput robotic platforms, parallel experiments should be reproducible whereas the generated data must be FAIR. To this aim, higher levels of automation for planning, redesigning, executing, and monitoring of related experimental-computational workflows are needed. In this work, an automation hierarchy for closed-loop optimization based on Bayesian update, belief propagation and Thompson sampling is proposed. For online redesign of parallel dynamic experiments, asynchronous *rolling out beliefs about beliefs* based on simulated data is used for counterfactual assessment of the effect of alternative (re)design decisions on the distributions of model parameters. A computational implementation of the Bayesian automation hierarchy using Apache Airflow is described. Simulation results obtained using an *E. coli* case study are presented to argue that parallel dynamic experiments made using the proposed Bayesian hierarchy are reproducible whereas experimental-computational workflows and data are FAIR by design.

**Keywords:** automation hierarchy, closed-loop experimentation, belief propagation, FAIR principles, reproducibility crisis.

## 1. Problem statement

Bioprocess development requires to explore efficiently huge design spaces for specific bioproducts and involves efficient strain selection, bioprocess optimization, scale-up, and optimal control strategies for reproducible industrial production. The shift towards high-throughput technologies and automation in bioprocess development (Cruz Bournazou et al., 2017; Bromig et al., 2022) demands a more autonomous approach for generating informative data sets to support model-based experimental design in the face of uncertainty. For reproducible bioprocess development and decision-making provenance, experimental data sets used for predicting the dynamic behaviour of genetically modified microorganism and the physiological effect of different combinations of process parameters on the productivity levels after scale-up must be obtained by following FAIR principles (Wilkinson et al., 2016; Mione et al., 2022). A significant impact is expected from using these principles in model-based autonomous experimentation for strain selection and the optimization of bioprocess parameters based on FAIR data, experimental protocols, and computational workflows. In this work, an automation hierarchy for integrating Bayesian inference with experimental (re)design and execution control using probabilistic models and belief propagation is proposed.

## 2. Bayesian automation hierarchy

First and foremost, automating the execution of an experiment requires that the specific objective for data gathering is clearly stated, the *a priori* available knowledge be explicit modeled, and the initial uncertainty quantified. Without any loss of generality, it is assumed here that a causal probabilistic model (see Martinez et al, 2021 for details) of the microorganism dynamic behavior is going to be used to guide experimental off-line design, online redesign, execution monitoring and control. The aim of the asynchronous parallel experiments would be to gather FAIR data to increase the model predictive power so that biomass production is maximized. Alternatively, the objective of the experiment would be strain screening for physiological robustness after scaling up. Gathering data for model selection would also be the aim of an experiment. In this work, it is assumed that the *a priori* uncertainty is summarized in the means and variances corresponding to the (normal) distributions of the parameters for the causal dynamic model.

A schema of the proposed automation hierarchy in the chosen Bayesian setting is given in Fig. 1. The top layer deals with off-line design where the *a priori* optimal sequence of control actions for a given objective is calculated alongside with the expectations regarding observations based on prior distributions for model parameters. In the middle layer, as new data is available, the *posterior* distributions are revised using variational Bayesian inference. Then, the optimal sequence of redesign decisions is re-estimated and future data expectations, which are needed to monitor the experiment execution, are updated accordingly. In the bottom layer, a predictive control strategy is used to safely implement (re)design decisions by properly handling both physiological and platform-related constraints using (stochastic) model predictive control.

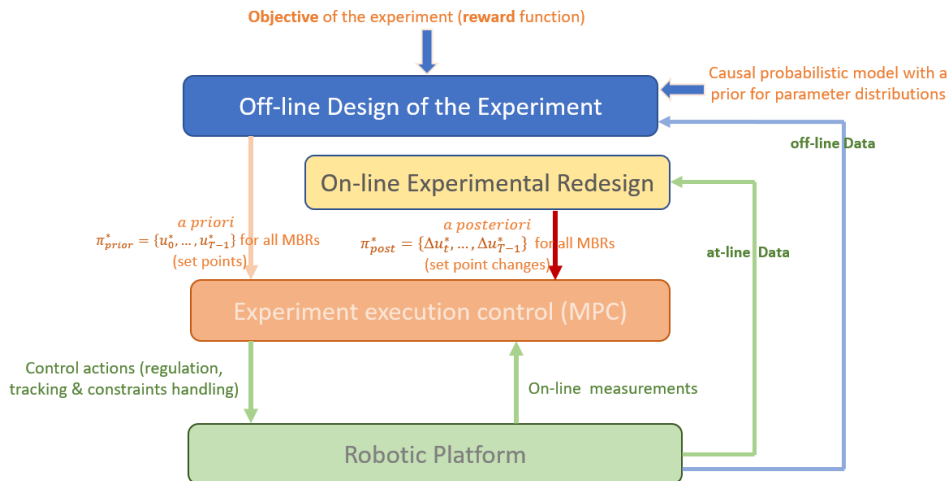

Figure 1. Bayesian hierarchy for closed-loop optimization of robotic platforms

At their three layers, the unifying approach is that by considering the counterfactual consequences of alternative (re)design decisions in generating alternative sampled data, belief propagation (Friston et al., 2021; Martinez et al., 2021) is used to update posterior distributions about the evolution of hidden states and the estimated sequence of optimal redesign decisions for each MiniBioReactor (MBR) in the platform based on simulated sampled data and Thompson sampling of the posterior distributions for model parameters. This recursive form of propagating beliefs over the shrinking horizon of a dynamic

experiment effectively implements a deep tree search over alternative sequences of optimized (re)design decisions and their corresponding expectations regarding state evolution and sampled data at different times for dynamic parallel experiments.

For asynchronous *rolling out beliefs about beliefs* in each MBR, the same recursive procedure in Fig. 2 is used for both off-line experimental design and on-line redesign as new observations from all MBRs are available to update the distributions  $f(\theta)$  for model parameters. The internal loop implements a forward pass where, for a given MBR, a *prior* density is increasingly converted into a *posterior* density for model parameters upon simulated data in a rollout where a stagewise greedy design procedure based on Thompson sampling (Russo et al., 2018) is recursively implemented. At each redesign iteration  $k$ , a decision is chosen to implement in the  $i$ th MBR by solving an optimization problem for the expected look-ahead reward based on the  $r_t(\hat{y}_{t+1}^i)$  computed from simulated data  $\hat{y}_{t+1}^i$  for alternative design decisions in a bounded set  $\Omega$  and accounting for physiological and platform constraints  $C(x_{i,t}, u_{i,t})$ :

$$u_{i,t}^* = \operatorname{argmax}_{u_i \in \Omega} r_t(y_{t+1}^i), \text{ subject to: } C(x_{i,t}, u_{i,t}) \geq 0 \quad (1)$$

*Inputs:*  $T, K, x_{i,0}$ , prior  $f(\theta)$ ,  $n_{MBR}$ , state evolution and observation functions  $f, g$

▷ **For**  $t = 1$  to  $T - 1$

*Infer* current state  $\hat{x}_{i,t}$  using  $u_{i,t-1}^*$ ,  $\hat{x}_{i,t-1}$  and Thompson *Sampling* of prior  $f(\theta)$

▷ **For**  $k = 1$  to  $K$

$\hat{f}(\theta_k) = f(\theta)$

**While**  $t < T$  (Forward Pass)

▷ **For**  $i = 1, 2, \dots, n_{MBR}$  **do**

Thompson *Sampling* of the prior  $\hat{f}(\theta_k)$ :  $\Theta_k = \mathbf{TS}[\hat{f}(\theta_k)]$

$u_{i,t}^k = \operatorname{argmax}_{u_i \in \Omega} (r_t(\hat{y}_{t+1}^i) | \Theta_k, \hat{x}_{i,t})$ , S. to:  $f, g$  &  $C(x_{i,t}, u_{i,t}) \geq 0$

*Simulate* redesign using  $u_{i,t}^k$  and predict  $r_{t+1}(\widehat{y}_{t+1}^k | u_{i,t}^k, \hat{x}_{i,t})$

*Update* prior:  $\hat{f}(\theta_k) \leftarrow \hat{f}(\theta_k | u_{i,t}^k, \hat{x}_{i,t})$  using  $(u_{i,t}^k, \hat{x}_{i,t})$

*Accumulate* reward:  $\mathcal{R}_k = \mathcal{R}_k + r_{t+1}(\widehat{y}_{t+1}^k | u_{i,t}^k)$

▷ **End for**

**End while**

Define the redesign policy:  $\pi_t^k = \{u_{i,t}^k, \dots, u_{i,T-1}^k\}$  with its corresponding  $\mathcal{R}_k$

▷ **End for**

*Rank* policies  $\pi_{i,t}^k, k = 1, \dots, K$ , using  $\mathcal{R}_k$

*Select* the best policy  $\pi_{i,t}^* = \{u_{i,t}^*, \dots, u_{i,T-1}^*\}$  with the highest  $\mathcal{R}_k$

*Redesign the experiment* in the MBR  $i$  using only  $u_{i,t}^*$  and measure  $y_{i,t+1}$

*Update* prior:  $f(\theta) \leftarrow f(\theta | u_{i,t}^*, y_{i,t+1})$  using data  $(u_{i,t}^*, y_{i,t+1})$  from all MBRs

▷ **End for**

*Outputs:*  $\pi^* = \{u_{i,1}^*, \dots, u_{i,T-1}^*\}, (u_{i,t}^*, y_{i,t+1}) \ i = 1, \dots, n_{MBR}, f(\theta)$

Figure 2. Asynchronous rolling out beliefs about beliefs for online redesign in an MBR.

where  $r$  is a *reward* function for observations and their underlying hidden states which accounts for the specific objective of the experiment. The predicted observation  $\hat{y}_{t+1}$  and the estimated optimal action  $u_{i,t}^*$  are then used to update the posterior distribution for model parameters  $\hat{f}(\theta_k)$  to be used at  $t+1$ . Thompson sampling is again applied and using

Eq. (1) the action  $u_{i,t}^*$  is calculated and the corresponding simulated observation  $\hat{y}_{t+2}$  is computed, and so on and so forth. This forward pass ends when  $u_{i,T-1}^*$  is computed and the *optimal* redesign sequence  $\pi_{i,t}^* = \{u_{i,t}^*, \dots, u_{i,T-1}^*\}$  is completely defined for a given MBR. For each iteration of the outer loop, a different sequence  $\pi_k$  is computed. The generated sequences are then ranked based on their corresponding cumulative rewards  $\mathcal{R}_k$  over the planning horizon  $[t, \dots, T]$ . From the top ranked redesign policy  $\pi_{i,t}^*$ , only the first action  $u_{i,t}^*$  is used for redesigning the dynamic experiment in the *i*th MBR and, at the next sampling time  $t+1$ , the observation  $y_{i,t+1}$  is obtained. Using sampled data  $(u_{i,t}^*, y_{i,t+1})$  from all MBRs, the joint posterior distribution  $f(\boldsymbol{\theta})$  for the parameters of the probabilistic model is updated using variational Bayesian inference (based on the Laplace approximation) and the master (external) loop begins re-estimating the optimal redesign sequence  $\pi_{i,t+1}^*$  for each MBR from  $t+1$  until the end of the experiment at time  $T$  using belief propagation. It is worth noting that online redesign in each MBR is only coupled with others' MBRs redesign by the global update of the posterior distribution  $f(\boldsymbol{\theta})$ .

### 3. Implementation in Apache Airflow

The FAIR principles (Wilkinson et al., 2016), describe a set of requirements for data management and stewardship to make research data **F**indable, **A**ccessible, **I**nteroperable, and **R**eusable. The FAIR principles are a set of guidelines that aim to maximize the value and usefulness of experimental data and highlight the importance of making experimental protocols and workflows digital objects findable and reusable by others. To this aim, the representation of the automation hierarchy in Fig. 1 and the (re)design algorithm in Fig. 2 using directed acyclic graphs (DAGs) foster their implementation in the Apache Airflow ecosystem to enforce FAIR principles by design in high-throughput experimentation facilities. For details on making experimental-computational workflows FAIR in Apache Airflow (Harenslak and de Ruiter, 2021), the interested reader is referred to (Mione, et al., 2022) for details.

In Fig. 3, an abstract DAG is used to represent the hierarchy in Fig. 1 as a pipeline for implementing computational tasks such as update of parameter distributions as soon as new sampled data are available from all MBRs, followed by asynchronous experimental redesign using the algorithm in Fig. 2 and then predictive control of redesign changes to the set-points for controlled variables to guarantee feasibility. It is worth noting the importance of execution control nodes since due Thompson sampling changes to the set-points of control loops may violate physiological constraints. For FAIRness and reproducibility, is key to save all seeds used for random number generation in posterior sampling at each iteration  $k$  in the belief propagation algorithm for each MBR. As a result, the parameter values used for solving optimization problems in Eq. (1) will be known.

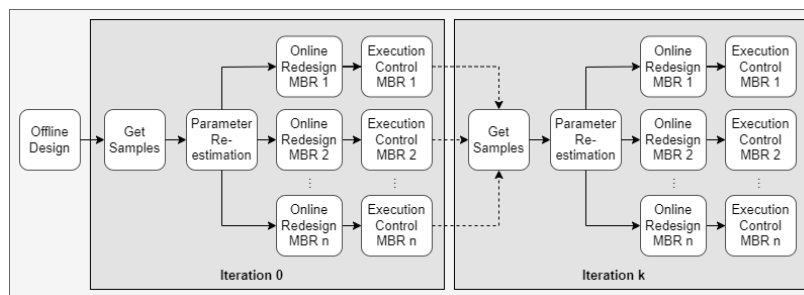

Figure 3. The Bayesian hierarchy with belief propagation as an Airflow pipeline.

#### 4. Case study

The proposed method was tested using artificial data generated based on the model proposed in Nickel et al. (2017), consisting of six differential equations and eighteen parameters. Eight MBRs for *Escherichia coli* fed-batch cultivations were run over a six-hour period. Samples are taken every thirty minutes and biomass ( $X$ ), glucose ( $Glc$ ) and acetate ( $Ac$ ) concentrations are measured at-line, whereas the dissolved oxygen tension ( $DOT$ ) in each MBR is measured continuously using an online sensor. Based on new data, the sequence of glucose pulses for each MBR are computed to implement model-based optimized feeding strategies (see Fig. 2) so that the experiment is redesigned online to maximize the information content. The aim of the experimental design is to find *a posteriori* an optimal feeding profile that maximizes the amount of biomass obtained at the end of the run and prevents the  $DOT$  to drop below 20% throughout. For details regarding all the assumptions, models, software packages, parameters and hyper-parameters used to implement the automation hierarchy, the reader is referred to the repository:

<https://git.tu-berlin.de/bvt-htbd/kiwi/tf2/experimental-computational-workflows/-/tree/escape>

Once the parallel eight experiments have been completed, the probabilistic model is the updated using the complete data set. The Bayesian nature of the resulting probabilistic model allows for a chance-constrained formulation of the optimization problem

$$u^* = \operatorname{argmax}_{u \in \mathcal{U}} E[m_{X,end}] \quad (2.1)$$

$$\text{Subject to } \Pr(DOT_{min} > 20) > 95\% \quad (2.2)$$

where  $m_{X,end}$  is the biomass amount obtained (in g/L) at the end of a testing experiment and  $DOT$  is in percentage of saturation. The decision variables are the duration of the batch phase and the feeding profile. Some results obtained using the *posterior* parameter distributions are shown in Fig. 4 to highlight the effectiveness of the proposed approach.

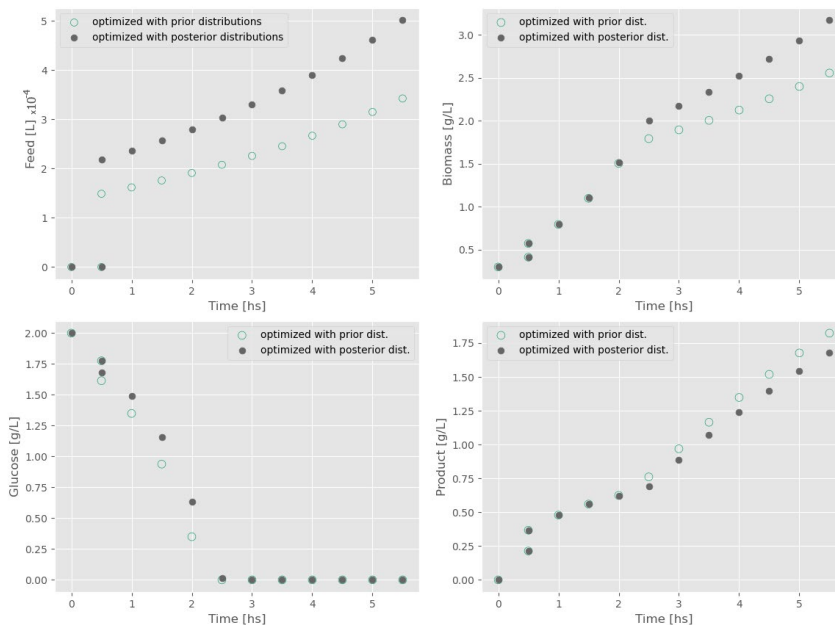

Figure 4. Feed rate optimization with prior and posterior distributions compared.

As it is shown, the *a priori* optimized feeding profile is more cautious than the one with the probabilistic model using the *a posteriori* distributions of model parameters. For the later, a higher amount of biomass is obtained which is aligned with the experiment objective which bias data gathering in the operating region where biomass is maximized whereas the dissolved oxygen tension is safely kept above the threshold value of 20% during the optimized run. The effect of data bias is clear in Fig. 5 which describes the evolution of the distributions of some sensitive model parameters as the iteration count  $k$  increases. The parameter distributions for Iter. #1 are the priors before the experiment.

Figure 5. Evolution of two distributions of model parameters during the experiment.

## 5. Concluding remarks

A new automation hierarchy for closing the loop in high-throughput robotic platforms was proposed. The implementation of the hierarchy in Apache Airflow makes possible to reproduce the computational experiments and make sampled data FAIR. Finally, the asynchronous belief propagation algorithm in Fig. 2 is best suited for parallel processing.

## Abstract

Genome-scale metabolic models (GSMMs) and flux balance analysis (FBA) have been extensively used to model and design bacterial fermentation. However, models that can simulate co-culture fermentation dynamically with quantitative accuracy are relatively scarce. To investigate metabolic interactions in yogurt starter culture of *Streptococcus thermophilus* (ST) and *Lactobacillus delbrueckii subsp. bulgaricus* (LB), this study built a dynamic community-level metabolic model based on metagenomic data. We first assessed the quality of the model by comparing the predicted growth curve with reference experimental data, and then used it to simulate the impact of different initial ST:LB ratios and search for the optimal composition of starter culture for efficient acidification for yogurt fermentation. The modeling pipeline presented in this work provides a basis for an efficient tool for computer-aided process design of the production of fermented dairy products, contributing to the development of precision fermentation in the food industry.

**Keywords:** Metagenomics; Fermentation; Flux balance analysis; Genome scale metabolic model; Proteome allocation.

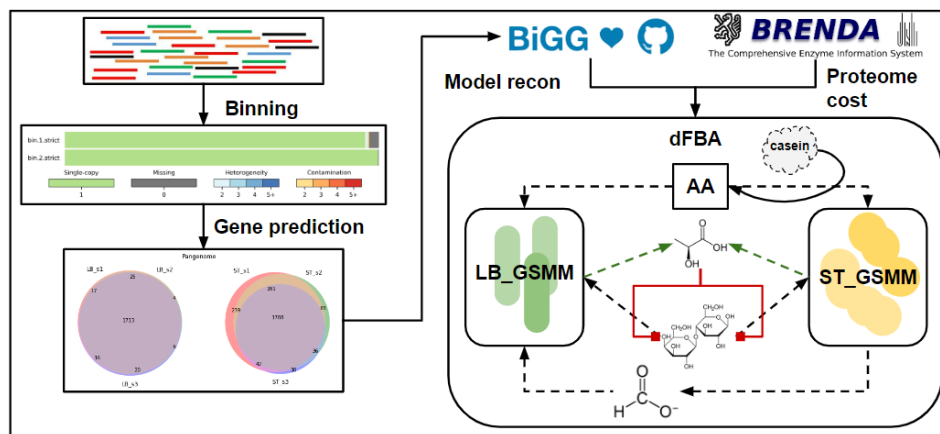

## 1. Introduction

Yogurt is an important fermented dairy food, traditionally made by lactic acid bacteria (LAB). In industrial production of yogurt, the control of the fermentation process, in terms of acidification and flavor/probiotic compound production, largely depends on the composition of the starter culture. To investigate and engineer the microbial community of yogurt starter culture, a community-level metabolic model of LABs used in the production of yogurt is needed. Currently, several genome scale metabolic models (GSMMs) for dairy-origin LABs have already been reconstructed, and a dynamic co-culture metabolic model for cheese starter culture using those GSMMs has been built (Özcan et al., 2021). However, there is still a lack of metagenome-scale metabolic models (different from GSMMs of certain strains) that can simulate the growth and metabolism of the actual (as opposed to an assumed) LAB community in yogurt fermentation.

Furthermore, existing models could not simulate unique inter-species interactions in yogurt fermentation. In this work, we built a dynamic community-level metabolic model with reconstructed GSMMs of major species identified in the starter culture, i.e., *Streptococcus thermophilus* (ST) and *Lactobacillus delbrueckii subsp. bulgaricus* (LB), using the information obtained from metagenomic analysis. We then showed how the model can be used to design the control strategy of the yogurt fermentation process.

## 2. Methodology

Building the dynamic community-level metabolic model of the yogurt starter culture comprised two steps: 1. from metagenome to annotated protein coding genes; 2. from coding genes to GSMMs (**Figure 1**). With GSMMs, dynamic flux balance analysis (dynamic FBA, or dFBA) was implemented to simulate bacterial growth and metabolism.

**Figure 1.** the workflow diagram of metabolic modeling from metagenomic analysis to GSMM reconstruction and dFBA.

### 2.1. Metagenome assembly, binning, and protein coding gene identification

Three parallel DNA samples of the commercial yogurt starter culture were sequenced by Illumina PE150. Reads were filtered for high quality ones, and then assembled by MEGAHIT.

MetaBAT2, MaxBin2 and CONCOCT were used to obtain individual genomes from the assembled metagenome. Bins were then processed using refinement and reassembly modules in metaWRAP. The final outputs are individual genomes of high quality, assessed by CheckM. GTDB-Tk performed taxonomic classification for refined individual genomes to identify major species.

Protein-coding gene prediction for each individual genome was done by Prodigal, generating the nucleotide sequence and translated protein sequence of each gene. Then, functional annotation provided information on cellular pathways, carbohydrate active enzymes and biosynthetic gene clusters.

### 2.2. Reconstruction of genome-scale metabolic models

Non-redundant protein sequences were filtered from concatenated protein sequences of different samples and used as the input for automatic GSMM reconstruction by CarveMe.

In addition to protein sequences, other inputs were chemically defined media (CDM) for gap filling and the universal bacterial template. The CDM was adopted from the co-culture metabolic model of cheese starter (Özcan et al., 2021). The universal bacterial template used for reconstruction was specialized for gram-positive bacteria.

The growth function (normalized to be the formation of 1gDW biomass) was adjusted based on biomass composition reported in previous studies and existing GSMMs of the same species. The non-growth associated ATP maintenance was set to be 0 to avoid infeasible solutions. Based on functional annotation of coding genes and existing GSMMs, reactions included erroneously were removed and missing reactions were added. In addition, to model the proteolysis activity in the co-culture system, a self-defined reaction decomposing casein protein into amino acids was added to the GSMM:

Stoichiometric coefficients in the proteolysis reaction were approximated from average amino acid distribution in the casein protein.

### 2.3. *Dynamic flux balance analysis and proteome allocation constraint*

To simulate the growth of bacteria and the production of target metabolites in time, dFBA was adopted (Mahadevan et al., 2002). The intracellular metabolic fluxes,  $v_j$ , were computed by parsimonious FBA, maximizing the growth rate while minimizing the total sum of fluxes, based on the assumption that the cell minimizes the use of enzyme catalyzed reactions due to limited recourse (Eqs. 1, 2), subject to mass conservation (Eq. 3), in which  $S_j$  represented the stoichiometric matrix. Inter-species exchanges were not modeled directly, the concentration change of metabolites and biomass in the extracellular space was modeled by differential equations to account for biomass accumulation (Eq. 4) and exchange fluxes of metabolites  $M$  from major species (Eq. 5).

$$\text{Maximize } v_{j,Growth} \quad \forall j \in \text{major species} \quad (1)$$

$$\text{Minimize } \sum_{i=0}^{\#reactions} v_{j,i} \quad (2)$$

$$S_j v_j = 0 \quad (3)$$

$$\frac{d[Biomass_j]}{dt} = v_{j,Growth} [Biomass_j] \quad (4)$$

$$\frac{d[M]}{dt} = \sum_{j=0}^{\#species} v_{j,EX\_M\_e} [Biomass_j] \quad (5)$$

Furthermore, proteome allocation was implemented to constrain reaction fluxes of central metabolism to model the flow of carbon source uptake (Zeng et al., 2020). Proteome was divided into sectors of inflexible housekeeping (Q), anabolism (A), transportation (T), catabolism (C), and the free sector. The upper bound of all flexible sectors combined was assumed to be 50% of the total proteome (Eqs. 6, 7). The proteome cost on each reaction was computed as the flux divided by the multiplicative product of enzyme activity,  $a_i$ , and saturation degree,  $\sigma_i$  (Eq. 8). The saturation degrees,  $\sigma_i$ , were assumed to be 0.5, except

for the lactose transporter, which was considered as fully saturated by abundant lactose,  $\sigma_{LT} = 1$ . The activity of the ribosome,  $a_{ribosome}$ , for the anabolism sector was adopted from literature (Regueira et al., 2020). Other enzyme activities were obtained from BRENDA Enzyme Database. For the transportation of amino acids, the flux was constrained by michaelis-menten equation ( $v_{max} \frac{[S]}{[S]+K_m}$ ), average  $v_{max}$  and michaelis-menten constant  $K_m$  were set based on parameters obtained from BRENDA and SABIO-RK.

$$\frac{P_{tot}}{1 \text{ gDW}} = p_Q (\sim 50\% \frac{P_{tot}}{1 \text{ gDW}}) + p_C + p_A + p_T + p_{Free} \quad (6)$$

$$0 < p_C + p_A + p_T \leq 50\% \frac{P_{tot}}{1 \text{ gDW}} \quad (7)$$

$$p_C = \sum \frac{v_i}{\sigma_i a_i}; p_A = \frac{v_{Growth}}{a_{ribosome}}; p_T = \frac{v_{LT}}{\sigma_{LT} a_{LT}} + \frac{v_{lacT}}{\sigma_{lacT} a_{lacT}} + \frac{v_{act}}{\sigma_{act} a_{act}} \quad (8)$$

The activity of lactose uptake incorporated inhibition by undissociated lactate (LacH), the final product of glycolysis in anaerobic conditions. The exponential decay equation (Eq. 9) to model the inhibition of lactose transporter activity was adopted from Bouguettoucha et al. (2011). The concentration of undissociated lactate was computed with Henderson-Hasselbalch equation (Eq. 10), and pH was approximated as a linear function of lactic acid concentration,  $pH = C_1[Lac] + C_2$ .

$$a_{LT} = a_{LT}^0 e^{(-k_{LacH}[LacH])} \quad (9)$$

$$[LacH] = \frac{[Lac]}{10^{pH-pK_a}} \quad (10)$$

### 3. Results

#### 3.1. Major species identified and status of reconstructed GSMMs

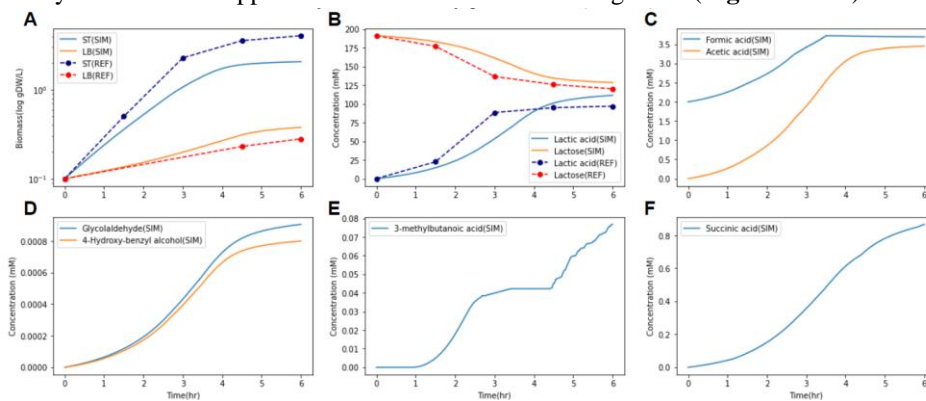

The taxonomic classification revealed that *Streptococcus thermophilus* (ST) and *Lactobacillus delbrueckii subsp. bulgaricus* (LB) were two major species in the starter culture. After binning and refinement, individual genomes of ST and LB showed good completeness and low level of contamination. There were 2499 and 1801 non-redundant protein coding genes predicted from ST and LB's genomes. In reconstructed GSMMs, reactions assigned with gene-protein-reaction relations were around 60% in both models. About 25% gap-filled reactions were added into the model for a complete metabolic network. The rest were boundary reactions for metabolite exchange.

#### 3.2. Simulation of growth and metabolism of ST/LB co-culture during yogurt fermentation

To assess the predictive power of the dynamic community-level metabolic model, dynamic simulation was performed using initial conditions of the fermentation system from reference data (Oliveira et al., 2012). For the biomass of ST and LB, the initiation

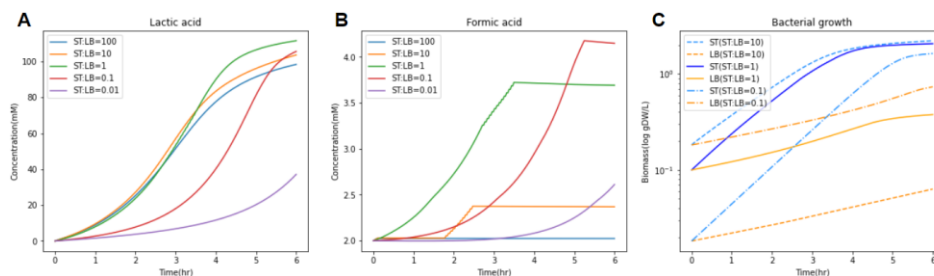

of exponential phase and transition to stationary phase were adequately captured by the model (**Figure 2A**). Besides, our model also predicted the consumption of lactose and production of lactic acid with fairly good accuracy (**Figure 2B**).

In addition to lactic acid, acetic and formic acids are also important fermentative products of glycolysis. The predicted concentration curve of acetic acid showed a similar trend with that of lactic acid (**Figure 2C**). The accumulation of formic acid produced by ST initiated the exponential growth of LB, as it activated LB's synthesis of purine, whose concentration was low in milk. In return, the activation of growth and metabolism of LB with strong proteolytic activity enhanced the growth of ST by supplementing amino acids and small peptides, which was also limited in milk (**Figure 2AC**). Apart from end products of glycolysis, the model also predicted the secretion of glycolaldehyde, 4-hydroxy-benzyl alcohol, 3-methylbutanoic acid and succinic acid, among which 3-methylbutanoic acid appeared unassociated with cellular growth (**Figure 2DEF**).

**Figure 2.** Model predictions of growth and metabolism of ST/LB co-culture during yogurt fermentation (solid line: simulation results, dashed line: reference experimental data; simulation results were obtained with a ST to LB ratio of 1, both 0.1g/L).

**3.3. Prediction of the impact of different ST:LB ratio on the fermentation behavior**  
 Perturbations on the initial ratio of ST and LB in yogurt starter culture was conducted to investigate its impact on the fermentation behavior and search for the optimal starter culture composition. The simulated concentration profile of lactic acid indicated that the acidification rate (the rate of lactic acid accumulation) by starter cultures of different ST:LB ratios ranked as follows: ST:LB = 1 > ST:LB = 10 > ST:LB = 100 > ST:LB = 0.1 > ST:LB = 0.01 (**Figure 3A**). When the acidification rate is selected as the sole objective to maximize, an optimal ST:LB ratio is predicted to be between 1 and 10. The concentration profiles of formic acid and growth curves for different ST:LB ratios showed that LB's exponential growth would be activated when formic acid accumulated to a certain level (**Figure 3BC**). The supplement of nitrogen source (amino acids and small peptides) by LB was also necessary for ST. When ST:LB increased from 1 to 10, the proteolytic activity became weaker due to the lower biomass of LB, and thus the growth of ST was inhibited, leading to reduced acidification achieved in 6 hours.

**Figure 3.** Simulation of yogurt fermentation by starter cultures of different ST:LB ratios (from 100 to 0.01, fixed total starting biomass of 0.2 g/L).

#### 4. Conclusion

Overall, this work presented the metabolic reconstruction of the classical yogurt starter culture, i.e., ST and LB, and provided a dynamic community-level GSMM modeling approach. The proposed model is able to capture the bacterial growth, the acidification of yogurt via lactic acid and predict active fluxes of flavor compounds like acetic acid, methyl butanoic acid and succinic acid during the yogurt fermentation process. Although several limitations remain to be overcome (e.g., the lack of calibration with experimentally determined biomass composition and ATP requirements), the model was shown to have the potential to offer an efficient tool to guide engineering decisions in the food industry, which could be used to address issues such as the optimal initial biomass ratio of ST and LB to maximize the rate of acidification and possibly other process targets.

## Abstract

Microbial cell population balance models are used because of culture heterogeneity due to complex intercellular phenomena governed by cell growth, substrate utilization, and product formation. To solve these models, an efficient multilevel system approach based on conservation of cell distribution moments is introduced. This conservation is propagated along the characteristic curves of these hyperbolic conservation laws. This is assured by the careful design of numerical discrete schemes that pass the conserved discrete information from the initial state to its final extracellular state. The discrete model on each layer is derived with a guarantee to satisfy the conservation of cell total number and the mean cell biomass. Many reference solutions based on the Chebyshev-QMOM, the maximum entropy method, and the Lax-Wendroff finite difference scheme are used to validate the developed model. When compared to these methods, the model exhibits extreme accuracy and rapid convergence at a low CPU time cost.

**Keywords:** Microbial cells; Population Balances; Multilevel; Discrete modelling.

## 1. Introduction

The continuous population balance equation (PBE) with particle nucleation, growth, and breakage is a nonlinear integral-partial differential equation. For microbial cell cultures, the PBE presents a framework to describe the complex phenomena manifested by cell growth, division, substrate utilization, and product formation. With no general analytical solution, this calls for numerical modeling to understand the cell culture behavior and to predict, optimize, and control cell growth in biochemical reactors (Mantzaris et al., 2001; Ramkrishna et al., 2014; Jerono et al., 2021).

Figure (1): Left-Multilevel system discretization approach for microbial cell dynamics. Right-system characteristic curves as predicted by ChQMOM using 7 quadrature nodes.

Since the heterogeneity of microbial cultures results from cell size and its intercellular concentrations of DNA, we confine ourselves to the mono-variate cell probability density

function  $f(x, t)$  with cell mass ( $x$ ) as its internal coordinate. These cells are embedded in a continuous extracellular environment with a single substrate ( $S$ ) (Durr & Buk, 2020; Jerono et al., 2021). Our numerical modeling method for this system starts by introducing a multilevel discrete approach that is evolved in five evolutionary layers, as shown in Fig. 1. This layer structure reflects the hyperbolic nature of the discrete conservation and population balance laws. The first layer in Fig. (1-Left) shows the initial conditions and the external feeds, which are considered an essential part of the internal inconsistency problem arising from the transformation of the continuous PBE into its discrete form. This is to prevent the propagation of internal inconsistency along the characteristic lines (Fig. 1-Right) associated with the growth, division, and extracellular information exchange layers, which if ignored would increase the computational cost. To explain this, given a discrete initial state vectors with cell boundaries  $x$  and centers  $\chi$  which satisfy  $x_i < \chi_i < x_{i+1}$  and initial cell population number concentration  $N_i(0)$ ,  $i = 1, 2, \dots, M$ . In this discrete framework, the integral properties such as total cell number and mass will never be the same as those calculated from its continuous probability density function except for only one integral property (Ramkrishna, 2000). For example,  $N_i(0) = \int f(x,0)dx$  but  $\sum x_i N_i(0) + \varepsilon = \int x f(x,0)dx$  where  $\varepsilon$  is called the error of moving the state from its continuous to its discrete states. Unfortunately, this error is of cumulative nature and is propagated from the initial state layer to the higher layers with increasing amplitude. Its elimination needs infinitely large number of discrete states of uniform grid:  $x_i = ix_{\min}$ . However, this error can be eliminated for two selected integral properties starting from the initial state layers and moving forward to the growth and division layers. As the total number and mass are the two most important cell transport properties, we derive our discrete PBEs that satisfies these properties in each layer within this multilevel approach as shown in Fig.(1-Left).

## 2. Mathematical model

The heterogeneity of the cell population is adequately modelled using the population balance equation (Ramkrishna, 2014). In this equation, the cell density function  $f(x,t)$  accounts for variances in the cell population in a homogeneous physical space (CSTR):

$$\frac{\partial f(x, t)}{\partial t} + \frac{\partial [G(x, t)f(x, t)]}{\partial x} = -D(t)f(x, t) + R\{f(x, t), S\} \quad (1)$$

where  $x$  is the physiological state of single cell (biomass components) which depends on the intercellular growth rate  $G(x,S)$ , where  $S$  is the single substrate concentration in the extracellular continuous medium, and  $D$  is the dilution rate.  $R$  is a volumetric source which represents the net number of cells per unit biomass volume due to birth of cells with the physiological state  $x$  because of binary division of all mother cells of size  $y$ :

$$R\{f(x, t), S\} = -\Gamma(x, S)f(x, t) + 2 \int_x^{x_{\max}} \Gamma(y, S) \beta(x, y) f(y, t) dy \quad (2)$$

In this equation  $\Gamma(x,S)$  is the cell division rate and  $\beta(x,y)$  is the cell partition probability function for a daughter cell of physiological state  $x$  given a mother cell of state  $y$ . This function should satisfy the mass and number conservation conditions as well as the symmetrical properties (Ramkrishna, 2000). The cell PBEs (1) and (2) are coupled with the dynamic abiotic environment through the substrate mass balance as shown by Eq.(3). In this equation the source term represents the net flow of substrate through reactor boundary along with the total loss of substrate as utilized by the microbial cells.

$$\frac{dS}{dt} = D(S_f - S) - \int_{x_{\min}}^{x_{\max}} q(x, S) f(x, t) dx \quad (3)$$

$$q(x, S) = \frac{1}{Y} \left( \frac{\mu_{\max} S}{K_s + S} \right) x \quad (4)$$

In these equations  $q(x, S)$  is single cell consumption rate of a substrate ( $S$ ),  $Y$  is a constant biomass product yield,  $\mu_{\max}$  is the maximum growth rate and  $K_s$  is the half saturation substrate concentration. The growth rate is given by  $G(x, S) = Yq(x, S)$ , and  $\Gamma(x, S) = \gamma(x)G(x, S)$  where  $\gamma(x)$  is expressed in terms of Gaussian probability density function (Mantzaris et al., 2001). The initial conditions are  $f(x, 0) = f_0(x)$  and  $S(0) = S_0$  while  $S_f$  is the substrate feed concentration and the boundary condition is  $f(x_{\min}, t) = f(x_{\max}, t) = 0$ .

### 3. Multilevel model discretization

A multilevel model discretization approach that is consistent with that shown in Fig.(1-Left) is used here to ensure the consistency of the discrete model when compared to the continuous one as given by Eqs.(1-4).

#### 3.1. Level 1: Initial conditions and feed discretization

The cell internal property is discretized into  $M$  contiguous numerical cells with geometric progression  $x_i = x_{\min}[r]^{i/M}$ , with  $r > 1$  and cell centers  $\chi_i = (x_i + x_{i+1})/2$ ,  $i = 0, 1, \dots, M$ .

$$N_i^0 = \alpha_0 N_i(0) + \beta_0 N_{i+1}(0), i = 0, 1, \dots \quad (5)$$

where  $\alpha_0$  and  $\beta_0$  are solutions of two linear equations to conserve the zero and first moments of the cell number concentration functions  $f_0(x, 0)$  and  $f_1(x, 0)$  in which 0 refers to the initial condition and 1 refers to the inlet feed distribution. This is a crucial step in this multilevel discrete framework to avoid the propagation of any discrete error along the characteristic lines of the system of Eqs. (1-4).

#### 3.2. Level 2: Cell growth

$$\frac{dN_i(t)}{dt} = \frac{2}{x_i} \frac{1}{r^2 - 1} (G(\chi_i, S)N_i(t) - rG(\chi_{i-1}, S)N_{i-1}(t)), i > 0 \quad (6)$$

At this level, the discrete cell growth needs to guarantee the conservation of total number and mass concentrations using a new first order upwind scheme as given by Eq.(6). This conservation law can handle smooth and discontinuous numerical fluxes with suitable flux-vector splitting depending on the sign of  $G(\chi, S)$  where  $r = [x_{\max}/x_{\min}]^{(1/M)}$ .

#### 3.3. Level 3: Cell division

$$\frac{dN_i(t)}{dt} = -\eta_i \Gamma(\chi_i, S)N_i(t) + \sum_{j=0}^M \sigma_j \Gamma(\chi_j, S)\pi_{i,j}N_j(t), i = 0, 1, \dots, M \quad (7)$$

This equation is the discrete counterpart of Eqs.(1) and (2) without growth term where the loss and formation terms in Eq.(7) are modified by placing the two discrete functions ( $\eta$  and  $\sigma$ ) to conserve exactly the zero and first moments of the cell population. This ensures passing the conserved information to higher levels without errors induced by the inconsistency problem. The two functions  $\sigma$  and  $\eta$  tends to unity as the grid is refined showing the consistency of these functions with the mean-value theorem of integrals over

$\beta(x,y)$ . The discrete function  $\pi_{i,j}$  calculates the total  $i^{\text{th}}$  fraction of daughter cells at any given mother of size  $y_j$ .

### 3.4. Level 4: Extracellular dynamics

$$\frac{dS(t)}{dt} = D(t)(S_f - S) - \sum_{j=0}^M q(\chi_j, S) N_j(t), i = 0, 1, \dots, M \quad (8)$$

This level provides a gate to pass the conserved discrete information from level 4 to the cell continuous environment and then returns any information from the continuous phase to the discrete one. The final discrete solution is then recovered at any time step as  $n(\chi_i, t) = N_i(t)/\Delta x_i, \forall i, i = 0, M$ .

## 4. Results and discussion

The multilevel discrete model that is given by Eqs.(5-8) provides a complete set of ODEs supplemented by consecutive equations for cell division rate, cell partition probability function, and cell intercellular growth rate.

Table (1): Parameters for test problem 2 as reported by Mantzaris et al. (2001).

$\mu_{\max}$	$K_s$	$Y$	$D$	$S_f$	$S_0$	Gaussian I.C.	
1.0/h	0.2 g/L	0.5 g/g	0.5/h	10 g/L	2 g/L	$\mu_0$	$\sigma_0$
Gaussian division probability function				$\mu_1 = 0.575$	$\sigma_1 = 0.125$	0.2875	0.0675

The initial condition and the cell division probability functions are taken as Gaussian densities with mean and standard deviations as shown in Table (1). The cell partition probability function is taken as a beta distribution:  $\beta(x, y) = c(q)y^{-1}(x/y)^{q-1}(1 - x/y)^{q-1}$  where  $c(q)$  is normalization factor and  $q = 40$  (Mantzaris et al., 2001).

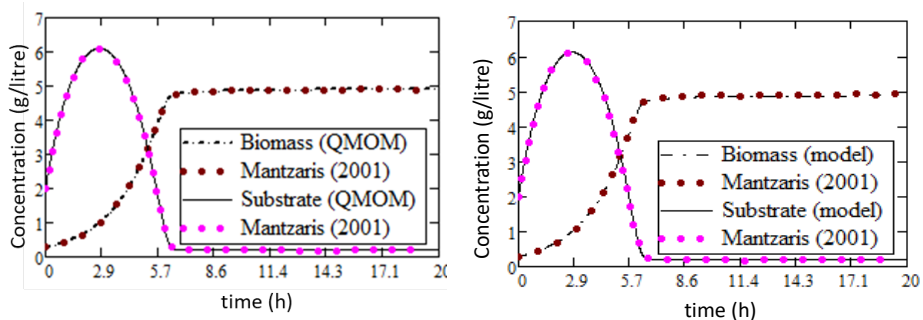

Figure (2): Dynamics of cell growth and division in a CSTR using Chebyshev-QMOM, the Lax–Wendroff scheme (Mantzaris et al., 2001, Toro, 1999) and the present multilevel discrete model.

### 4.1. Reference solutions

To validate the multilevel discrete model in terms of the conserved moments; namely, the zero (total cell number) and first moments (total cell mass) of the discrete cell distribution, two standard methods are used: The first one is the Chebyshev-QMOM (Upadhyay, 2012) and the conservative finite difference scheme FDS (Mantzaris et al., 2001). The Chebyshev-QMOM (ChQMOM) is superior to the standard QMOM which is based on the Product Difference Algorithm (PDA), and the Direct Quadrature Method Of Moments

(DQMOM) where ill-conditioned linear system of equations is encountered when the number of the quadrature nodes increases.

4.1.1. Chebyshev-QMOM reference solution

The system of Eqs.(1-5) can be written in compact form in terms of the moments of  $f(x,t)$  where the unclosed integrals are approximated using the Chebyshev-QMOM. The cell internal property integration domain is  $\Omega = [x_{min}, x_{max}] = [0, 1]$  where the resulting system of ODEs was solved using the explicit Adams-Bashforth method with error tolerance =  $10^{-3}$  and number of quadrature nodes  $N_q$  equals to seven.

4.1.2. Mantzaris et al. (2002) reference solution

The second reference solution for Eqs.(1-5) is regenerated from the work of Mantzaris et al. (2001) using conservative discretization finite difference schemes for a system of hyperbolic conservation laws. The results from the Lax-Wendroff scheme are generated with the same numerical parameters as shown in Table (1). The results are displayed in Fig.(2) where the number of numerical cells used by this scheme is 500.

4.1.3. Comparison of the present model predictions with reference solutions

Firstly, we compared the substrate and biomass dynamics as predicted by the ChQMOM and the reference solution of Mantzaris et al. (2001). The results are found indistinguishable using seven quadrature nodes which is obvious from the results shown in the left panel of Fig.(2). This result is not surprising since the ChQMOM is well-known for its high accuracy in predicting distribution moments (Attarakih et al., 2012, 2014). Secondly, and as gaining trust in the solution of the present model, the multilevel discrete model (Eqs.(5-8)) is solved in time using the explicit Adams-Bashforth method with error tolerance =  $10^{-3}$  and number of grid points  $M=50$ . To ensure the correct propagation of information along the hyperbolic laws characteristic curves (Fig.(2-Right)), the Gaussian I.C. with parameters given in Table (1), is discretized according to the scheme shown in Eq.(5). This solution conserves exactly the total number and mass concentrations.

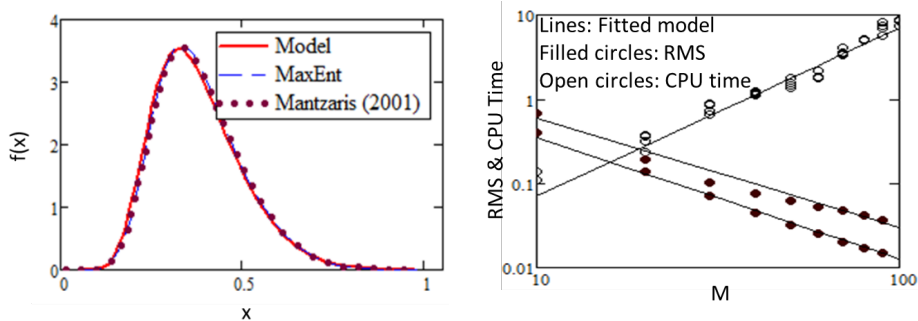

Figure (3): Left-Converged cell distribution. Right- CPU time (s) denoted by open circles and RMS (Root Mean Square) error in zero and 1<sup>st</sup> moment of cell distribution (Filled circles).

Starting from the first layer (see Fig.(1-Left)) and for  $M = 50$ , the factors  $\alpha_0$  and  $\beta_0$  are found to be 0.99 and 0.01 respectively. This means 99.0 percent of the discrete population is assigned to the  $i^{\text{th}}$  numerical cell center while only 1.0 percent is assigned to the next larger numerical cell center. This ensures the correct prediction of the population moments even if low number of numerical cells is used (e.g. 15). Based on this, the cell growth layer conserves exactly zero and first moments of the cell distribution which are then propagated correctly to the cell division layer in spite of the numerical diffusion associated with the used first-order upwind schemes (Toro, 1999). In the cell division layer, and as implied by Eq.(7), the computation of the two correction functions ( $\eta, \sigma$ )

are computed offline and are found to depend on the cell cell partition distribution function ( $\beta(x,y)$ ) and the numerical grid structure. Once these correction vectors are available, the cell division is advanced in time and is then propagated to the extracellular dynamic layer without loss of any global information because of discretization. As a result of this system conservation approach, the biomass and substrate utilization are correctly predicted by our model as compared to the two reference solutions mentioned in sections (4.1.1 and 2). This is clear by referring to the right panel of Fig.(2). In a second level of validation, our model is compared with the FDS of Mantzaris et al (2001) and the Maximum Entropy (MaxEnt) method of Attarakih and Bart (2014) to predict the cell population distribution. Our present model converges rapidly to the FDS and the MaxEntM as the number of numerical cells increases. In Fig.(3)-Left, we used  $M = 50$  as compared to the FDS solution using 500 numerical cells. On the other hand, five moments are used in the MaxEnt method to reconstruct the distribution at final time of 20 hrs. To quantify the convergence characteristics of the present model, the RMS error is calculated using the zero and first moments of the distribution as function of  $M$ . Fig.(3)-Right shows rapid decrease in the RMS as function of  $M$  with approximate order of  $O(M^{-0.4})$ . Concerning the computational cost of the present discrete model, and as can be seen from Fig.(3)-Right, the mean CPU time (four runs are used per  $M$  value) is increasing as  $O(M^2)$ .

## 5. Summary and conclusions

To conclude, the present multilevel discrete model is yet simple, with equations that are elegant in structure, efficient in implementation, and that handle the cell culture dynamics with high accuracy. These equations conserve the propagated information along the characteristic lines of the hyperbolic conservation laws through a hierarchical structure. When compared to the QMOM and the FDS, the present model converges rapidly as the number of numerical cells is increased. With more than four quadrature nodes, the present model computational cost is lower than that of the FDS or the ChQMOM.

## Abstract

We develop a machine learning framework that integrates high content/high throughput image analysis and artificial neural networks (ANNs) to model the separation between chemical compounds based on their estrogenic receptor activity. Natural and man-made chemicals have the potential to disrupt the endocrine system by interfering with hormone actions in people and wildlife. Although numerous studies have revealed new knowledge on the mechanism through which these compounds interfere with various hormone receptors, it is still a very challenging task to comprehensively evaluate the endocrine disrupting potential of all existing chemicals and their mixtures by pure *in vitro* or *in vivo* approaches. Machine learning offers a unique advantage in the rapid evaluation of chemical toxicity through learning the underlying patterns in the experimental biological activity data. Motivated by this, we train and test ANN classifiers for modeling the activity of estrogen receptor- $\alpha$  agonists and antagonists at the single-cell level by using high throughput/high content microscopy descriptors. Our framework preprocesses the experimental data by cleaning, scaling, and feature engineering where only the middle 50% of the values from each sample with detectable receptor-DNA binding is considered in the dataset. Principal component analysis is also used to minimize the effects of experimental noise in modeling where these projected features are used in classification model building. The results show that our ANN-based nonlinear data-driven framework classifies the benchmark agonist and antagonist chemicals with 98.41% accuracy.

**Keywords:** machine learning, artificial neural networks, estrogenic potential, high throughput analysis, nonlinear classification.

## 1. Introduction

There is a wide array of naturally occurring and synthetic chemical substances that interfere with the endocrine system and cause detrimental developmental, reproductive, neurological, and immunological consequences in humans which are referred to as

endocrine disrupting chemicals (EDCs). The interaction of these substances with the estrogen receptor (ER) ligand binding domain induces the activation or blockage of the biological response, known as an agonist or antagonist chemical, respectively. Thus, rapid and accurate endocrine disrupting potential identification is a crucial task in environmental risk assessment.

By observing the mechanistic endpoints in the ER signaling pathway, it is possible to assess the estrogenic potential of various substances using cell-based or cell-free assays. While these approaches can be used to accurately assess a small number of substances, evaluating tens of thousands of chemicals and their mixtures becomes quickly infeasible. On the other hand, the availability of larger data sets from high throughput experimentation, increased computing capabilities, and cutting-edge machine learning models such as deep neural networks that can be trained to capture highly nonlinear behaviors in datasets make it possible to mathematically model and predict the expected biological activity of any chemical compound with prompt function evaluations.

Previous studies by Chierici et al. (2019) and Collins and Barton-Maclaren (2022) investigated a variety of machine learning models, including Support Vector Machines (SVMs), Random Forest (RF), ANNs, for predicting the ER potential of chemicals in binary and/or multi-class classification settings. However, the predictive performance of these studies has suffered from relatively low predictive balanced accuracies in certain blind testing sets with wide performance margins ranging from 59% to 93%.

In our earlier studies, we also presented a framework to categorize chemicals according to their ER activities using population-averaged high content imaging data. By analyzing different subsets of feature groups using correlation analysis, we formulated linear (Logistic Regression) and nonlinear classification models (RF) that achieved an accuracy of more than 90% on the benchmark chemicals (Mukherjee et al., 2020). Subsequently, we integrated RF and SVM algorithms with the single-cell ER data, where characteristic shape features of the non-central gamma distribution that were used to fit the cell populations (alpha, beta, and gamma) were used as descriptors in our predictive models (Ganesh et al., 2021). Most recently, we demonstrated a predictive modeling pipeline for the endocrine disrupting potential identification that directly uses the single-cell level information, along with principal component analysis, and SVM and RF classifiers (Aghayev et al., 2022). We were able to show that the SVM model classifies unseen testing chemicals with more than 96% accuracy and data preprocessing plays a key role in achieving favorable performance from the trained classifiers.

Different than our previous studies, here, we are proposing an ANN-based predictive modeling framework that will further improve the classification accuracy and sensitivity of the separation between agonist and antagonist chemicals using single-cell level data. By further incorporating a feature selection routine based on the Fowlkes-Mallows (FM) Index in the analysis pipeline, we analyze smaller feature subsets of the high-dimensional experimental data and quantify the predictive performance of the final models using standard evaluation metrics.

## 2. Methods and Materials

### 2.1. Experimental Methodology

Sixty reference EDCs with known ER $\alpha$  activities are analyzed with an engineered biosensor to collect the image-based high content data. The studied compound library contains 32 agonists with different activity levels (very weak, weak, moderate, strong), 15 antagonists, and 13 inactive chemicals. To record the estrogenic activity of these

reference chemicals, biosensor cells were treated with varying concentrations of the chemicals for two hours, and high-throughput microscopy and image analysis pipelines detailed in Ashcroft et al. (2011) are followed. This analysis yielded 70 size, shape, and intensity attributes that relate to the various mechanistic endpoints on the ER signaling pathway with measurements recorded for every single treated cell (Szafran et al., 2017). Further details of the experimental data generation, processing, and quantification are provided in Aghayev et al., 2022.

## 2.2. Computational Methodology

### 2.2.1. Data Preprocessing

Once the multidimensional imaging data were generated and standardized using robust z-score, we conducted percentile analysis over cells that have visible nuclear spots (receptor-DNA binding, array positive cells). The goal of this step is to expand the dataset with engineering features that will potentially enable a better separation than the raw descriptors. We previously explored different percentile ranges and their effects on nonlinear classification algorithms (Aghayev et al., 2022). Based on our findings, only single-cell features that fall into the middle percentile (between 25<sup>th</sup> and 75<sup>th</sup> percentiles) were preserved and the dataset size was decreased from 165,525 to 22,286 observations.

The produced dataset was then put through missing data check and rigorous cleaning steps, where cell data representing the inactive compounds and control treatments were eliminated from the analysis. As a result, we end up with a preprocessed dataset size of 9420 observations  $\times$  36 features prior to the feature selection phase.

### 2.2.2. Feature Selection via Clustering Analysis

We used clustering analysis to identify promising subsets of the original features that will facilitate the separation of agonist and antagonist compounds. To this end, we created 11 different feature groups that capture different compartments and characteristics of the measured cells (e.g., cytoplasm, nucleus, nucleoplasm, shape, etc.), including the full set of features. We then performed hierarchical clustering on the mean cell response of each active compound and selected feature subsets using Euclidean distance and complete linkage. Each clustering dendrogram is then compared to a synthetic “ideal” cluster, where this cluster shows perfect separation between agonistic and antagonistic compounds. The cluster similarity of the subset features and the ideal dendrogram is quantified using the FM index (Onel et al., 2019). FM index evaluates the similarity between two dendrograms using the geometric mean of precision and recall (Eq. 1).

$$FM = \sqrt{\frac{TP}{TP + FP} \cdot \frac{TP}{TP + FN}} \quad (1)$$

A higher FM index value (1-perfect match, 0-no match) indicates greater similarity between the analyzed dendrograms which in this case shows that the studied set of features will either yield a similar clustering to the ideal case or not. This way we can make deductions about whether a feature subset can yield a perfect classifier and have superior performance compared to the full feature set. Additionally, we tested the correlation between the dissimilarity matrices of the clusters using the Mantel test across 10,000 permutations and computed Pearson’s product-moment correlation coefficient to assess whether any observed relationships were due to random arrangement.

### 2.2.3. Principal Component Analysis (PCA)

After identifying promising feature subsets, these datasets were standardized to conduct PCA. As a result, the selected subsets of feature groups were projected to a new feature

space - new orthogonal features that are the linear combinations of the original features – principal components (PCs) with descending explained variance. Fig 1 demonstrates the scree plot of % explained variance and the top 10 PCs for the dataset with all features. Based on the location of the elbow of the scree plot, the first 3 PCs are enough to retain around 91.07% of the variation in the original datasets.

Following the feature selection and dimensionality reduction steps, the transformed datasets are split for the training and testing of the ANNs. To train the model effectively, we considered a compound-wise split procedure by considering their ER activities. During this process, we kept the testing set unseen to assess the predicted performance of the model without any bias.

#### 2.2.4. The Deep Neural Network Model

The proposed neural network model is a feed-forward neural network with 3 nodes in the input layer and 2 nodes in the output layer. Every single partition of PCs is propagated through 3 fully connected hidden layers with 8, 16, and 20 nodes, respectively. For all the layers Rectified Linear Unit (ReLU) activation functions are used (Eq. 2).

$$g(z) = \begin{cases} 0 & \text{if } z < 0 \\ z & \text{otherwise} \end{cases} \quad (2)$$

To estimate the network parameters, we use the Adaptive Moment Estimation (Adam) optimizer which inherits characteristics of both the Adagrad (Adaptive Gradient Descent) and RMSprop (Root Mean Square Propagation) algorithms (Kingma and Ba, 2014). Regarding the loss function selection, as we are trying to categorize the compounds according to their agonistic and antagonistic behaviors (binary classification), we used binary cross-entropy. Finally, after training the model, its predictive capability is measured using accuracy, sensitivity, specificity, and balanced accuracy criteria by classifying the testing set that was reserved unseen to the model.

### 3. Results and Discussion

The results obtained from the feature selection phase are provided in Table 1. After thorough statistical analysis of the listed 11 feature groups, we found that the FM index value for 4 of them (highlighted with grey shade) is equal to 0.89, which means that they have high similarity to the ideal clustering of agonist and antagonist compounds. These 4 feature subsets, including all features, also have highly correlated distances matrices with respect to the ideal cluster and their p-values are below 0.05. This indicates that the observed correlations are not by random arrangement and the results are statistically significant. The other feature subsets are observed to have lower FM indices, and in one case p-value greater than 0.05, indicating that their dendrograms are more different than the ideal case with less distinct separation of agonist and antagonist compounds into two clusters. This shows that the underlying dataset might not yield a good classification model as the information carried on these features are not descriptive enough to have a

Fig 1. Scree plot of % explained variance and the top 10 PCs for the dataset with all features

generalized classifier. Hence, we only take the most promising feature subsets with the highest FM index to perform classification analysis. Although we have reduced dimensionality through this procedure, we still use PCA to decorrelate the experimental features and use the PCs to train the neural network. The training and testing results of the deep neural network are summarized in Table 2.

Table 1 The FM indices, Pearson's product-moment correlation coefficient ( $r$ ), and the p-value resulting from the Mantel test for the studied feature subsets.

Feature Subset	FM Index	Mantel Test $r$	p-value
Array	0.80	0.93	0.0001
-Array	0.89	0.94	0.0001
Cell	0.89	0.92	0.0001
Cytoplasm	0.57	0.37	0.0001
Nucleus	0.89	0.94	0.0001
Nucleoplasm	0.58	0.93	0.0001
Intensity	0.74	1.00	0.0001
-Intensity	0.64	0.23	0.0104
Secondary	0.53	0.16	0.0534
Shape	0.59	0.31	0.0001
All	0.89	1.00	0.0001

According to the classification results, the dataset with all features outperforms the other 3 feature groups with 98.41% accuracy. This dataset has the highest accuracy, sensitivity, and balanced accuracy values, as well as a very high specificity value. However, datasets with only nucleus features and without array features have nearly perfect specificity values, which represent the fraction of correctly predicted antagonist compounds. Interestingly, although the dataset with only nucleus features mapped nearly all the antagonist compounds correctly (only 1 cell misclassified out of 1791 cells), its capability is very limited for agonist compounds (67.55%). We observe the opposite trend for the dataset with only cell features, where a deep neural network constructed with the projected set of these features yields a classifier with 97.54% sensitivity and 67.67% specificity in the testing set. Overall, the results show that the neural network classifier constructed from the dataset with all features outperforms other models and provides consistently very high performance scores in both training and testing steps.

Table 2 Performance metrics of deep neural network model for the 4 selected feature groups.

Feature Group	Set	Accuracy	Sensitivity	Specificity	Balanced Accuracy
W/o Array Features	Testing	92.42%	84.28%	<b>100.00%</b>	92.14%
	Training	98.64%	99.05%	98.27%	98.66%
Cell Features	Testing	82.07%	97.54%	67.67%	82.61%
	Training	94.35%	99.40%	89.77%	94.59%
Nucleus Features	Testing	84.33%	67.55%	99.94%	83.75%
	Training	98.09%	96.01%	99.97%	97.99%
All Features	Testing	<b>98.41%</b>	<b>97.66%</b>	99.11%	<b>98.39%</b>
	Training	98.96%	100.00%	98.02%	99.01%

#### 4. Conclusion

We provided a classification framework based on multidimensional imaging data and deep neural networks to assess the endocrine disrupting potential of estrogen receptor- $\alpha$  (ER $\alpha$ ) agonists and antagonists. To overcome the curse of dimensionality, both feature selection and dimensionality reduction techniques were incorporated. Feature selection is performed using hierarchical clustering, FM index, and Mantel test techniques, where the similarity between different feature subgroups was quantified with the ideal grouping of agonist and antagonist compounds. Four feature subsets, including the entire set of features, were identified as the most promising ones that will enable the agonist/antagonist separation. Principal component analysis is also performed to further reduce the dimensionality of the studied datasets and to remove any correlations between the features. The results show that the dataset with all features succeeded in predicting the estrogenic activity of unknown chemicals with 98.41% accuracy, which was followed by the dataset without array features (92.42%). Additionally, we observed an interesting trend in the sensitivity and specificity values of the other two datasets; while the dataset with only cell features could predict the ER activity of agonist compounds with very high accuracy (97.54%), the dataset with only nucleus features classified 1790 out of 1791 cells correctly (99.94%) for antagonist class. Overall, we demonstrated that highly accurate neural network models can be constructed to predict the biological activity of chemical compounds. This research was funded by the U.S. National Institutes of Health (NIH) grant P42 ES027704.

## Abstract

In this work, a model is developed and implemented for GFP<sub>UV</sub> production with aerobic fed-batch fermentation of *E. coli* BL21 (DE3). The model parameters are estimated using historical process data and minimizing the prediction and measurement error. The model implements an extended Kalman filter for non-linear state estimation of biomass, glucose, and dissolved oxygen concentration. The filter includes an existing cascade feed-back loop for dissolved oxygen control which improves the predictive accuracy of the filter. The estimator is used during fermentation to predict the induction point based on a threshold glucose concentration which is otherwise determined exclusively with at-line measurements. The validation examples presented in this work show great agreement between the estimated and measured glucose concentrations, making it a useful tool for predicting the time until induction without requiring high-frequency at-line sampling.

**Keywords:** Digital Twin, Biobased Manufacturing, Operator Support, Scheduling

## 1. Introduction

Digitalisation in biomanufacturing aims to increase production efficiency and reduce time-to-market by tightly integrating physical and digital entities to enable smart manufacturing and faster characterization of fermentation kinetics through improved data-utilization [1,2]. Despite many biobased manufacturers are improving their digital infrastructures and data collection paradigms, few have addressed specific value generating activities associated with improved data access and -generation [2]. A challenge in biobased manufacturing is the generally low degree of automation compared to the petrochemical industry. The complex and non-linear nature of microbial and metabolic systems make it difficult and computationally expensive to predict the fermentation progression [1]. Understanding how to operate these processes and mitigate disturbances during operation often require operators with significant hands-on experience to ensure a steady operation thus making manufacturers heavily dependent on maintaining a stable of skilled operators (and clear procedures) to meet production targets [1]. Retaining the operator knowhow could help to reduce the time and cost of educating new employees and simultaneously guide the new operators during operation [3].

This work presents a protocol employing a standard host organism, *Escherichia coli* BL21 (DE3), commonly used to produce recombinant proteins in the biopharmaceutical industry [4]. The protocol is used in a course curriculum where students with little experience conduct a pilot-scale exercises. Here the operators are required to sample the fermentation broth and measure the glucose concentration and optical density at-line to determine when to induce. After induction, the operators initiate a fed-batch phase. Induction shifts the metabolic pathways to favour the formation of the recombinant protein, and mistimed induction has previously been shown to significantly affect the yield and productivity [5]. Tools that support the operators during the experimental run is therefore especially valuable to ensure a steady and predictable operation. Since the protocol is employed extensively as part of the course curriculum, there exists a large historian of process- and at-line lab data pertaining to the production of green fluorescent protein by *E. coli* aerobic fermentation. This data will be used to build a non-linear state-estimator to predict the induction timing based on concentration thresholds dictated by the protocol.

## 2. Materials & Methods

### 2.1 Fermentation Protocol

The presented protocol serves as a practical exercise in a short course curriculum on topics in advanced fermentation offered at the Golden LEAF Biomanufacturing Training and Education Center (BTEC), located at North Carolina State University. Recombinant green fluorescent protein (GFP<sub>UV</sub>) exhibiting a high ultraviolet (UV) reflectivity is produced from a batch- & fed-batch aerobic fermentation of *E. coli* BL21 (DE3). Initially a seed culture is inoculated with a glucose- and yeast extract rich media and fermented in aerobic batch conditions at 50% dissolved oxygen (DO) saturation. The glucose is added in excess, resulting in the production and accumulation of Acetic acid during the lag and log phase. After running the batch condition for 5-6 hours, the glucose concentration has decreased to approximately 2 g/L. The operator then induces the broth with isopropyl  $\beta$ -D-1-thiogalactopyranoside (IPTG), shifting the metabolic pathways to favour the formation of the recombinant GFP<sub>UV</sub>. The fermentation then enters a fed-batch phase, where the operator controls the feed flow rate of a 2 L glucose and yeast extract rich media until the supply runs out. As the organism enters the stationary phase and the feeding media is depleted, the accumulated Acetic acid is also consumed. Approximately 24 hours after inoculation the fermentation is terminated, and the product is harvested.

### 2.2 Equipment and Data Handling

BTEC employs 5 identical 30L Sartorius® bioreactors to run several instances of the protocol in parallel. Each bioreactor is augmented with high frequency sensors measuring pressure, temperature, DO, pH, and optical density (OD). The OD sensor measures near-infrared (NIR) wavelengths and correlates the results to OD<sub>600</sub> absorbance. The absorbance at 600 nm corresponds to the dry cell weight of *E. coli* and functions as a soft sensor determination of the cell density. Additionally, the operator periodically takes samples from the broth and perform at-line determination of the glucose concentration and OD<sub>600</sub> through spectrophotometric methods. The DO is controlled by a closed loop cascade that manipulates agitation and aeration. The cascade control strategy primarily manipulate agitation until it reaches a maximum value. The inner control loop will then start to manipulate air sparging flowrate to reach the DO setpoint.

Data collection, storage and querying is orchestrated by AVEVA PI hosted on a central database server located at BTEC. A human-machine interface (HMI) is developed using AVEVA's DeltaV software and hosted on the same central server. The operator can easily input at-line measurement results through the HMI ensuring that the low-frequency measurements are stored in the same concise database and historian as the high-frequency sensors. Online accessibility and tight integration between the digital- and physical entities allow for easy online monitoring and control of the bioreactors. This presents itself as a digitally mature system with a great potential for augmenting a digital twin as depicted in Figure 1. This can be used to support operators with control suggestions during run-time or as virtual laboratories to practice operation strategies before the exercise.

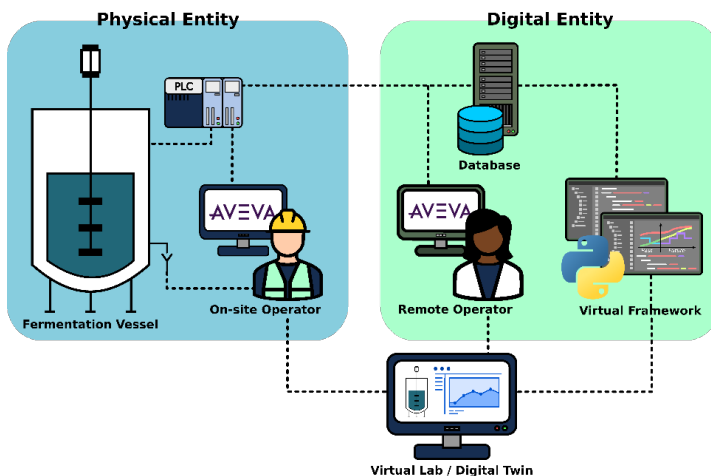

Figure 1: A schematic representation of the digital infrastructure at Golden LEAF BTEC. Data flows from the process unit to a central database and historian hosted with AVEVA PI and human machine interface (HMI) built in DeltaV. The HMI can be accessed remotely for control and monitoring when located on the BTEC network. The Virtual Laboratory / Digital Twin can be used to perform high-level model development and operator support during run-times.

A total of 53 fermentation runs have been extracted from the PI Vision database, conducted between 2020 and 2022. The measurements from these experimental runs are used in the objective function presented in Table 1 and include sensor- and at-line OD, DO sensor and at-line glucose.

### 2.3 Model & Nonlinear State-Estimator

This study employs an acetate overflow model to describe the metabolic behaviour for GFP<sub>UV</sub> formation in *E. coli* BL21 (DE3) this model is derived from a modification to the implementation originally presented by Christina et al. in 2003 [6]. The model by Christina et al has served as a foundation for recent studies in similar systems of *E. coli* BL21 (DE3) [5, 7]. The protocol only requires operators to collect endpoint titer data, which complicates parameter estimation for kinetic GFP production. Therefore, it is not currently possible to include product formation as a modelled state in the dynamic model. Since this study has focus on the pre-induction kinetics, the formation of GFP can be assumed to be reasonably small such that it should not skew the estimated yield coefficients significantly by excluding it from the mass balance constraints. Instead, the aim is to develop an accurate glucose concentration estimator to assist operators in

determining when the glucose concentration is expected to reach the induction target given by the fermentation protocol. The number of parameters in the model explodes with increasing complexity. As a result, the final model is restricted to three rate expressions [4,5,7]. Parameter bounds are determined from literature review and heuristics to reduce the solution space [4,7]. Regardless, the problem is currently a concave optimization problem, and solutions will thus depend heavily on initial conditions. Good initial guesses are therefore necessary to extract dynamics that have realistic behaviour. The yield coefficients ( $Y_{ij}$ ) are restricted to satisfy a mass balance for each rate expression. In the equations presented in Table 1. the species Glucose (S), Acetate (A), Oxygen (O), Carbon Dioxide (CO<sub>2</sub>), Biomass (X) and Yeast Extract (YE) are modelled with Monod expressions, including the parameters, maximum rate ( $q_{S,max}$ ,  $q_{O,max}$ ,  $q_{A,max}$ ), half-times and inhibitors (K and K<sub>I</sub>).

Table 1: stoichiometric equations, rate expressions, objective function and parameters used in the presented model.

<b>STOICHIOMETRY</b>

<b>RATE EXPRESSIONS</b>		
Critical substrate uptake rate	$q_{S,crit} = \frac{q_{O,max}}{Y_{OS}} \cdot \left( \frac{K_{IA}}{K_{IA}+A} \right)$	
Substrate uptake rate	$q_S = q_{S,max} \cdot \left( \frac{S}{K_S+S} \right) \cdot \left( \frac{O}{K_O+O} \right)$	
Acetate uptake rate	$q_A = q_{A,max} \cdot \left( \frac{A}{K_A+A} \right) \cdot \left( \frac{O}{K_{AO}+O} \right) \cdot \left( \frac{K_{IS}}{K_{IS}+S} \right)$	
<b>REACTION RATES</b>		
	$\mu = \begin{bmatrix} \mu_1 \\ \mu_2 \\ \mu_3 \end{bmatrix} = \begin{bmatrix} \min(q_S, q_{S,crit}) \\ \max(0, q_S - q_{S,crit}) \\ \max(0, q_A) \end{bmatrix}$	
<b>PARAMETER FITTING</b>		
Objective function	$obj = \min_{\theta}  y_{DO,OD,S} - \hat{y}_{O,X,S}(\theta) _Q$ s.t.	
Mass balance	$mb = \sum Y \cdot \mu$	
Redox balance	$rb = \sum Y \cdot \mu \cdot \epsilon$	

The objective function is defined to minimize the error between sensor measurements and the simulated results. This includes online optical density and dissolved oxygen sensor values combined with at-line determination of OD<sub>600</sub> and glucose concentrations. The weights are assigned to improve prediction accuracy for glucose and balance the contribution from at-line and online OD measurements. The optimization scheme employs a Nelder-Mead algorithm that penalises a scaled error between the measured- and simulated state, restricted by mass- and redox-balances. From the parameterized model, a non-linear state estimator is constructed. For this purpose, the Extended Kalman Filter (EKF) is formulated.

### 3. Results & Discussion

A preliminary assessment of the datasets shows high variance in total GFP titer ( $2.57 \pm 1.05$  g/L), product yield on the substrate ( $0.0743 \pm 0.0011$  g/g), glucose concentration at

the induction point ( $2.57 \pm 1.05$  g/L), and induction time after inoculation ( $5.91 \pm 0.27$ ). These results support the hypothesis that inexperienced operators naturally infer high variance to a process despite following the same protocol. To validate the performance of the parameterized model, two batch runs are assessed that were not previously included in the parameter estimation scheme. Here an  $R^2$ -value for prediction of glucose and biomass were found to be 0.93 and 0.90 respectively, confirming a good accuracy between the model and the system.

Assuming that the most recent sensor measurements for the two cases are collected at  $\sim 5.25$  hours and  $\sim 5.80$  hours, it is possible to predict the evolution using the EKF. The measurements and mixture details at inoculation are passed to the EKF, which computes states and predict measurement trajectories. A qualitative assessment of the predictions presented in Figure 3 show a reasonable agreement between the predictions and sensor measurements, especially for determination of glucose concentration. The glucose predictions are then used to determine an estimate for timing the induction.

Figure 2: Measurements and predictions for two fermentation runs (left #1 & right #9) over time, beginning at inoculation of the fermentor. (left) Achieves induction close to the desired condition. (right) Overshoots the induction point by approximately 15 min reducing the concentration of glucose to 0.94 g/L.

As show that in Figure 2 the batch runs are expected to reach induction conditions approximately 6 hours after inoculation. In this way, operators would be able to receive the prediction in advance and adequately prepare for induction at the desired conditions without relying solely on at-line glucose measurements. Alternatively, it could assist operators in determining sections in the fermentation run where high-frequency at-line sampling has an added value. As evident by the case depicted on the right-hand side of Figure 2, operators miss the induction point by approximately 20 min. This could be caused by too infrequent at-line sampling during the phase with steep consumption of glucose leading to the operators being poorly prepared to perform the induction. From the

results presented by Lopes et al. [5], this deviation should be identifiable in the yield and productivity by comparing the two batch runs at the end of the fermentation. However, assessing the final GFP<sub>UV</sub> titer at harvest after 24 hours shows that both fermentation runs achieve a similar titer and yield on substrate despite the run on the right-hand side initiating induction 20 min past the suggested glucose concentration listed in the protocol. Since the post-induction dynamics change and include feeding of the glucose and yeast extract solution, there are elements potentially explaining how the delayed induction run bounces back, which the current model cannot account for. Variations in later operating points could justify this observation, but another cause could be that the selected induction condition is not optimized to maximise the GFP<sub>UV</sub> yield or productivity. A more thorough study of final GFP<sub>UV</sub> maximisation and the inclusion of fed-batch fermentation behaviour post induction could address this caveat.

## Conclusion

Existing historical data from pilot scale experiments were contextualised and used to estimate parameters in a suggested mechanistic model for *E. coli* BL21 based on state-of-the-art acetate overflow models. The system was validated against process data and used to develop an extended Kalman filter that predicts the evolution of biomass growth, glucose, and oxygen consumption with reasonable accuracy. In contrast to shake flask experiments investigating the same system, delayed induction did not appear to have a significant effect on the final fermentation performance. Since the agitation and aeration are controlled by the closed loop cascade with a DO setpoint at 50% for all fermentations, the root cause of the observed variation must be found elsewhere. The current implementation only account for the pre-induction dynamics, and variance in the glucose feeding strategy after induction might have greater influence on the performance than previously anticipated.

## Abstract

Recent years have seen a growing interest in studying new methods to predict the correct dose of levothyroxine (LT<sub>4</sub>) that is used as a synthetic drug for hypothyroidism treatment and supplements/substitutes the T<sub>4</sub> hormone secreted by the healthy thyroid. The paper proposes a quantitative procedure for the optimal administration of LT<sub>4</sub> through a model-based approach dependent on some individualized parameters of the patient to free the endocrinologist from the current rough guesses of LT<sub>4</sub> dosage. A dedicated algorithm receives as input data the patient features along with the major indicator of thyroid status, *i.e.* the serum concentration of TSH, the thyroid-stimulating hormone. Then the procedure calculates the Residual Thyroid Function (RTF), which quantifies the thyroid efficiency status, and eventually the optimal LT<sub>4</sub> dose. As a complement to the quantitative models available in the scientific literature, we also take into account the age of the patient to determine the optimal dose that can avoid any suboptimal prescriptions regarding hypothyroidism diagnosis for both young and elderly individuals.

**Keywords:** LT<sub>4</sub>; TSH; individualized medicine; anthropometric parameters.

## 1. Introduction

The thyroid gland is the largest organ in our body capable of hormonal secretion, located in the lower part of the neck in front of the trachea, below Adam's apple. It is divided into two conical lobes linked by an isthmus. The physiological functional sites of the gland are the follicles. They comprise a central nucleus, a so-called colloid, which is surrounded by cuboidal cells. These cells exchange the necessary biological elements and products through the cardiovascular system that highly perfuses the thyroid gland. The thyroid is unique among all body organs thanks to its ability to store and concentrate iodine above forty times the normal plasma concentration. Iodine is the essential substance involved in the complex mechanism of hormone production. Elemental iodine is introduced into the body with nourishment, and it is later exploited by the thyroid to produce triiodothyronine (T<sub>3</sub>) and tetraiodothyronine (T<sub>4</sub>), the two main hormones secreted by the gland. The role of this organ is of vital importance since it can modulate processes such as thermoregulation, body growth, cellular metabolism, breathing, and heart rate. The two thyroid-secreted hormones are synthesized in the follicle in a complex series of metabolic interactions, mainly involving thyroglobulin protein, which is produced in the thyrocytes and then delivered into the colloid. Here, it interacts with iodine to form T<sub>3</sub> and T<sub>4</sub> precursors, containing three and four iodine atoms per molecule respectively, which are

metabolized by specific enzymes to obtain the actual hormones eventually released into the bloodstream. A specific pituitary-secreted molecule called thyroid-stimulating hormone (TSH), which in turn is stimulated by the hypothalamic hormone thyrotropin-releasing hormone (TRH), promotes the cascade of events related to hormonal synthesis. From these intricate relations, it is evident the tight interconnections that link the hypothalamus, pituitary gland, and thyroid, in what is known as the H-P-T axis. These organs enable a peculiar control mechanism. TSH can stimulate the thyroid gland by increasing its  $T_3$  and  $T_4$  production, but the thyroid hormones, especially  $T_3$ , inhibit the TSH release by acting on the gene expression of TRH, which consequently hinders the TSH secretion (Werner *et al.*, 2005). Thyroid diseases can be traced back to the failure of critical links in the chain of events that have been described so far. These disorders can be divided into hypothyroidism and hyperthyroidism. Hypothyroidism is the most common thyroid disorder, where the patient experiences a low level of  $T_4$  and a high level of TSH, caused either by pathologies directly linked with thyroid failure, referred to as primary hypothyroidism, or pathologies associated with hypothalamus or pituitary gland dysfunction, better known as central hypothyroidism. This disease has an estimated incidence of 4 to 5 individuals every 1000 per year in women and 0.6 to 0.9 individuals every 1000 per year in men. Prevalence exceeds 5% of the global population (Flynn *et al.*, 2004).

Researchers in the last six decades put constant efforts into establishing a mathematical model capable of mimicking the thyroid behavior. More recently, there has been an attempt to use the available models to predict the drug dosage for specific thyroid pathologies. The implementation of such models is motivated by two main controversies regarding the diagnosis of hypothyroidism and the prescription criterion of levothyroxine ( $LT_4$ ), which is the active principle used to cure hypothyroidism and is the levorotatory enantiomer of the actual  $T_4$  hormone in the form of sodium salt. The first issue concerns the evaluation methods of the hypothyroidism status, which are primarily based on the analysis of the TSH values, whose allowed range must fall between 0.45 and 4.5 mIU/l even though that range is mired in debates (Werner *et al.*, 2005, Chapter 46). Based on data belonging to patients under levothyroxine treatment, it is rather common to register miscalculations of the  $LT_4$  dose, which is a major health risk. This issue should be considered of utmost importance. Health studies showed that 22% of analyzed subjects were improperly treated and that 18% of them were receiving higher  $LT_4$  doses than necessary, with consequent negative side effects, namely dyslipidemia, cardiovascular disorder risks, and, particularly, iatrogenic thyrotoxicosis (Werner *et al.*, 2005, Chapter 46). In addition,  $LT_4$  has been classified as a narrow therapeutic index drug, given the utter care that must be put into the titration of the dose, considering that even small changes can significantly affect the existing equilibrium of the H-P-T axis (Werner *et al.*, 2005, Chapter 13A). Current goal of the recently developed thyroid models is including individualized parameters in the attempt to set new standards for hypothyroidism diagnosis and  $LT_4$  prediction. Among the available models, p-Thyrosim stands out for its capability of simulating the thyroid biological mechanism as a function of the patient's parameters such as gender, height, weight, residual thyroid function (*i.e.* quantification of the hypothyroidism status), and  $LT_4$  administered dose (Cruz-Loya *et al.*, 2022).

## 2. Methods

Eisenberg and coauthors (2008) outlined the base structure of a multi-compartmental PBPK model to describe the physiological feedback control of the H-P-T axis. The reference model explains the H-P-T axis components by means of homogenous

compartments. There are three main submodels: thyroid hormones (TH), Brain (B), and TH input (THI). The interconnection of each of them represents the interaction of the H-P-T axis that allows evaluating the trend of both TSH and the thyroid hormones in plasma. The TH submodel includes a set of ordinary differential equations that govern the thyroid hormones' fluxes from the plasma to the tissues and vice versa, occurring in the whole body. Then, the B submodel describes the endogenous circadian TSH secretion by lumping the interaction between the pituitary gland and the hypothalamus in a single equation, which is mainly a function of the  $T_3$  level in the brain. Finally, the THI submodel contains the equations concerning the exogenous administration of  $LT_4$  employing four alternative paths: intravenous, intramuscular, subcutaneous, or oral administration (Eisenberg *et al.*, 2008). This model saw a relevant development described in Cruz-Loya *et al.*, (2022) where the authors succeeded in implementing individual parameters such as body weight, height, and gender and proposed a suitable formulation to describe the circadian oscillation of TSH that affects the thyroid secretory pattern.

In case of patients with thyroid problems, it is common practice to consider the TSH concentration measured with a first blood analysis. If there is a positive match for hypothyroidism, the endocrinologist proceeds with an initial dose of  $LT_4$ , which can be determined in a variety of ways. The preferred  $LT_4$  dose is  $1.6 \mu\text{g}/\text{kg}$  per day but there is also an extremely simplified approach based on a one-size-fits-all of  $100 \mu\text{g}/\text{day}$ . Afterwards, the patient has to take the remedy every morning before breakfast for at least six weeks after which a new blood sample provides the updated value of TSH that allows establishing if the thyroid levels belong to the recommended ranges. If they are not, the dose is empirically adjusted, and the procedure is iterated until normal hormone levels are reached (Werner *et al.*, 2005, Chapter 46). It is rather common to undergo a few iterations before an optimal prescription is achieved, which makes the whole procedure demanding for the patient and subject to the biased evaluation of the endocrinologist. Therefore, an optimized, individualized, and unbiased protocol is highly recommended.

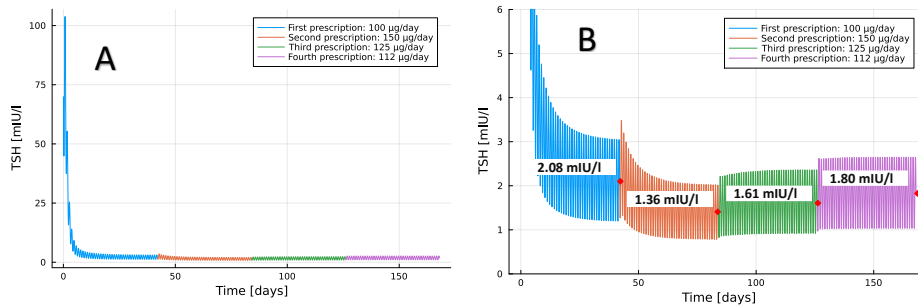

Figure 1: Panel (A) simulated endocrinologist trial and error approach in  $LT_4$  dose administration for a 70-year-old hypothyroid female patient of 78 kg, 1.63 m, and TSH starting level of 71.44 mIU/l. Panel (B) zoomed trend. Red diamonds report the asymptotic TSH values after the iterative adjustments of  $LT_4$  prescriptions.

Panel A of Figure 1 reproduces a hypothetical situation based on the traditional approach to the  $LT_4$  dosing scheme where the endocrinologist wants the TSH to be far from the upper limit to prevent the persistence of hypothyroidal symptoms. Based on this assumption, the optimal value of TSH is set below the average of the euthyroid range (0.45-4.5 mIU/l), to a value of 1.9 mIU/l. A 70-year-old female, weighing 78 kg and 1.63 m tall undergoes a blood sample to measure her TSH concentration for the first time. TSH is 71.44 mIU/l, and the endocrinologist (neglecting any individualized features) prescribes a theoretical starting dose of  $100 \mu\text{g}/\text{day}$  (Werner *et al.*, 2005, Chapter 46).

This produces a six-week asymptotic TSH value of 2.08 mIU/l, which is higher than the expected value and might make the symptoms persist. The dose is then increased to 150 µg/day and, after six weeks, TSH reaches 1.36 mIU/l, which is now too low to be acceptable and bearable for prolonged treatments. The endocrinologist then fine-tunes the dose to 125 µg/day after which TSH reaches 1.61 mIU/l. Since the LT<sub>4</sub> has a narrow therapeutic window, the endocrinologist chooses to further change the dose to 112 µg/day, which eventually corresponds to a TSH of 1.80 mIU/l which is a rather good value reasonably near to the expected one (1.9 mIU/l).

An alternative approach consists of the automated optimal LT<sub>4</sub> dosing by exploiting the power of quantitative deterministic models such as p-Thyrosim. With respect to the above iterative search for a suitable prescription by the human interaction between the endocrinologist and the patient, now the goal is to minimize the blood samples (and therefore the time to find the optimal dosage as each dose adjustment calls for 50-60 day more settling times) by getting the starting dose right the first time. To this purpose, we implemented an optimizing procedure that can return the optimal LT<sub>4</sub> tablet dose for hypothyroid patients, using p-Thyrosim and accounting for the patient's individual features such as weight, height, gender, age, and the TSH value from a recent blood sample. First, the proposed procedure evaluates the RTF (Residual Thyroid Function) value by zeroing the following function:

$$f(RTF) = TSH^{exp} - TSH(RTF) \quad (1)$$

Where the  $TSH^{exp}$  and  $TSH$  [mIU/l] are the TSH blood sample and the p-Thyrosim asymptotic prediction of the in-silico individualized patient  $TSH$  plasma dynamics, respectively. Once RTF is computed, the procedure zeros Equation (2), by determining the optimal LT<sub>4</sub> dose that would yield to euthyroid values of both  $T_4$  and  $TSH$ :

$$f(LT_4) = \left| \frac{TSH^{sp} - TSH(LT_4)}{4} \right| + \left| \frac{T_4^{sp} - T_4(LT_4)}{60} \right| \quad (2)$$

where  $TSH^{sp}$  [mIU/l] and  $T_4^{sp}$  [µg/l] are the optimal expected values (*i.e.* setpoints) for the corresponding euthyroid values. Initially,  $TSH^{sp}$  was set at 1.80 mIU/l for any hypothyroid patient as Cruz-Loya *et al.*, (2022) suggest a minor dependency from age as far as euthyroid conditions are concerned. However, given the high precision that must be kept in drug dosage, we also accounted for the dependency of  $TSH^{sp}$  from age. We derived an age-dependent trend for the upper limit of TSH euthyroid from Raverot *et al.*, (2020) that took to Equation (3).

$$TSH_{M,F}^{sp}(age) = \frac{TSH_{M,F}^{ul}(age) - TSH^{ll}}{2.7} \quad (3)$$

Where  $TSH_{M,F}^{ul}$  and  $TSH^{ll}$  are the upper and lower limits of the TSH range respectively for either a male or female euthyroid patient.  $TSH_{M,F}^{ul}(age)$  was evaluated by extrapolating the values from the TSH upper limit trends, both for males and females, from the work of Walsh (2022). Therefore, the data of Figure 2 were regressed with a nonlinear procedure. This methodology generates also the TSH upper limit formula from which it is possible to calculate, for every combination of age and gender, the associated upper limit and eventually derive the correct  $TSH^{sp}$ :

$$TSH_{Male}^{ul}(age) = 4.642520589559373 - 0.02039878317500956 \cdot age + 0.0002614981700062368 \cdot age^2 \quad (4)$$

$$TSH_{Female}^{ul}(age) = 4.1777986229928485 + 0.00463599130382207 \cdot age + 0.0001309278501772748 \cdot age^2 \quad (5)$$

Instead, the  $T_4^{sp}$  plasma values have been considered equal for both genders and fixed at 80 µg/l as the literature does not report any significant variability with age (Werner *et al.*, 2005, Chapter 11A).

Figure 2: TSH upper limit trend for males and females at different ages derived by a nonlinear regression procedure.

### 3. Results and discussion

The proposed automated algorithm predicts the necessary  $LT_4$  tablet dose (commercially available) to be administered to a hypothyroid patient by accounting for their individual features and endogenous TSH (before the treatment). The procedure, based on the p-Thyrosim model (Cruz-Loya *et al.*, 2022) can investigate how the optimal dose changes as a function of the patient's age. The dependency of  $TSH^{ul}$  with age, seen in Equation (3), affects  $TSH^{sp}$ . If the TSH upper limit is somehow increased, the  $LT_4$  dose must decrease according to Equation (2). Thus, the implementation of the automated procedure of the  $TSH^{sp}$  age dependency ensures the achievement of different dosages for the same hypothyroid patient at different ages, allowing a better approach to individualized treatment.

Figure 3: (A) Simulated TSH plasma value for a 70-year-old hypothyroid female patient with a weight of 78 kg, 1.63 m, and TSH starting level of 71.44 mIU/l under  $LT_4$  treatment calculated through the double-step algorithm routine. (B) Simulated TSH plasma value for the same patient highlighting with a red marker the achievement of the correct TSH setpoint thanks to the theoretical optimal  $LT_4$  dose (99.62 µg/day) evaluated by the optimizing procedure.

With reference to Figure 3, we tested our double-step algorithm for the same female hypothyroid patient in Figure 1. The main differences between the graphs must be searched in the diverse  $LT_4$  dose treatment schemes and in the age-dependent approach related to the individualized  $TSH^{sp}$  value. Figure 1 shows how the iterative human-based procedure resulted in a total of 160 days and 4 adjustments before identifying the correct  $LT_4$  dose centered on the endocrinologist's perspective. Conversely, Figure 3 shows the direct assessment of the optimal dose, which allows for reaching the expected TSH

optimal value by a one-shot prescription. Furthermore, the TSH setpoint chosen in the dosing scheme of Figure 1 does not account for the  $TSH^{ul}$  dependency with age as the patient is assigned a constant setpoint at any stage of their life. Thus, the proposed optimizing procedure assigns the TSH setpoint as a function of both the patient's age and gender. For the considered 70-year-old female patient the correct TSH level should be 2.08 mIU/l, which is achieved by an  $LT_4$  dose of 99.62  $\mu\text{g}/\text{day}$ , found by the optimization algorithm. That dose is not available in commercial tablets and should be rounded to the nearest available formulation of 100  $\mu\text{g}/\text{day}$  which would bring an asymptotic TSH value of 2.07 mIU/l, almost equal to the optimal one. It is worth observing that the scenario reported in Figure 1 calls for the involvement of an earnest physician. In real life, the endocrinologist might not look for those precise adjustments and might be satisfied with any reasonable dosages. Nonetheless, our automated and unbiased procedure can overcome the endocrinologist's sensitivity in the dose prescription and displays a lower time to reach the optimal dose based on a one-shot and more accurate treatment that takes into account the individual features of the patient.

#### 4. Conclusions

The findings reported in the present paper were made possible by the decades-long studies published in the scientific literature. Our efforts concerned the application of compartmental models simulating thyroid secretion to replicate real-life scenarios, in the attempt to increment the precision of the first  $LT_4$  tablet dose for hypothyroid patients. We developed an automated approach through a double-step procedure to support the endocrinologist's decisions in terms of optimal  $LT_4$  dosage by exploiting the individualization features and unbiased calculations of p-Thyrosim. The attempt of implementing age as a further individualized parameter for hypothyroid patients allowed for outlining the dependency of TSH at different stages of life and improving the evaluation of the  $LT_4$  optimal dose.

## Abstract

Technoeconomic modelling links engineering performance to economic outcomes. In this paper we present a method for embedding technoeconomic unit process models within a geographically distributed supply chain simulator. This enables the simultaneous optimization of how and where processing is performed. This is particularly suited to waste remediation, where the costs of transporting hazardous materials may outweigh those of performing some stages of treatment at the waste source. The approach is applied to a microalgal-bacterial remediation of hydrocarbon waste (sump oil mainly) produced by the MOD Sites (military bases) across the UK. Through this treatment, valuable bioproducts are recovered from algae which consumes hydrocarbon waste and CO<sub>2</sub> as it grows.

**Keywords:** Technoeconomic analysis, supply chain modelling, waste remediation.

## 1. Introduction

Technoeconomic modelling has long been a basic step in process design, linking engineering performance to economic outcomes (Seider et al 2019). The operation and optimisation of individual processes within wider, distributed supply networks is typically considered with simplified models of the underlying processes, and may be independent of the scheduling of the operations contained therein (Garcia et al 2015). In this study, we address this by presenting software for embedding technoeconomic unit process models within a geographically distributed supply chain simulator. This enables the simultaneous optimization of how and where processing is performed. This is particularly suited to waste remediation, where the costs of transporting hazardous materials may outweigh those of performing some stages of treatment at the waste source.

As an example, the approach is applied to a microalgal-bacterial remediation of hydrocarbon waste. Microalgal-bacterial remediation is a multi-stage process to cultivate, extract and exploit the bioproducts produced by microalgae grown in hydrocarbon effluent. Through this treatment, valuable bioproducts are recovered from algae which consumes hydrocarbon waste and CO<sub>2</sub> as it grows (Zahra et al 2020). This offsets the costs, both economic and environmental, of our global abundance in hydrocarbon effluents, used oils and lubricants (Fregie et al, 2019).

Unit operations are represented by kinetic models for each stage that is linked to economic performance via cashflow modelling of revenue streams, resource costs (OpEx) and plant costs (CapEx). The unit processes (stages) are implemented as agents in an agent-based supply chain model. Incorporating transport costs, processing is then optimized across

the entire network of waste producing and processing sites. This enables optimal choices between local and centralized processing.

## 2. Architecture

The basic problem architecture, embedding a hierarchy of agents (i.e. agents containing lower-level agents) in a geographically distributed supply chain network is depicted in Fig. 1.

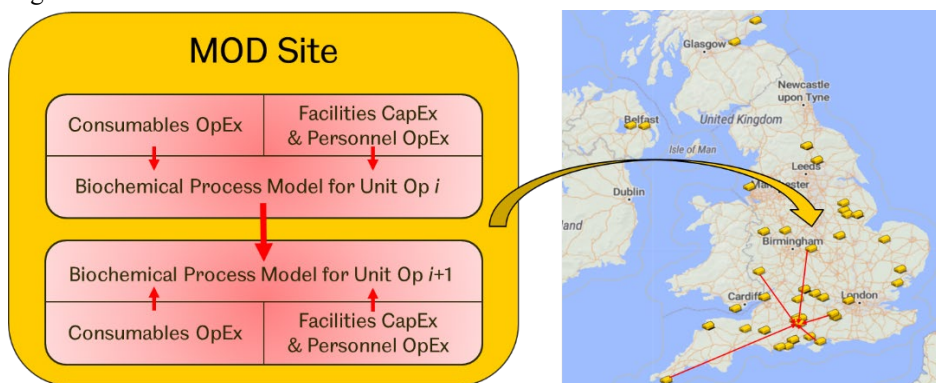

Fig.1. Embedding the layers of architecture – MOD Sites containing Unit Ops – in a supply chain network

### 2.1. Implementation

The Agent Based Model is implemented in AnyLogic (Borshchev 2014) extended with our own Java code). At every level, the representation in AnyLogic/Java is as generic as possible, the details of implementation being stored in a separate Excel spreadsheet for each layer of the agent hierarchy. Each spreadsheet ultimately lists every agent at that level of the hierarchy, providing for each a description specifying every parameter required to construct the agent. Upon model startup, the MOD Sites (military bases) are located by the postcode embedded in the (Excel) description of the site. This automatically exposes the road distance between any two sites, as a feature of AnyLogic.

### 2.2. MOD Site

The description of an MOD Site goes far beyond geographical location, populating all of the parameters in Fig. 2. These specify, amongst other matters, the frequency and amount of material to be processed at this site. Material is based on a single limiting consumable (e.g. hydrocarbon waste) by which to scale reagent amounts and energy requirements. The limiting consumable may be produced at another site, transported and received here, or be hydrocarbon waste produced onsite (the limiting consumable amount). Once processed, products 0-4 may be dispatched to destinations 0-4, which are MOD Sites specified in the description with product routing information. These matters are handled on the right of Fig. 2, by the receiver and dispatcher agents, which calculate scheduling (based on the trucks listed in this MOD Site's description), mileage, and thereby Haulage OpEx including fuel, depreciation per km and personnel.

The type of an MOD Site is used to populate the sequence of Unit Ops to the right of Fig. 2. For example, if the MOD Site is described as "Empty" it does nothing but produce and.

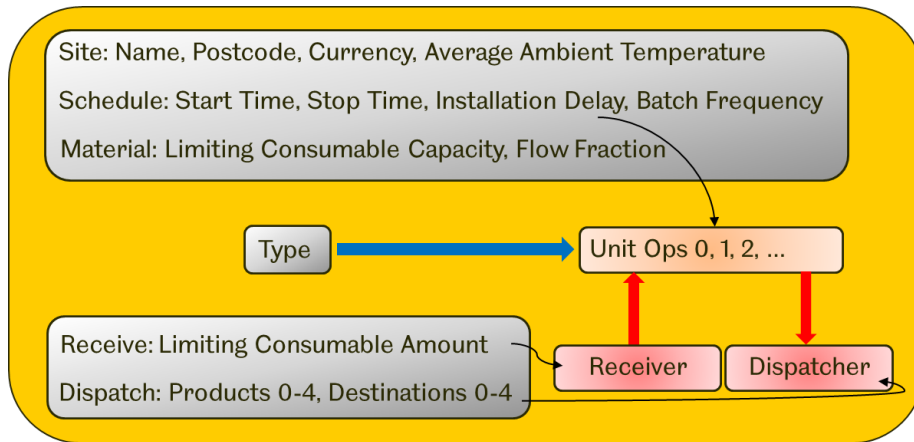

Fig. 2. A generic MOD Site, whose Unit Ops sequence is determined by the Site Type. Parameters in grey feed information according to black arrows. Material flows according to the red arrows.

dispatch hydrocarbon waste, whereas “Cultivation-Centrifuge” processes waste into biomass then dries it

### 2.3. Unit Op

In this implementation a Unit Op is an agent encapsulating the kinetics of a physio-chemical process together with its economics. Based on a generic template (base class or agent), there are dedicated sub-types of Unit Op for each stage of processing -- in this case study cultivation of biomass, dewatering and drying. Further Unit Ops could be added for downstream processing such as cell disruption, and bio-oil extraction and separation. Each Unit Op may operate in batch or flow mode, or a combination of the two. After each regular batch duration the reactor and the outlet are emptied into the product store, cleaned, and refreshed by recovering (from the product store), purchasing and/or receiving the consumables required for the next batch duration. The OpEx record is amended accordingly at this time.

The batch intervals are fixed by the Unit Op’s start time, stop time, installation delay and batch frequency, which are inherited from its parent MOD Site. This information is simultaneously used to calculate CapEx cashflows, including any amortization or depreciation in the description. The product store is at any time available to supply the next Unit Op and/or the haulage dispatch agent at this MOD Site.

There remains the problem of sizing the facilities for any Unit Op, which dictates CapEx expenditure, and heat requirements via volume and surface area. For the initial Unit Op at any MOD Site, the size is determined by the limiting consumable annual capacity scaled by batch frequency. This is used to calculate a product capacity for this Unit Op. This product capacity is used to calculate the limiting consumable annual capacity for the subsequent Unit Op, enabling us to size it, and calculate its product capacity. This reasoning is repeated along the sequence of Unit Ops at any MOD Site.

### 2.4. Economy

At the bottom of the agent hierarchy there is a simple economy layer, encapsulating cashflow schedules, amortization and depreciation, discounting, inflation and currency

Fig 3. A fragment of the Excel description for a dewatering or drying Unit Op, showing some key inputs. Start and stop times are inherited from the parent MOD Site, not the Unit Op description.

Exchange rates. Consumables are stored in a price list that governs purchase, inflation, insurance and other consumables rates. Waste and sewerage are consumables that we sell for a negative price. Likewise, facilities and personnel are stored in a price list, which governs all economic matters including purchase, salvage, lifetime, inflation, contingencies, maintenance, Lang factors and scale factors. These default to industry benchmarks from (Fasaei et al 2018, Seider et al 2019) and market values circa 2021.

### 3. Results

The agent based supply chain model has been applied to preliminary studies of microalgal-bacterial remediation of hydrocarbon waste. Biomass cultivation is assumed to follow Monod kinetics (Monod, 1949), calibrated from laboratory work in a phycoflow reactor. The techno-economic inputs for dewatering and drying are based on literature review (Fasaei et al 2018). The cultivation and dewatering Unit Ops are flexibly distributed amongst 41 military bases across the UK. Scheduling consists of dispatching available products to the receivers of their destinations at the end of each batch duration. Transit times incorporating a loading/unloading delay are taken into account automatically, but must currently be scheduled manually in setting the start and stop times for each MOD Site. Optimal scheduling has not been automated.

A typical simulation result is shown in Fig. 5. This is summary information for the entire network, a complete breakdown of the time evolution of reactants and products, and all CapEx and OpEx cashflows is available down to the Unit Op Level (Fig. 6). This information has been used to show, for example, that centralized processing saves some £5.5m over six years in this network, as economies of scale outweigh transport costs. Surprisingly, drying locally cultivated biomass centrally saves £1.8m over local drying. So economies of scale dominate transport costs, even though wet biomass is very bulky.

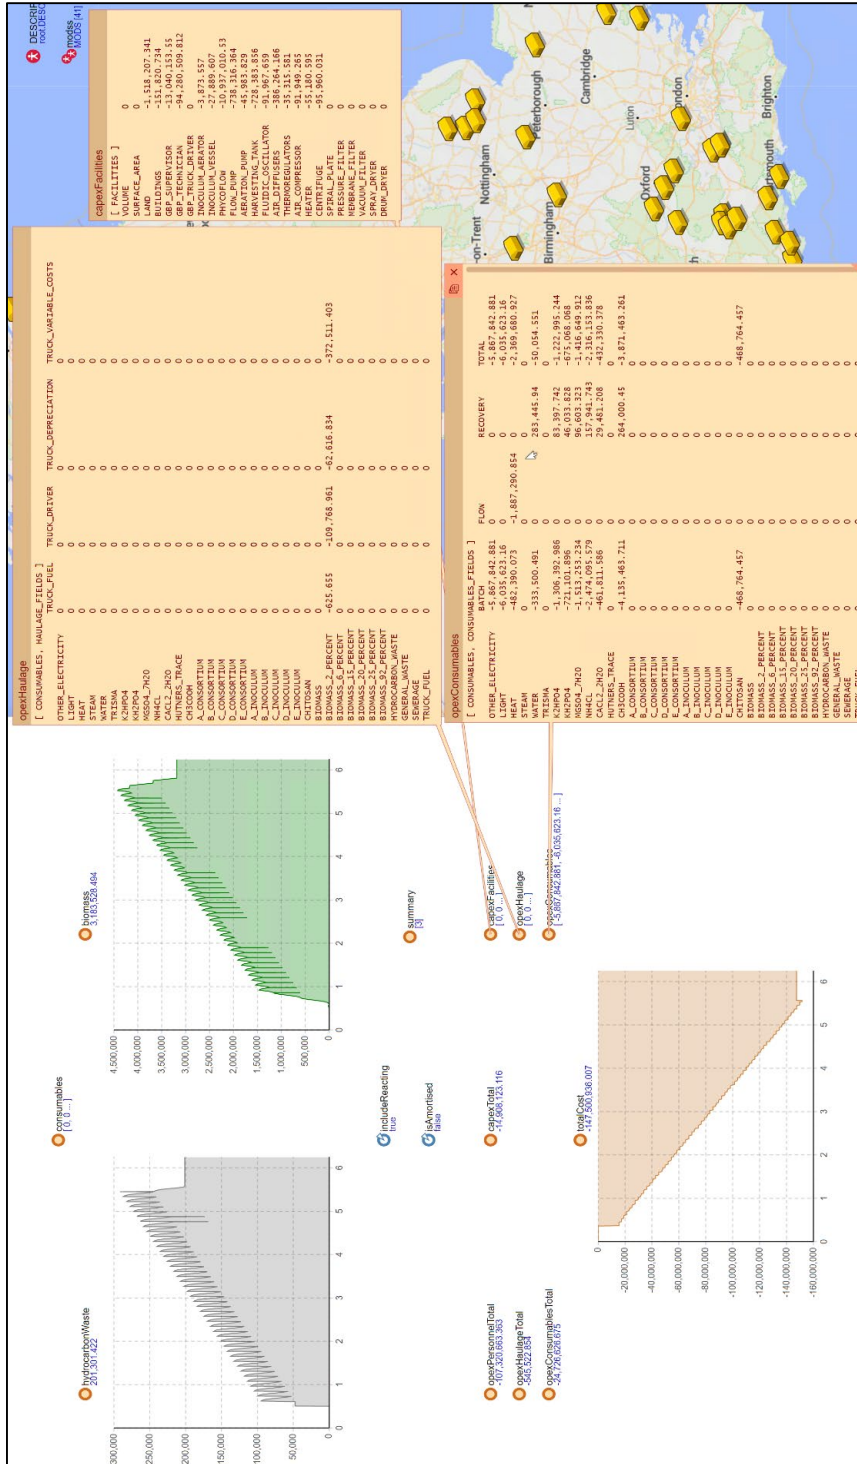

Fig. 5. Accumulated results for a six year nationwide project, showing hydrocarbon waste processed and biomass produced, above expenditure.

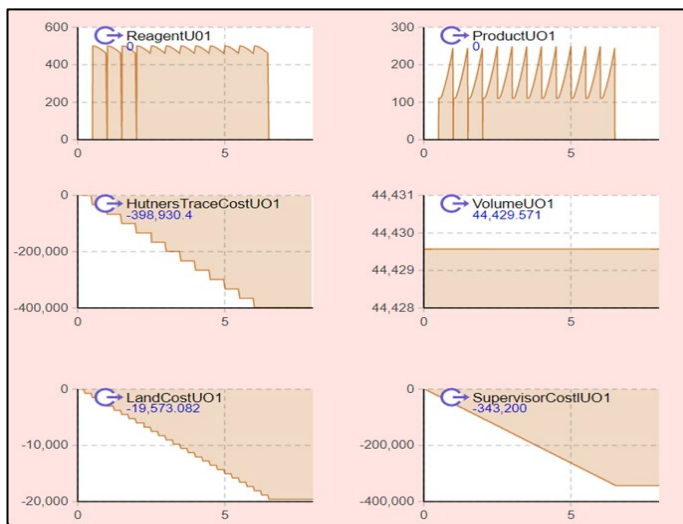

Fig 6. Drill-down results from a cultivation Unit Op.

#### 4. Conclusion

In this paper we have presented a techno-economic process model distributed within a supply chain network. The model is designed as a set of building blocks (Unit Ops) which may be distributed within the supply chain as desired. The many key parameters are neatly organized in a spreadsheet interface of descriptions, specifying location, timing, kinetics and economics. The software is highly extensible, and is almost agnostic to the nature of the Unit Ops. Adding new Unit Ops can be done in a few hours. The runtime for the 41 sites and 82 Unit ops considered is a few seconds. The software architecture is very satisfactory in these regards.

The major challenges only partially addressed concern optimal site capacity and transit scheduling. These could perhaps be optimized automatically in future work. Furthermore, the key outputs – namely material consumed, material produced and economic cost/benefit – should ideally be considered in some optimization scheme in future. Ultimately, it would be wise to analyse the sensitivity of any results to the techno-economic inputs, the future values of which may be quite uncertain.

## Abstract

Bio-industrial processes can be optimized considering climate change using climate change impact assessments. These are based on models that describe the effect of climate on the affected sector. In this case, we focus on milk safety, thus we study Somatic Cell Counts (SCC), which is an indicator of mastitis, and Total Bacterial Counts (TBC), an indicator of the microbiological state of raw milk. The objective is to identify SSC and TBC patterns by looking into their spatial variability. For this purpose, traditional data mining methods are adopted to cover both space and time using data from 53 farms (2014-2019). According to the results, both SCC and TBC indicate spatial correlation. This means that apart from the already established temporal dependency, there is also a spatial dependency. In conclusion, collecting temporal data only from one farm may be misleading. Climate change-proof process design is essential for the dairy sector.

**Keywords:** milk, climate change, data mining, spatio-temporal analysis

## 1. Introduction

As climate change is expected to impact all aspects of life on the planet, it ranks high in both public and private decision making. The main tool needed in such decision making is climate change impact assessments, enabling a climate change-proof process design. It is based on impact models that describe the effect of multiple climate factors on affected sectors (Ahmad et al., 2001), here the dairy sector.

By utilizing these impact models, future food safety risks can be estimated under climate change (Katsini et al., 2021). For example, Gunn et al. (2019) estimated milk yield losses. By looking into raw milk quality, the already established processing standards can be revisited and re-optimized by taking into account the climate change impact on raw milk. A major consideration for process design is milk safety, i.e., the reduction of microflora in milk. Thus, the analysis involves the Somatic Cell Count (SCC), which is an indicator of the inflammation of the breast tissue of cattle, known as mastitis. In such a case, the milk is unsafe and not fit for human consumption. Moreover, the Total Bacterial Count (TBC) is studied, which is an indicator of the microbiological quality as it expresses the plate counts of the total amount of microflora in raw milk. TBC and SCC are recorded on

a regular basis as they form regulatory thresholds for raw milk according to the EU legislation (EC 2073/2005).

The seasonal patterns of SCC and TBC have already been identified (Stürmer et al., 2018), nevertheless microbial dispersal takes place both in space and time. Thus, the objective of this work is to identify spatial patterns of milk contamination by analyzing the SCC and TBC temporal and spatial variability using data-driven modelling approaches.

## 2. Materials and Methods

### 2.1. Data set and data pre-treatment

Data from 682 dairy farms, located in Spain (A Coruña, Galicia), collected over the timespan 2014–2019 comprise the dairy data set. The first step of data pre-treatment was to screen the farms based on data completeness, e.g., cover all the years. After this screening, 53 farms were selected. Secondly, as the sampling frequencies of different farms were inconsistent, data was resampled to obtain the same sampling frequency for all farms, i.e., every 4 days. Existing outliers were removed and the gaps arising from the previous step were filled in using the median of the adjacent samples (10% interpolated data). Finally, the temporal trajectories for each farm were smoothed using a moving window weighted average. The address of each farm is represented in terms of longitude and latitude coordinates.

### 2.2. Methodology

The farms are clustered using non-linear unsupervised learning methods in terms of their temporal variability. The resulting clusters of farms are compared with their real topology in terms of coordinates. Farms that belong to the same cluster and are located close to each other indicate spatial correlation. SCC and TBC data are treated independently, which means that the above is done first for SCC and then repeated for TBC. On the one hand data-driven modelling techniques can be valuable to find patterns in data, however they remain black-box approaches, which means that the results are not always interpretable.

#### 2.2.1. *t-Distributed Stochastic Neighbor Embedding (t-SNE)*

The first method applied in this paper is the non-linear t-distributed stochastic neighbor embedding (t-SNE), which was introduced by van der Maaten et al. (2008). t-SNE performs dimensionality reduction by resulting in a two-dimensional space, that enables the visualization of data in clusters. The method aims at keeping the probabilities of pair distances of the data in the original space as similar as possible to the corresponding probabilities in the reduced space. The clustering is done by visualizing data that have similarities in the original space as points close to each other in the reduced space. In this paper, this method is used, firstly, to identify the number of clusters of farms for SCC and TBC. Secondly, t-SNE results are exploited to assess any possible spatial correlations among pairs of farms. The results were obtained from the `tsne` function of MATLAB using perplexity equal to 4 and the distance metric as the Euclidean.

#### 2.2.2. *Self-Organizing Map (SOM)*

The second data mining methodology exploited is self-organizing maps (SOMs), which is a type of artificial neural network (Kohonen 1982). It is an unsupervised learning method that performs dimensionality reduction by maintaining the topological and metric aspects of the input space. The high-dimensional input space is compressed in a two-dimensional space, which comprises neurons. The SOM algorithm assigns each data point to one of the neurons. Augustijn et al. (2013) explain in detail how SOMs can serve

spatio-temporal analysis. In this paper, the SOM has the same number of neurons as the number of the resulting clusters from t-SNE for SCC and TBC. The selforgmap function of MATLAB is used with two grids. The grid is chosen to be hexagonal and the SOM batch algorithm is used to train the network for 1000 epochs.

### 3. Results and Discussion

#### 3.1. Clusters based on t-SNE

The geographical coordinates act as the reference to assess the clustering of the farms as resulting from the t-SNE technique. t-SNE results are illustrated by the topology of the farms in the two-dimensional space. In the following figures, each dot represents one farm. The farms that are located close to each other for both the t-SNE reduced space and the geographical coordinates are connected by black lines. The dots representing those farms are accompanied by a label including the corresponding code of each farm to facilitate the comparison of their proximity in terms of geographical coordinates.

##### 3.1.1. Results for SCC

Figure 1. The t-SNE reduced space based on SCC.

Figure 2. Clustering of farms based on SCC using t-SNE.

In the case of SCC, three clusters are identified in the reduced t-SNE space. By assessing the topology of each farm in the reduced space (Figure 1) with regard to their map coordinates (Figure 2), four pairs of farms come up, i.e., farm 127 & 215, 333 & 138, 324 & 320, and 112 & 170, as well as a cluster of four farms, i.e., farm 96, 101, 353 & 295. This indicates spatial correlation among those farms in terms of SCC temporal variability.

### 3.1.2. Results for TBC

Figure 3. The t-SNE reduced space based on TBC.

Figure 4. Clustering of farms based on TBC using t-SNE.

The t-SNE clustering based on TBC results in three clusters as well (Figure 3). Following the same rationale as in the case of SCC (Figure 3 & 4), two pairs of farms can be identified, i.e., farm 248 & 251 and 222 & 170. Furthermore, one group of three farms, i.e., farm 181, 114 & 54, along with one group of four farms, i.e., farm 40, 53, 57 & 117, are found. Lastly, the group formed by farm 298, 327, 147, 333, 233, 295, 416 & 324, are located close to each other (Figure 4), however in the t-SNE reduced space (Figure 3) they form a line instead of a group of points. This indicates spatial correlation among those farms in terms of TBC temporal variability as well.

### 3.2. Clusters based on SOM

As mentioned in the previous section, the SOM for each variable has the same number of neurons as the clusters resulting from the t-SNE analysis. In the case of SCC, three clusters of farms are formed in the t-SNE reduced space, thus the SOM is formed by three neurons which represent three groups of farms. However, for TBC, the clusters are less clear in the t-SNE reduced space. Thus, two SOM structures were assessed for TBC, one with two and one with three neurons or groups of farms. The results from the SOM with three neurons are presented here as it provides more insights. The clustering results are presented in terms of the geographical coordinates of the farms, i.e., each farm is depicted as a dot and colored based on the neuron it is assigned to after training the neural network.

#### 3.2.1. Results for SCC

Results from the SOM trained based on SCC data with three neurons indicate clustering of farms with spatial characteristics (Figure 5). Groups 1 and 3 mostly consist farms that are located in the western part of the map, while Group 2 is in the eastern one. Furthermore, all the farms with an indication of spatial correlation following the t-SNE technique (Figures 1 & 2) are clustered accordingly based on the SOM methodology.

Figure 5. Clustering of farms based on SCC using SOM.

#### 3.2.2. Results for TBC

In the case of the SOM trained based on the TBC data with three neurons, the geographical distinction is less clear compared with the SOM for SCC (Figure 6). Group 1 mostly consists of western while Group 3 of eastern farms and Group 2 shows no such geographical characteristic. Nevertheless, Group 3 appears to represent farms that are located around the longitude -8.6. Interestingly, some of these farms appear close to each other in the t-SNE reduced space (Figures 3 & 4) as well, i.e., the group of farms that forms a line in Figure 3.

The agreement between the t-SNE and SOM methodologies both based on SCC and TBC for those sets of farms makes a stronger argument regarding the hypothesis of this study, i.e., whether there is a spatial correlation among dairy farms in terms of SCC and TBC. Even though the results do not show a clear geographical clustering, the indication of its existence is presented, as resulting from these two methodologies.

Figure 6. Clustering of farms based on TBC using SOM.

#### 4. Conclusion

Processes such as milk pasteurization, can be optimized considering climate change using climate change impact assessments. As pasteurization aims to reduce the microbial load, such an impact assessment is based on a model that describes the effect of multiple climatic factors on milk contamination, which is expressed with SCC and TBC. This study aimed at identifying spatial correlations among dairy farms in terms of SCC and TBC by applying data mining techniques. According to the results, both SCC and TBC indicate spatial correlation among dairy farms. This means that apart from the temporal dependency between SCC and TBC and climate, there is also a spatial dependency among farms. Therefore, collecting data only from one farm may be misleading. In this way, predicting food safety aspects of milk under climate change is less uncertain. Assessing the application potential of such models to different locations may be realized by evaluating if predictive models developed from Spanish data can explain the spatio-temporal characteristics of raw milk produced in another region.

## Abstract

The emergence of Quality by Design (QbD) and Process Analytical Technology (PAT) paradigm supported by the FDA imposes a strong motivation for digital transformation in biopharmaceutical industry. The inherent complexity of bioprocess dynamics, batch-to-batch variability resulting from raw materials and process operations, as well as the need for accelerating product manufacturing, makes dynamic soft sensors such as Kalman Filters highly desirable for process development, monitoring, and control. In this work, we develop an Ensemble Kalman Filter framework in the context of monoclonal antibody bioprocessing, where the noise on physical sensors is mitigated for extracellular metabolite states by integrating the process' dynamic mechanistic model and sensor measurements. More importantly, the framework accurately estimates the nucleotide sugar concentrations, an intracellular state of the cell that is not routinely measured in industry due to experimental complexity. The proposed EnKF soft sensor retrieves this knowledge through state inference, providing valuable insights for monitoring and control of key quality attributes such as glycan distribution.

**Keywords:** Antibody Bioprocessing; Metabolites; Nucleotide Sugar Donors; Ensemble Kalman Filter

## 1. Introduction

Glycoproteins such as monoclonal antibodies represent the largest group of biologically derived medicines with substantial market growth in the foreseeable years. Nucleotide sugar donors (NSD) are activated forms of monosaccharides that act as direct co-substrates for synthesizing glycosylated proteins, with their intracellular levels providing insights on the cell state. Real-time NSD information in bioprocesses can support decision-making on extracellular nutrient feeding towards controlling and monitoring key product quality attributes such as glycan distribution. However, NSD measurements are challenging to obtain experimentally and are therefore not routinely performed in industry. As NSDs are synthesised metabolically, several predictive models have been built to link extracellular metabolites with intracellular NSD concentrations. Whilst these models can be highly accurate in predicting NSD concentrations (Kotidis et al., 2019, Jedrzejewski et al., 2014, Sou et al., 2017, Villiger et al., 2016), they are usually system-specific and require extensive re-parameterization for changes in experimental conditions, cell line or product.

As an alternative to the system-specific predictive models, Kalman Filters (KF) employ a mechanistic process model to predict system transition from a previous to the current

state while integrating the information from hard sensor measurements. In addition to unmeasured state inference, the idea of KF is to produce better estimations of the measured states compared to either measurements or model predictions alone (Narayanan et al., 2020). Here, a Monte-Carlo based KF for non-linear systems, Ensemble Kalman Filter (EnKF), is proposed to estimate NSD concentrations using a mechanistic model and corrected by easy-to-obtain extracellular metabolite measurements. The EnKF is able to filter noise in metabolite measurements and subsequently enables a more accurate estimation of NSD concentrations. The combination of sensor observations and first principles modeling reduces the reliance on highly specific mechanistic models and makes obtaining accurate NSD knowledge possible without directly measuring them, offering great promise for applying the QbD paradigm to ensure product quality during manufacturing.

## 2. Material and Methods

### 2.1. Experiment Description

A fed-batch CHO cell culture process producing an IgG antibody was used to evaluate the performance of the EnKF-based soft sensor, where the culture was supplemented with glucose and amino acid nutrients on even days of the entire 12-day cell culture period. Daily measurements were taken for all of the metabolites and NSDs. The experimental set up and associated dataset can be found in full in Jędrzejewski (2015).

### 2.2. Mechanistic Model Description

The mechanistic model used in this study consists of two parts, the cell culture model and the NSD metabolic model. Briefly, the cell culture model describes the cell growth and death, extracellular metabolism, and antibody production, whereas the NSD metabolic model was formulated to account for the specific cell growth rate, intracellular metabolite reactions and the transport of NSDs into the Golgi. A detailed model description can be found in Kotidis *et al.* (2019).

### 2.3. Simulation of True Values

Here, it is assumed that the true value for each of the extracellular metabolites and intracellular NSDs can be simulated by adding a white Gaussian process noise to the mechanistic model. Although true values are not available in real-life scenarios, the simulated true states are only used to examine the effectiveness of the EnKF-based soft sensor and their values are not used in executing the algorithm.

### 2.4. Data Augmentation of Experimental Observations

Due to nonlinearities in the growth rate equation, the availability of additional, artificial measurements allows implementation of a more stable and robust EnKF estimation. For this purpose, we have augmented the experimental dataset with artificial measurements. The latter were generated by adding sensor noise, in the form of variance calculated from the experimental triplicate to the true state trajectories described in 2.3.

### 2.5. Ensemble Kalman Filter

The EnKF is a Monte-Carlo based KF, where an ensemble of state vectors is randomly sampled from a large cloud of states that represents a specific probability density function. The ensemble is then integrated forward in time through the true non-linear process model and updated when a new observation becomes available (Evensen, 1994). The update step in EnKF introduces additional approximations when non-Gaussianity or non-linearity are involved, where the ensemble ‘shift’ towards the new observation through linear Gaussian state-space model (Katzfuss et al., 2016). Regardless, EnKF has been successfully applied to many complex non-linear and non-

Gaussian cases, although the deviation from Gaussian behaviour becomes more important when the ensemble predictions are substantially different from the observations (Aanonsen et al., 2009).

Figure 1 presents the implementation of the EnKF in this work. The algorithm starts by sampling an ensemble of states for each metabolite and NSD, with a mean equal to the estimated initial conditions and a covariance representing the uncertainty of this first-estimate of the initial state. The number of draws for the ensemble is determined by  $2L+1$  where  $L$  is the number of states, a rule of thumb that is commonly used in Unscented Kalman Filter (UKF) (Hommels et al., 2009). Since UKF is an approximation of EnKF and this rule of thumb is used to propagate the approximate distribution on the UKF, we decided to apply the same heuristic to approximate the distribution via Monte Carlo by the EnKF. The selected EnKF ensemble is then propagated through the non-linear process model  $f$ , with a white Gaussian noise  $w$  added at every time step. Here, the effect of the error propagation through correlated states must be taken into account when designing the covariance matrix of the process noise  $w$ . This is to ensure a reliable evolution of the ensemble variance, as a sensible estimate of the model variance is of vital importance for the success of EnKF (Evensen, 1994). In practice, the design of process noise covariance matrix is a trial-and-error procedure based on which matrix yields the most accurate state estimation for that specific filter structure (Alag and Gilyard, 1990).

The mean at time step  $k$ ,  $\hat{x}_k \in \mathbb{R}^{n_x}$ , of the ensemble is then calculated following the prediction step and the state covariance,  $P_k \in \mathbb{R}^{n_x \times n_x}$ , can be estimated from the spread of the ensemble  $X_k$ . It should be noted that the state covariance  $P_k$  is not an explicitly expressed matrix for implementation of EnKF, but rather an intermediate state for calculating the Kalman gain in the update step (Houtekamer and Mitchell, 2005). In this work, the EnKF algorithm has been designed to only go through the update step if the measurement is available at that time point. Following the prediction step, the Kalman gain  $K$  in the update step can be interpreted as a ratio of how much the algorithm trusts the model prediction versus the measurement. The Kalman gain  $K$  is then used as a weighting factor to scale the residual between sensor measurement and model prediction, which ultimately output the filtered state  $x$  for the next prediction step.

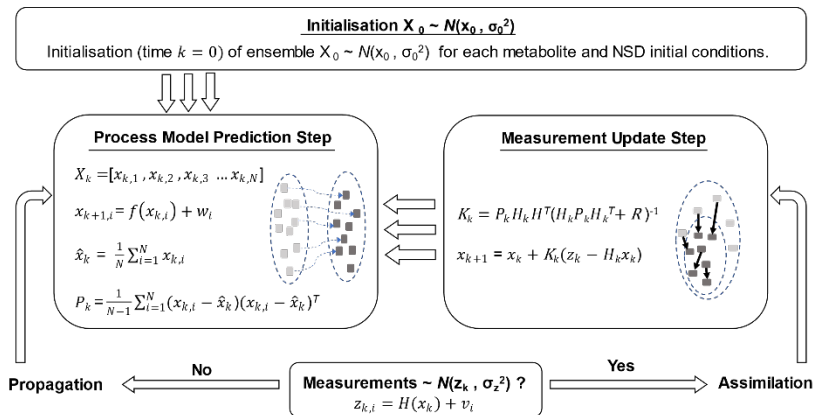

Figure 1. The Ensemble Kalman Filter algorithm, adapted from Pellenq and Boulet (2004). **Notations:**  $X$ , sampled ensemble;  $f$ , process model;  $w$ , white Gaussian noise of process;  $x$ , process states;  $P$ , state covariance;  $K$ , Kalman gain;  $H$ , measurement function;  $R$ , measurement noise covariance;  $z$ , measurement;  $v$ , white Gaussian noise of measurement

### 3. Results & Discussion

#### 3.1. Metabolites correction

As shown in Figure 2, the EnKF showcases an excellent performance on predicting the viable cell density, antibody titre, extracellular metabolites glucose and ammonia concentrations when plotted against the true trajectory of the states. As the Kalman gain  $K$  is involved in the update step as a scaling factor, the filtered results will lie in-between the measurements and the model prediction. The mechanistic model predicts all four states accurately from the start of the cell culture period until the lag phase, and then gradually deviates from the true value. This results in an overestimation for viable cell density and antibody production titre, underestimation of glucose levels, and slight underestimation and then overestimation of the ammonia levels in the exponential and stationary phase, respectively. In contrast, the EnKF estimation is closer to the true value for the entire cell culture period and converges with time propagation. This phenomenon is particularly obvious for glucose, for which the EnKF lies closer to the model prediction than the true value from Day 4 to Day 6, but gradually converges towards the end of the culture period and matches almost exactly to the true value trajectory.

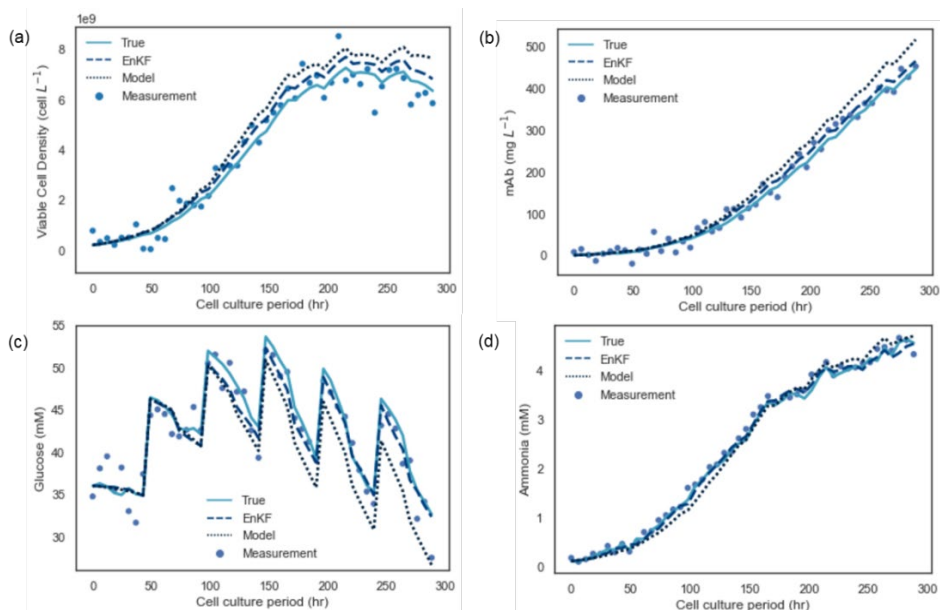

Figure 2. Comparison of true trajectory (solid line), states estimated by EnKF propagation (dashed line), mechanistic model prediction (dotted line) and noisy measurements (scatter) for (a) viable cell density  $X_v$  (b) antibody titre  $mAb$  (c) glucose concentration and (d) ammonia concentration

#### 3.2. NSD estimator

The estimation of unmeasured NSD states, UDP-Galactose (UDPGal) and UDP-glucose (UDPGlc) concentrations, is compared with their respective true value trajectories, as illustrated in Figure 3 (a) and (b). UDPGlc is the high-energy donor form of glucose, which synthesizes glycogen and other glucose-containing molecules such as dolichol P-glucose, the key substrate for initiating the glycosylation process (Varki, 2017). On the other hand, UDPGal serves as the main precursor for galactosylation, a highly desirable characteristic for enhanced antibody-dependent cellular cytotoxicity (Kotidis et al.,

2019). Therefore, real-time estimation of UDPGal levels offers valuable knowledge on developing process engineering strategies for optimizing the product glycan distribution. For example, extracellular galactose feeding has been consistently reported to increase the UDPGal pool, which then promotes galactosylation on the recombinant product (Blondeel and Aucoin, 2018). Here, although sensor measurements for UDPGal and UDPGlc concentrations are not directly available for implementation of the EnKF, the extracellular data appear to be correlated with intracellular NSD levels. NSD concentrations are therefore implicitly corrected from the available extracellular metabolite measurements through the EnKF update step and propagated forward in time with the EnKF prediction step. Overall, the EnKF outperforms the mechanistic model, especially towards the end of the cell culture period where the EnKF converges towards the true value. The computed time-resolved mean squared error (MSE) in Figure 3 (b) and (c) shows that pure mechanistic model is more prone to system instability and model inaccuracies. The MSE for both NSD concentrations is consistently lower for EnKF. For UDPGal concentration estimation, the MSE reduces past the exponential phase, while the MSE for UDPGlc concentration remains low throughout the culture period, in contrast with that for the mechanistic model, which increase rapidly in late-stage culture.

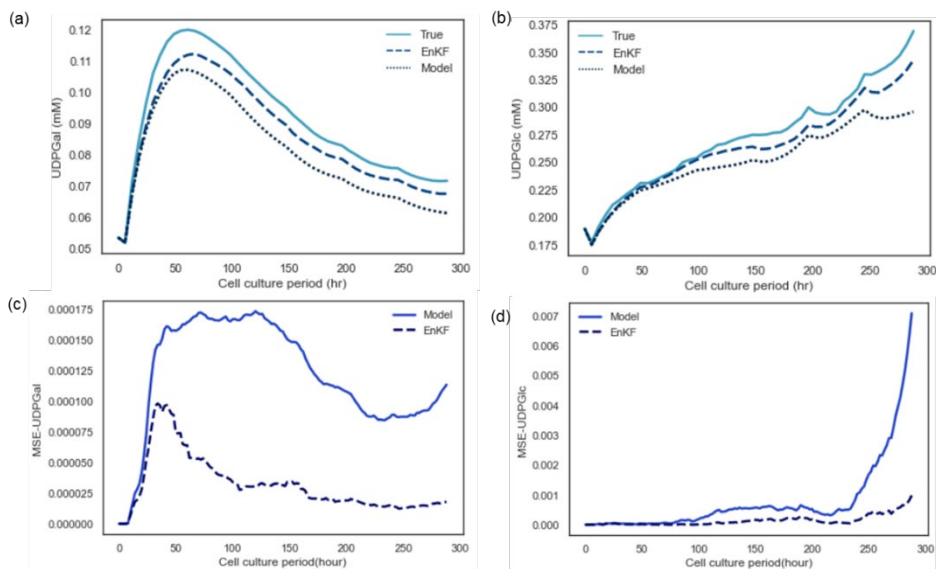

Figure 3. Comparison of true trajectory (solid line), states estimated by EnKF propagation (dashed line), mechanistic model prediction (dotted line) for (a) UDPGal concentration (b) UDPGlc concentration. Model prediction and EnKF estimation MSE computed against the true trajectory for (c) UDPGal concentration and (d) UDPGlc concentration

#### 4. Conclusion & Outlook

Herein, we present the implementation of EnKF for estimation of intracellular NSD concentrations. The proposed EnKF framework performs well with respect to reducing sensor noise and estimating unmeasured NSD levels accurately, which therefore support in-process decision-making and product quality control based on easy-to-obtain extracellular measurements. Moreover, the incorporation of time-discrete sensor

observations infuses a degree of data-driven characteristic to the mechanistic process model while retaining the system dynamic knowledge, thereby potentially providing greater flexibility in transferring the framework to other process conditions, cell line or product.

## Abstract

Biomanufacturing has been increasingly receiving attention in the past few decades due to the need for sustainable production of various consumables, global energy crisis, and climate change. The biomanufacturing sector or the so called biosolution has found application in the production of various products such as fine and bulk chemical, pharmaceuticals, food and feed products, and biofuels. However, this industrial sector is facing a lot of challenges mainly due to scalability issues and lack of fundamental understanding from the process development point of view, which need to be addressed. Hence, a unified systematic multi-scale approach is required to address some of the current challenges by providing profound knowledge of the fundamental phenomena at various scales for a more efficient process scale-up. In this study, a conceptual systematic framework is proposed that incorporated the fundamental knowledge from various disciplines that potentially could tackle some of the aforementioned challenges within the biosolutions framework.

**Keywords:** multi-scale, modelling, scale-up, bioprocess, microalgae.

## 1. Introduction

Biosolutions is a multidisciplinary commercial area that targets the use of biological systems such as enzymes, microorganisms, bio-based chemicals, and bio-based materials. The ongoing “green transition” and the increasing demand for nutritious and sustainable foods for the growing global population are key drivers of biosolutions. Novel proteins satisfy both aspects and remain a field of high interest. Industries involved in the production of commodities or foods (such as biofuels and novel proteins) in large quantities suffer from low profit margin thereby making the economic /environmental feasibility very sensitive to for example (i) scale of production and thus the scale-up process, (ii) raw material prices, and (iii) energy prices. Therefore, a robust scale-up methodology and experimental infrastructure are of utmost importance. Biosolutions often lean towards large scales of production and low value raw materials (e.g., local raw materials, valorization of “waste” streams such as CO<sub>2</sub> and process water) to obtain a feasible business case. Biosolutions Zealand is an international lighthouse project that aims to develop state-of-the-art biosolution technologies with commercial focus, while strengthening its sector in Denmark with a focus on Kalundborg Symbiosis. The

symbiosis in Kalundborg, Denmark, known as one of the largest symbiosis self-sufficient networks, is comprised of various production facilities for water, energy, food, feed, and biopharmaceutical products and has been an originally-evolving environmental collaboration for more than five decades. The network aims to tackle sustainability challenges within economic, social, and environmental scopes by exploiting the potential within a sustainable collaboration framework. A multi-scale strategy can have a crucial role in developing a fundamental understanding of process development activities in such a complex framework. This could potentially lead to optimized process operation, less lab and pilot experiments, lower unnecessary product losses, and more importantly lower time required from process development to meeting market demands. As the energy crisis is rapidly growing as a global challenge, such a strategy will lead to optimum energy utilization, potentially lower global warming potential and harmful emission within a production facility or a production network such as Kalundborg Symbiosis. In this work, we sketch a framework that provides a suitable chronological methodology and toolbox to bring a potential product to the market by virgin raw materials or by upgrading waste stream(s) microorganisms. The challenges and perspectives are highlighted and discussed for each step. Finally, a case study within the Biosolutions Zealand project is presented.

## 2. Framework for Biosolutions

It is well-known that bioreactors comprise a multi-scale complexity, in the sense that the links between hydrodynamic (bulk scale), local fermentation media conditions experienced by the individual cells (heterogeneities), and the cellular reactions and networks, are far from established. Therefore, experimentation is currently considered as an inevitable yet costly and time-consuming activity in production scale-up. Ideally, scale-up can be performed successfully and robustly *in silico* (simulation) using minimum amount of experimental work. This framework (Figure 1) summarizes the promising tools for the process of taking a target product to the market (a biosolution), and incorporates the scale-up elements presented by (Wang et al. 2014; Wang et al. 2020).

### 2.1. Step 1. System Identification

An idea for a biosolution either arises from a targeted desired product or a targeted technology with the aim of identifying valuable product(s) for a given symbiotic environment. A targeted technology could be microalgae photobioreactor (as the case study presented later). Hence, in this step, all  $P$  product candidates,  $S$  material side-streams must be systematically identified. Additionally, all energy sources must be identified, however, this is only used for Step 6. Due to advances in strain optimization using either genetic engineering (i.e., genetically modified organisms, GMO's) and high throughput cultivation for natural random mutations, we recommend also to list the  $N$  potential candidate production host microorganisms. The biosolution identification problem now comprises a  $P \times S \times N$  multidimensional search space as a single-product example.

High throughput screening (HT) has become common practice in most biobased manufacturing. It is carried out in micro-liter scale at controlled conditions, with typical commercial configurations up to 96 simultaneous cultivations (e.g., 96 well-plate). The target is to screen among the many candidates using optical or spectroscopic measurement techniques to significantly reduce the search space. Parameters such as mass transfer, strain robustness towards concentration changes, etc., are commonly not

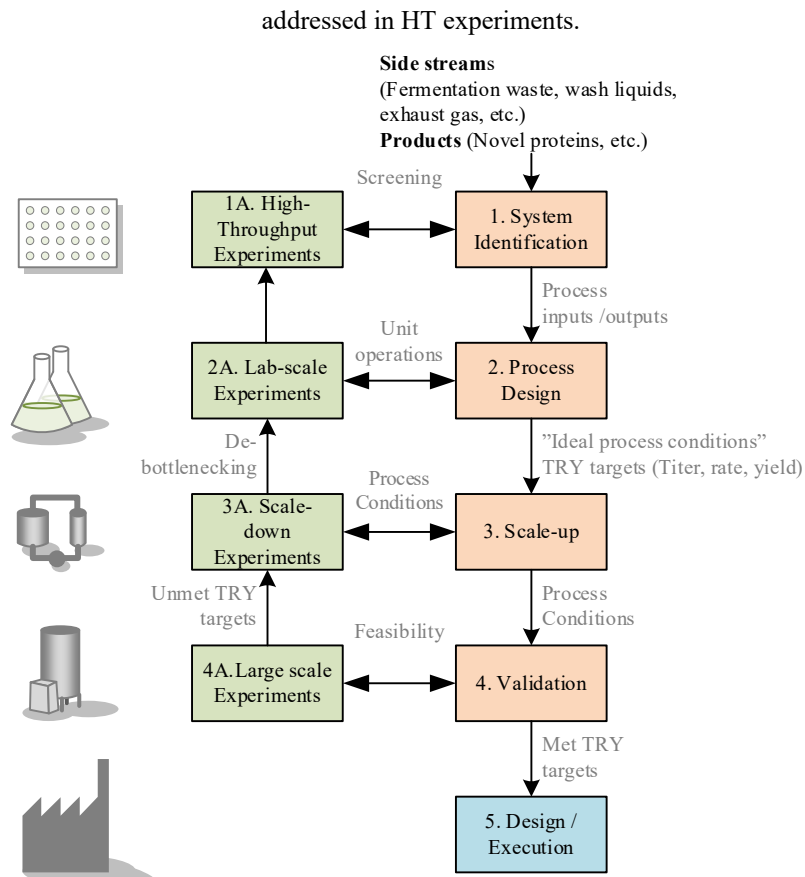

Figure 1. Biosolutions Framework.

## 2.2. Step 2. Process Design

The conceptual is a classical discipline, that aims to identify process flowsheet, mass balance, overall plant layout, techno-economic and sustainability feasibility, and a coarse price estimate. Another important aspect of the conceptual design includes assessment of performance indicators (PI's), which covers as a minimum the techno-economic feasibility and sustainability. The process design task will define targets for the process and hence the following tasks. The targets are titer (gram product per volume), rate (gram product per volume per time), yield (gram product per gram raw material), together with recovery rates at each separation step. The targets define the techno-economic feasible design space. Titer, rate, and yield are commonly known as TRY.

Laboratory experimentation may be used to identify feasible upstream and/or downstream unit operations. For upstream, the experiments could cover shake flask and bench-scale bioreactors. The aim of shake flask studies is to map the optimal ("ideal") conditions of the microorganisms. Such studies typically involve data-driven optimization such as one factor at the time or factorial design (e.g., RSM, Response surface methodology), complemented by statistical tools such as ANOVA. When the optimal conditions are identified, kinetic models must be fitted to the experimental data. Simple stoichiometric models should be developed to obtain the ideal cultivation trajectory. The conditions

determined at this step will be a proper initial estimate of the trajectory that must be further refined during the scale-up procedure using model-based scale-up techniques. Integration of Step 1 and Step 1 are possible with modern facilities, e.g., Gamble et al. 2021.

### 2.3. Step 3. Scale-up

The main task in performing scale-up is to understand the metabolic–hydrodynamic coupling during fermentation and achieve your final goal. Computational Fluid Dynamics (CFD) Euler-Lagrangian particles appear to provide a useful tool for this, in which the lifeline of single cells can be analyzed quantitatively (Lapin et al. 2004; Haringa 2022), thereby facilitating targeted experimentation, e.g., down-scale studies (Lapin et al. 2004; Noorman 2011). Hence, CFD can be coupled with a segregated description of the cell population (Pigou & Morchain 2015). Wang et al. (Wang et al. 2020) highlight the four key challenges in model development for scale-up studies:

- I. Lack of metabolic data representing the variable conditions inside bioreactors.
- II. Kinetic models do not capture the nonlinear structure of cellular kinetics.
- III. Inappropriately designed experiments for parameter identification and estimation.
- IV. No minimization of uncertainty via data reconciliation.

Metabolomics is one of the promising tools to support key challenges outlined in points I, II, and IV. It has been demonstrated that metabolic activity depends on the culture media (Pigou & Morchain 2015; Noorman 2014; Xu et al. 1999).

### 2.4. Step 4. Validation

Validation is performed to address the uncertainty associated with scale-up. Access to an experimental scale-up facility comprises a huge challenge for companies (in particular small to SME's, small and medium-sized enterprises) due to high investment cost and due to the gap of knowledge that lies across various scales in process development. To avoid unnecessary capital investment, several alternatives exist and continue to emerge, such as rental facility, e.g., mobile scale-up facility (containerized) (Fahr et al. 2022). On another note, these validation scale-up strategies should be coupled with model-based scale-up solutions to support the validation phase quite efficiently. In the biosolutions project, a combinatorial strategy using model-based scale-up and mobile facilities are explored to provide a understanding in depth of the various process steps and to avoid large investment on a fixed facility. A more generalized solution can be developed to support as many production facilities as possible that are capable of mimicking the larger scale process steps. The intention is to develop a mobile facility that is easier to adapt to a variety of processes by using a modularity concept. The modularity concept in this project lies on the different process steps such as upstream and downstream, waste handling and utility management. However, on the early-step design of the mobile unit, several considerations have been made in terms of capacity and compatibility for replacing unit operations at various steps.

### 2.5. Step 5. Design /Execution

Upon completion of conceptual design (Step 4A through 4C), the following phases focus on the translation of process to physical equipment, via specifications, etc., during basic design (BD). Following BD is the detailed design (DD) in which technical drawings,

equipment and pipe sizing are made to initiate the execution (construction, C&Q, and validation). Process design changes should be minimized at this step since degrees of freedom are lowered with project progression.

### 3. Case Study: Microalgae

Microalgae can be a source of high valued biomolecules such as proteins and lipids of interest of food and /or pharmaceutical production, while being relatively robust to the process conditions of side streams (Andrade et al. 2018). Hence, they are subject of bioremediation and valorization applications.

Five industrial side streams from a Danish company was investigated initially to illustrate the proposed methodology. At present *Chlorella vulgaris* was selected as the microorganism and photobioreactor was selected as the technology. The following aim is to valorize the side stream by selecting valuable compounds produced by microalgae after cultivation.

The *Chlorella vulgaris* was cultivated in the five different side streams at three different concentrations as a preliminary example of HT screening (diluted versions of the side stream) and under sterile and non-sterile conditions (Figure 2A). As a control experiment, cultivation was also carried out in a chemically defined media (CDM). The experiments were conducted under controlled environment (150 rpm, 25 C, 40  $\mu$ mol intensity, 12h/12h cycle).

The results suggested that *Chlorella vulgaris* presents a favorable growth pattern using one of the side-streams rather than CDM (Figure 2B) which is supposed to be tested at larger scales that allow extended process monitoring and control with a subset of conditions from the HTS.

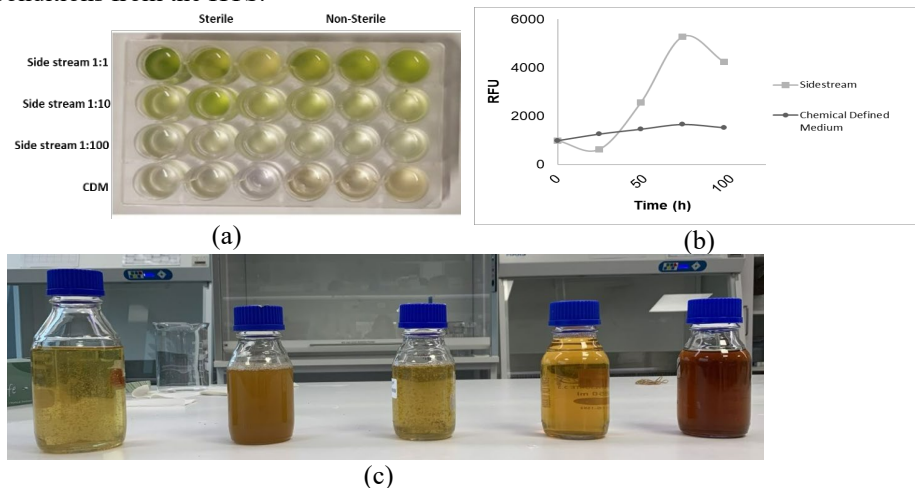

Figure 2. Step 1A HT Screening example (a) 24 well-plate of cultivation at different side streams (b) Absorbance of 24 well-plate experiment that is used to correlate the growth rate. (c) Industrial side streams.

At the time of writing, the necessary biomass is produced in shake flasks to quantify the TRY. Furthermore, the biomass will be used in supercritical CO<sub>2</sub> extraction lab-scale test to quantify the recovery. Ultimately, the goal of this microalgae study is to develop a

process that can be validated in containerized pilot scale at the company's facility. I.e., up to Step 4.

## Abstract

The development of Process Systems Engineering tools that can integrate experimental information with models is fundamental to obtain higher yields and increase productivity of a bioprocess. This is not a simple task, and there is a need for tools that facilitate the collaboration in a multidisciplinary group. In this context, developing computational frameworks for simulation and parameter estimation of bioprocesses that could be used comprehensively by researchers with different backgrounds is the goal of this work. The structure of such frameworks is carefully designed based on an ontology to describe bioprocesses. A helpful tool is the Unified Modeling Language and its use for software generalization is demonstrated along with a case study, showing that the software could serve as a model or example of good practice of software development for guiding simulations and parameter estimations of bioprocess in a structured way.

**Keywords:** bioprocesses, object-oriented programming, prototype, systems biology, unified modelling language.

## 1. Introduction

Biotechnological processes promote microorganisms' synthesizing ability to produce complex molecules that are difficult to access by traditional chemical synthesis, besides to promoting a sustainable and eco-friendly alternative. However, to make the production of a target compound economically viable, a bioprocess needs to be designed and developed to adapt an engineered microbial producer strain (Hemmerich et al., 2021). Process Systems Engineering (PSE) tools together with an experimental effort are necessary to improve the economic potential and sustainability of a new bioprocess. Besides, the required dataset size increases steadily over the years, mainly due to the technical improvements in the data measurement techniques. Often, the extensive experimental data can only be processed and interpreted through the development of quantitative methods. Combining PSE and biotechnological abilities is not a simple task, and there is a need for tools that facilitate the work and collaboration in a multidisciplinary group, which is the mark of the systems biology area (Meyer and Saez-Rodriguez, 2021). Systems biology is the scientific field that studies how the properties of biological systems emerge from the interaction of multiple components. This approach has become essential to cope with the increase in information (Bassalo and Gill, 2016; Meyer and Saez-Rodriguez, 2021). An advanced systems biology model would ideally be based on

physical laws and verified by comparing how its predictions fit experimental data. However, this is not always possible. Indeed, knowledge of the fundamental physical principles that give rise to biochemical processes is often incomplete, even for simple systems, and the available information which describes a biological system requires simplifying assumptions to allow model building. Thus, terms based first principles can be studied and incorporated into models, making them more and more complete through the years (Meyer and Saez-Rodriguez, 2021). This is the reason why systems biology is considered a multidisciplinary topic, which indicates that rarely a single person will have a deep knowledge in all fields (Zuo and Zhao, 2018).

In this context, developing computational frameworks become desirable to guide applications in bioprocess modeling. It is recommended the structure be carefully designed, since researchers with different backgrounds are able not only to use the software, but also to contribute with new models as studies in biotechnology are updated. In this way, architecture software becomes as important as developing it. Even in simple cases, it is recommended that the entire system be modeled before starting its implementation, since systems often tend to increase in size, complexity and scope. Developing the architecture is common in the computer science field, and demonstrates the software's flexibility to new editions. For the reasons given, it is interesting to bring these concepts to biotechnology to have a tool along these lines. To guarantee the (re)usability of the system, ontologies are an option to support the sharing of information structures (Guedes, 2018). Ontology is an explicit specification of a conceptualization, and typically involves classes, their relationships and axioms to describe the intended semantics (Marquardt et al., 2010). It is important that every party involved, from developers to users, reach a common understanding of the abstractions and semantics, since the software is intended to be distributed across multiple locals and researchers.

The knowledge represented by ontology allows instantiations of bioprocess components, which makes the information easy and readily shared since these components are standardized and organized. One of the tools used for the design of ontologies is the Unified Modeling Language (UML), which provides the basis for developing software architecture in an organized and generalized way and avoids inconsistencies between requirements specification documents and implementation (Arora et al., 2020; Yurin and Dorodnykh, 2020). In this work, methods and techniques which can describe bioprocesses are implemented in Julia, covering options of growth models, as well as different operation modes. The use of UML for software generalization is demonstrated with a case study, showing that the software could serve as a model or example of good practice of software development for guiding simulations and parameter estimations of bioprocess in a structured way.

## 2. Methodology

### 2.1. Software architecture: ontology for bioprocesses

Ontology has a philosophical origin, where there is interest in the conceptualization of the world of what exists and the essence of things. The basic element of the ontology is the class, which represents a collection of components that share common characteristics. It is organized by hierarchy, in which each inherited property is assigned to subclasses. Components belonging to the same class are called instances, and the characteristics or parameters of the class are the attributes. Each attribute can be identified by its name and has one or more values specific to the class it belongs to. More details can be described in the visual tool that represents ontology: UML (Marquardt et al., 2010; Zhang et al.,

2013). A flowchart that summarizes the methodology used in this paper is shown in Figure 2.1.

Figure 2.1. Overview of methodology for software architecture

For this work, UML diagrams were implemented using the StarUML software (version 4.5.1), and two types of diagrams were chosen: use case (Figure 3.1.b) and class diagrams (Figure 3.1.a). The first is the most general form of UML and presents an external version of the functionality that the system should offer to users, without details about how such functionality will be implemented. It presents a simple and easy-to-understand language, so that users can readily get an idea of how the system will behave. This diagram is of great help in identifying and understanding the system requirements, helping to specify, visualize and document the system features, functions and services desired by the user. It consists of two main items: actors and use cases. The actors, represented by “skinny dolls”, can be the users, other systems or even some special hardware that will use the system in some way. The functionalities that the system will make available to the actors are known as use cases, which is represented by ellipses containing a succinct text describing the action. Interactions between them are represented by lines (Guedes, 2018). The second diagram (class diagram) includes classes, interfaces and relationships. Classes are the model for creating objects, providing specification of attributes and operations that an instance of the class can complete. These operations are treated as functions or procedures, i.e., how actions will happen. Each class can implement more than one interface and each interface can be implemented by several different classes. Relationships have a similar concept to that in the use case diagram, but with more details and more types of relationship (Guedes, 2018).

## 2.2. Bioprocess modelling: starting equations

Bioprocess are represented by the class diagram, abstraction and classification of its components are done based on equations in the most generic way possible, which allows additions of more complex concepts related to the component to be made, either in the class itself or through interactions with other created ones. The first class created was *OperationMode* and the abstract characteristics for it came from the general mass balance (Doran, 2013):

$$\frac{dM}{dt} = M_i - M_o + R_G - R_C \quad (2.1)$$

where the derivative  $dM/dt$  is the mass accumulated within the system and it is zero if the system is in steady-state,  $M_i$  is the mass entering through system boundaries, i.e., the mass flow rate of a component entering the reactor,  $M_o$  is the mass flow rate leaving the system,  $R_G$  is the mass rate of generation of a component by reaction, and  $R_C$  is the mass rate of its consumption. Inherited classes are created for: continuous mode, which considers the entire equation, batch and fed-batch mode with same characteristics, but differing by the first having  $M_i$  and  $M_o$  equal to zero, while in the second only  $M_o$  is zero.

Considering that, when a bioprocess is carried out by microorganisms,  $R_G$  is given by:

$$R_G = \mu_X X \quad (2.2)$$

where  $\mu_X$  is the specific growth rate. A similar situation can be found for  $R_C$  with a specific death constant.

$$R_C = k_d X \quad (2.3)$$

Continuing with the creation of classes, it becomes noticeable that a class for microbial growth and death should be created. Cell growth and product formation reflect general kinetics and stoichiometry of intracellular reactions. So, the new class *CellGrowth* will interact with the  $R_G$  attribute of the *OperationMode* class, as *CellDeath* with  $R_C$ . *CellGrowth* will enable that different types of growth can be chosen for the system, since rates like  $\mu_X$  can be described in several ways. One of the most commonly used method is relating  $\mu_X$  to substrate  $S$ , taking the form of saturation kinetics. For example, when it is assumed that a single substrate  $S$  is limiting for  $\mu_X$ , while changes in other nutrient concentrations have no effect, this can be described by the Monod equation or alternative ones, such as Blackman, Tessier, Moseer and Contois equations. On the other hand, when substrate or product concentrations are high and inhibitory substances are present in the medium,  $\mu_X$  depends on the inhibitor concentration. Then, these situations can be described by others equations. A similar situation occurs with the *CellDeath* class, which must consider the mechanisms for decreasing cell mass, for example, when temperature changes,  $K_d$  can vary according to the Arrhenius equation (Shuler et al., 2002).

Growth kinetics has stoichiometrically related parameters, such as cell maintenance and yield coefficients, and it is also influenced by environmental conditions. There is a set of factors to be considered and consecutively, new classes arise and interactions with other classes can be performed. For example, in aerobic processes, oxygen becomes a limiting factor for growing and therefore, the oxygen transfer (OTR) from the gas phase to the liquid phase and the oxygen consumption rate (OUR) should be considered as subclasses belonging to a new *Oxygen* class, which can describe the model's dissolved oxygen. Thus, the architecture provides situations and paths for assembling models (Shuler et al., 2002).

### 2.3. Case study for bioprocess

The intended use of the system and the mentioned classes, both projected so far in the UML diagrams, were used to guide the software programming. The language chosen for the implementation of the code was Julia by its high-performance, flexibly dynamic and open source. A case study to evaluate its operation was carried out with the properties: data simulation of biomass (X), substrate (S) and product (P) in batch, with cell growing by Monod equation. The parameters are  $\mu_{max} = 0.3 \text{ h}^{-1}$ ,  $K_S = 0.2 \text{ g/l}$ ,  $Y_{XS} = 0.06 \text{ g/g}$ ,  $Y_{PS} = 0.46 \text{ g/g}$  and initial values of  $X_0 = 0.06 \text{ g}$ ,  $S_0 = 9.54 \text{ g}$  and  $P_0 = 0.00 \text{ g}$  (Doran, 2013).

## 3. Results and discussion

### 3.1. Software architecture: UML diagrams

A prototype representing the system and some definitions are shown in a section of the class diagram in Figure 3.1a, and the use case diagram, which describes an overview of actions, is shown in Figure 3.1b. In Figure 3.1.a, the bioreactor mass balance is represented by the *OperationMode* class, which is divided according to the data they will receive from Equation 2.1. Each operating mode is a subclass, which inherits mass balance characteristics and are called by the *Continuous*, *BatchMode* and *FedBatchMode* subclasses.

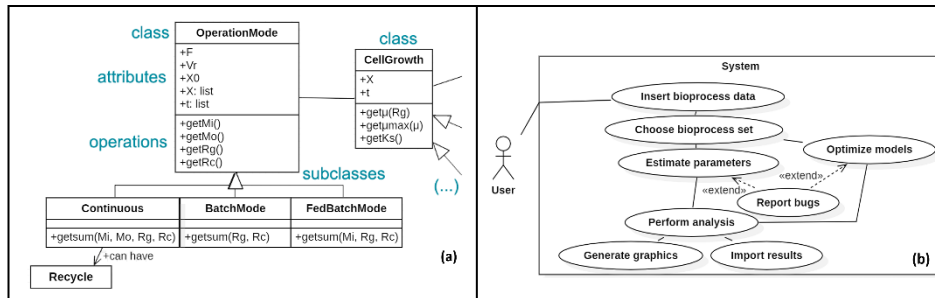

Figure 3.1. UML diagrams of bioprocess system: (a) class and (b) use case diagrams.

The equations for each of these classes depend on mass that enters or leaves the system. Within the *Continuous* subclass, recycle can be also considered. Other classes that have been generated are *CellGrowth* and *CellDeath* and may also be present in operating modes. *CellGrowth* subclasses were determined in a similar way as seen in *OperationMode* and include the different limitations that can occur for cell growth. These subclasses are represented by three dots to also indicate that the class diagram is dynamic, as the software architecture is, and can grow depending on what is added to the model.

Figure 3.1.b shows the cascade of actions, from the insertion of bioprocess data in the system to the generation and import of results. The idea is that the users indicate what they would like to do in the system according to the data they have: simulate or estimate parameters, or even optimizing them. For simulation they should indicate the operating mode and the type of growth, plus the kinetic parameters necessary; for parameter estimation, bioprocess data should be provided; and for optimization, a complete model and objective function should be defined, choosing which variables will be free and what will be optimized, according to the purpose of the model.

During the development of this structure, it was noticed that the abstraction of concepts involving bioprocess must be done with care, in order to generate several options, and it should allow for increasing complexity and flexibility of the analysis.

### 3.2. Simulation modelling

In the case study, a batch bioreactor is simulated and shown in Figure 3.2.  $X$ ,  $S$  and  $P$  data were generated considering total time of 100 h.

Figure 3.2. Data simulation for batch bioprocess.

The equations used to generate this simulation data can be recycled to perform, in other contexts, parameter estimation and optimization. In addition, the system can grow in number of equations to be considered in the model, which could make the differentiating of equations more laborious. To cover these issues without compromising the software's

functionality, the code implemented in Julia was adapted to the JuMP language in advance. JuMP is a domain-specific algebraic modeling language embedded in Julia and has a syntax that mimics natural mathematical expressions (Dunning et al, 2017). Because it only comprises algebraic equations, the differential equations (ODE) were discretized using Implicit Euler, which is a first-order orthogonal collocation method. Higher orders of this method can be implemented to deal with stiff problems (Biegler, 2010), which is interesting to be considered in this work to cover more complex bioprocesses that may involve stiff ODE systems. Although JuMP is mainly used to perform optimization, it can be adapted for simulation, as it happened here. The premeditated use of it will positively impact the software's development to deal with more complex problems and also involving optimization cases.

#### 4. Conclusions

This prototype can bring new perspectives for bioprocesses modelling, as currently the software community has given great attention to architectures as a key abstraction in design process. The use of UML for software generalization is demonstrated with a case study, showing that the software could serve as a model or example of good practice of software development for guiding simulations and parameter estimations of bioprocess in a structured way. In summary, this prototype is an alternative tool for model-based integration and analysis of data, which can be the seed of a new, robust and sophisticated tool for systems biology.

## Abstract

Remediation of per-and poly-fluoroalkyl substances (PFAS) is challenged with complexities of solutions, recalcitrance of end products and stringent, evolving regulations. Grouping, characterization and classification of PFAS compounds, environmental contaminations and treatment technologies through knowledge modelling has potential to overcome these challenges. Treatment technologies are often required to work in sequences, called treatment trains to achieve complete removal of PFAS from the environment i.e. a removal/separation stage followed by a degradation stage. Here, an ontology framework is presented to classify PFAS compounds and treatment technologies. Potential applications for the knowledge model to support decision making in environmental remediation and technology research and development is discussed.

**Keywords:** Per-and poly-fluoroalkyl substances (PFAS); remediation; ontology; knowledge modelling; treatment trains

## 1. Introduction

Per- and poly-fluorinated alkyl substances (PFAS) are a class of ~10,000 persistent chemicals, used for >50 years to produce, surfactants, surface treatments, aqueous fire-fighting foams (AFFFs), and plastics such as polytetrafluoroethylene (PTFE) (Buck 2021). Complete remediation of PFAS is challenged by their recalcitrance and bioaccumulation in flora and fauna (Ahrens 2011). PFAS are released into the environment from landfill, manufacturing plants, ground contaminations and sewage treatment plants. Common PFAS are now restricted under the Stockholm Convention on Persistent Organic Pollutants. However, as PFAS are banned, replacement PFAS compounds (next-gen PFAS, e.g. GenX) are introduced with unknown, toxicity and persistence. PFAS are estimated to cost the EU €52-€84 bn per year in health-related issues (Goldenman 2019). PFAS degradation technologies are often limited by i) incomplete mineralisation leading to smaller PFAS fragments; ii) select efficacy, unable to degrade all PFAS; iii) toxic by-products; iv) high energy and/or long treatment times; v) impact of the matrix composition; and vi) integration into end-to-end treatment trains.

Ontology engineering is proposed to support implementation of treatment regimens for PFAS remediation. Approaches to treatment design (e.g. superstructure optimization in wastewater treatment plants) are challenged by the extensive, up-to-date domain-specific knowledge required. For example, variable contamination characteristics, emerging technologies, developing policies and new PFAS types. Ontologies have been used to address a wide range of knowledge-intensive tasks, from linked data (Samwald et al., 2011) to molecule modelling for drug discovery (Lin et al. 2017) and to industrial symbiosis, matching of waste streams to waste processing technologies (Trokanas 2014) with the aim to create processing paths. Ontology engineering can enable formalization of data and knowledge representation of complex data sets from chemical elements to

biological and genomic data, to enable the identification of missing relationships (or steps), support classification and clustering models, as well as graph learning approaches. However, within the domain of environmental remediation knowledge modelling is limited with some examples in management of resources (Goel et al 2013), planning (Safavi 2015), and water flow modelling (Chau 2007). The objective of this work is to present a classification framework that combines the use of knowledge modelling for representation of complex chemistries and PFAS treatment options. The framework is a first step towards a decision support tool for PFAS remediation.

## 2. Framework Development

### 2.1. PFAS Classification

PFAS are defined as any compound with a fully fluorinated carbon, i.e.  $-CF_2-$  ethyl group or  $-CF_3$  methyl group and can be classed as non-polymer and polymer substances. In the environment, non-polymer PFAS are more common with detailed information on nomenclature available in literature (e.g. Buck 2011). In 2018 The OECD identified 4,730 PFAS substances (OECD, 2018), however fewer than 6% are reported to be globally relevant (Buck 2021). For the development of the knowledge model, established chemical classifications are used to manually group classes and subclasses, (e.g. Table 1). PFAS compounds may belong to two or more classes, e.g., a long chain perfluoroalkyl acid (PFAA) may be a carboxylic or sulfonic acid. Chemical classifications allow integration with existing Chemical ontologies, e.g. Chemical Entities of Biological Interest (ChEBI).

Table 1. Example classes of PFAS compounds

Perfluoroalkyl Substances	Subclass	Chemical structure
<b>Perfluoroalkyl acids (PFAAs)</b> $C_nF_{2n+1}-R$ (where R is a hydrophilic functional group)	Perfluoroalkyl carboxylic acids (PFCAs)	$C_nF_{2n+1}COOH$
	Perfluoroalkyl sulfonic acids (PFSAs)	$C_nF_{2n+1}SO_3H$
	Short chain (SC) PFAA	$C_nF_{2n+1}-R \quad n \leq 5$
	Long chain (LC) PFAA	$C_nF_{2n+1}-R \quad n \geq 6$
Polyfluoroalkyl Substances		
<b>Fluorotelomer (FT) substances</b> Used or made from the fluorotelomer process	(n:2) Fluorotelomer alcohols ((n:2) FTOHs)	$C_nF_{2n+1}CH_2CH_2OH$
	(n:2) Fluorotelomer sulfonic acids ((n:2) FTSAs)	$C_nF_{2n+1}CH_2CH_2SO_3H$
<b>Perfluoroalkyl ether acids (PFEAs)</b> Perfluoroalkyl moieties connected by ether bonds	Perfluoroether carboxylic acids (PFECAs)	e.g. GenX or HFPO-DA with the same protonated form: $C_3F_7OCF(CF_3)-COOH$
	Perfluoroether sulfonic acids (PFESAs)	e.g. n:2 Cl-PFESA: $Cl(CF_2)_nO(CF_2)_2SO_3H$

Chemical classifications also create classes that underpin treatment efficacy, manufacturing methods, persistence, and degradation products. Initial manufacturing of PFAS was based on the PFAAs perfluorooctane sulfonic acid (PFOS) and perfluorooctanoic acid (PFOA) (where  $n=7$  and  $n=8$ , respectively) known collectively as PFOX. Now almost all bodies of water contain at least 1 ng/L of PFOX (Ahrens 2014), and most treatment and toxicology research is based on these two compounds. However, fluorotelomers (FTs) and perfluoroalkylether acids (PFEAs) have replaced PFOS and PFOA, leading to new profiles of persistent PFAS in groundwater (Backe 2013). FTs are

based on shorter perfluorinated carbon chains (usually C4 or C6), linked to a hydrophilic end group via what is usually a two-carbon alkane chain. The FT compound class leads to formation of shorter chain PFAAs, or fluorotelomer sulfonates, depending on the initial structure. PFEAs are manufactured from short perfluoroalkyl moieties connected by ether bonds and have worldwide persistence (Pan 2018). PFEAs are resistance to hydroxyl radical mediated oxidation, photolysis and biodegradation, and are highly mobile, hence have similar remediation issues to their predecessor compounds.

## 2.2. Classification of treatment technologies

Treatment technologies initially focus on treatments for water contaminations. In general treatments can be classed into two types; i) separation/concentration treatment where low concentration (<ng/L) waste streams can be treated, producing a clean water that meets regulatory standards, and ii) degradation treatments where the main aim is to degrade the PFAS compounds into smaller PFAS fragments and/or to complete mineralization. The difficulty in achieving complete mineralization of PFAS comes from their extremely strong C–F bond and the shielding of carbons by fluorine components of the molecule (Kirsch 2004). Hence developing appropriate treatment trains that also mineralize PFAS are one of the key challenges for PFAS remediation. Numerous reviews exist into PFAS treatment technologies (e.g. Ross et al 2018; Horst et al, 2018; Kucharzyk et al 2017) here we aim to discuss the nuances of different regimes to underpin the ontology framework.

### 2.2.1. Separation / concentration treatments

Separation / concentration methods are grouped into granular/powder activated carbons (GAC/PAC), resins and silicas, membrane separation and foam fractionation (Table 2). Treatment properties can be attributed to each treatment class, as defined in Table 2 (Rahman 2014). Within each class, data properties will be further identified to capture the nuances of the treatment regimen and subclasses identified.

Table 2. Separation / concentration treatments, with relevant properties. NR = not reported.

TREATMENT	Efficacy for different PFAS			Matrix effects	Waste/side streams
	PFEA	SC	LC		
<b>GAC / PAC</b>	None to moderate	Moderate /ineffective	Moderate (not all precursors)	Organics compete	Contaminated solid (PAC), solid for regeneration (GAC)
<b>Resins and silicas</b>	NR	IX is less efficient	Yes	Depends on absorbent	Regenerate solutions
<b>Membrane separation</b>	NR	Yes	Yes	Impacted by organics	Membrane rejectate, spent membranes
<b>Foam-fractionation</b>	NR	Yes	Yes	Unlikely to interfere	Concentrated PFAS solution (ppm range), sedimentation

### 2.2.2. Degradation treatment technologies

Degradation mechanisms can be thermal, oxidative, biological, physical and reductive. In each case the mode of operation / technology used varies, along with the efficacy and matrix effects. For example, advanced oxidative processes (AOPs) and biological treatments are not effective at complete PFAS mineralization (Ross et al, 2018) and leave shorter chain PFAAs. Incineration, a thermal treatment can convert ~20-45% of the fluorine to toxic hydrogen fluoride (HF) gas (Aleksandrov et al 2019; Taylor et al 2014) and can emit gaseous fluorocarbons and unconverted PFAS with insufficient incinerator temperatures or residence times (Meng et al, 2017). Electrochemical reduction can be non-selective and reduction of matrix elements must be considered (Horst et al 2018).

Classifications must allow for technologies that support multiple mechanisms. For example, reductive methods include metal-mediated reduction (e.g. catalysis in

supercritical water, zero valent metals) (Kucharzyk et al 2017) and methods that promote the generation of the hydrated electron (photolytic, electrolytic and plasma) (Ross et al 2018). However electrolytic and photolytic technologies can also use oxidative degradation. Similarly ultrasonic technologies (i.e. sonolysis) are considered to be oxidative at low frequency, and argued to be pyrolytic (thermal) or reductive via the aqueous electron at high frequencies (Sidnell et al 2022). The ontology structure is therefore developed to allow such classifications (Figure 1).

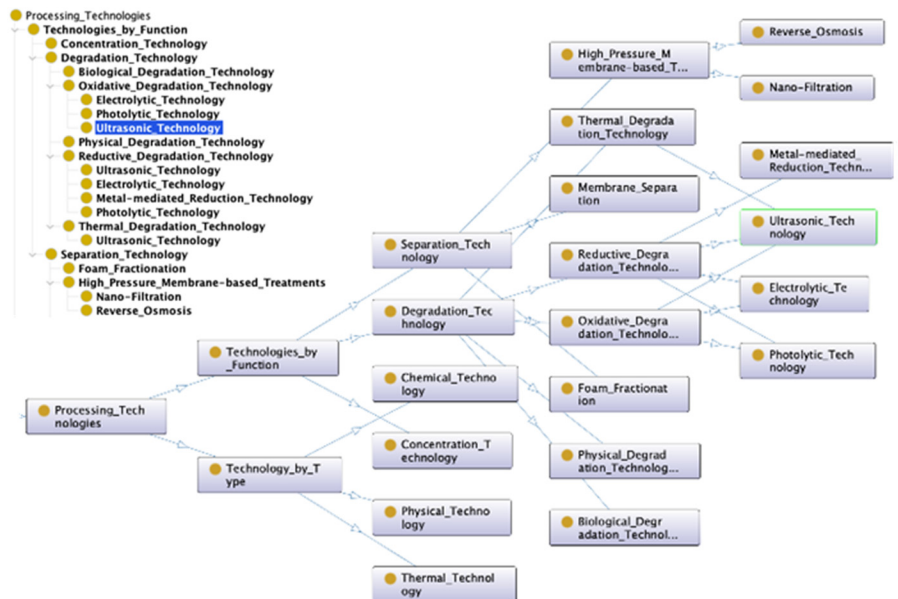

Figure 1. The PFAS Treatment technology ontology structure for a selection of treatment types.

### 2.2.3. Proposed ontology structure

Identified classes and object properties for technology classification (Table 3) are designed to capture the necessary considerations for overall remediation efficacy. The characteristics of function and type are chosen to allow for later development of knowledge graphs and inferencing around novel treatment technologies and/or new PFAS compounds, i.e. to handle missing information. Each technology may have more than one output stream, then each output stream can be classed according to environmental release laws, drinking water standards and potential further treatment options.

Within each treatment technology further object properties must be assigned to avoid sweeping generalizations around a class of technologies, often seen in literature. For example, ultrasonic degradation of PFAS can be highly dependent on frequency, additives, and reactor geometry. At low frequencies (<100 kHz) very little degradation is seen without additives, whereas at high frequency (100-1000 kHz) complete mineralization has been reported at ambient temperatures (Sidnell et al, 2022). Similarly electrolytic methods will depend on the electrolyte, electrode material and reactor configuration (Ryan et al 2021). Approaching the comparison and selection of technologies through knowledge modelling therefore highlights such nuances and enables better-informed decision making.

Table 3 Classes and object properties underpinning the PFAS treatment technology modelling

Classes	Examples
Function	Separation, concentration, degradation
Type	Thermal, physical, biological, chemical
By mechanism	Oxidation, reduction, membrane separation, ion exchange etc
Object properties	Examples
Output stream	F, CO <sub>2</sub> , SC PFAS, LC PFAS, PFAAs, co-contaminants...
Input composition	PFAS concentration, co-contaminants
Efficiency	Fluoride release rate, PFAS degradation / removal rate
Common parameters	Temperature, volume, pressure
Developmental stage	Laboratory, pilot scale, industrial scale
Cost	Capital, operational, energy consumption

### 3. Future applications and development of PFAS ontology

The classification framework for the PFAS ontology has potential application in supporting selection of treatment trains, provide predictions about technology efficacy, and focusing research and development of treatment technologies. Through modelling the inputs and outputs separation / concentration technologies can be matched with appropriate degradation technologies using matching algorithms (Trokanas 2014). This is especially useful since degradation technologies tend to be expensive at treating dilute solutions and more efficient at higher concentrations. For example, at concentrations in the mg/L range high frequency sonolysis tends to be zero order, but at lower concentrations is first order. Hence the zero-order regime is more energy efficient per gram of PFAS destroyed. Technology matching will show potential treatment trains given a composition profile of a PFAS contamination and desired PFAS output profile. Thus, has potential to inform economically and environmentally optimal treatment regimens.

One of the key challenges of PFAS remediation is the complete mineralization of all PFAS types. Due to the difficulty in destroying PFAS, many of the technologies applied are in various stages of development, with the majority of research on PFOS and PFOA degradation. Effective technologies often come at high energy and capital cost and more research and development is required to understand efficacies for new and emerging PFAS in a range of matrices. The nuances of each emerging technology are often only fully appreciated by subject-matter experts and there is danger in over-generalization of different treatment regimes. The ontology will inform knowledge graph development to facilitate machine learning to highlight necessary experiments and/or likely outcomes of various treatment regimes. If a known treatment has overlapping characteristics with an unknown treatment technology then the knowledge graph can be used to infer and predict the outcomes of the unknown treatment technology.

### 4. Conclusions

Here we presented a framework for developing an ontology around PFAS remediation. The ontology will be able to be integrated with existing knowledge models and is useful for creating a common language to model PFAS treatment regimes, support decision making on PFAS treatment trains and underpin research, development and learning around emerging PFAS degradation technologies.

## Abstract

Biotechnological products are promising sustainable alternatives to fossil-derived fuels and plastics. A modified strain of the bacterium *Pseudomonas putida* KT2440 produces 3-(3-hydroxyalkanoyloxy)alkanoic acids (HAA) from glucose, which can serve as a precursor for bioplastic and biofuel production. We investigate the use of acetate as alternative, sustainable, and low-cost substrate. We use an expanded version of the genome-scale metabolic model *i*JN1463 to improve the understanding of the metabolism. Rates and yields calculated from experimentally obtained data were used as input for flux balance analysis (FBA) and compared to computational data. Despite substantial model-experiment mismatch, FBA provides insights into the acetate metabolization. Finally, we utilize the optimization-based gene knockout method OptKnock to propose potential targets for strain engineering with the aim of improved product yields.

**Keywords:** Metabolic modeling, Biotechnology, Acetate, HAA, *Pseudomonas putida*.

## 1. Introduction

Genome-scale metabolic models (GEMs) contain the entire set of genes of an organism and the metabolic reactions encoded by those genes. GEMs are built based on experimentally obtained data and genome annotation data and are used to predict cellular responses and metabolic fluxes under different environmental conditions, *e.g.*, different substrates, by optimization techniques such as flux balance analysis (FBA) (Varma & Palsson 1994). Thus, GEMs help to understand metabolic processes in a cell and increasingly find applications in biotechnology to support and reduce experimental approaches. FBA formulates a cellular objective and metabolic constraints as a linear optimization program to quantify the metabolic state of a cell under the assumption of a steady state (Orth 2010). Thereby, optimal metabolic flux distributions are calculated to predict growth rates, as well as maximal theoretical biomass or product yields. The experimental results can in turn be used to validate and optimize the model predictions. Improving the performance of a biotechnological strain often requires time-consuming genetic engineering. To reduce experimental effort, the elimination of reactions that result in a beneficial metabolic configuration for improved product yields can be predicted with GEMs. The bilevel programming framework OptKnock was developed by Burgard *et al.* (2003) to propose optimal gene deletions in *Escherichia coli*.

We investigate the biosynthesis of 3-(3-hydroxyalkanoyloxy)alkanoic acids (HAA) with an engineered *Pseudomonas putida* KT2440 strain on acetate in an approach combining

experimental and computational methods. HAA can be produced recombinantly using *P. putida* KT2440 KS3 (Blesken 2020). The current production, however, relies on glucose. Herein, we focus on acetate as an alternative substrate, as it is a low-cost, biotechnological substrate due to its abundance in several side streams (Kiefer 2021) and can be produced from C1-gases, such as CO<sub>2</sub> (Kiefer 2021). Thus, acetate contributes to an improved CO<sub>2</sub> balance of the overall process. Although *P. putida* KT2440 KS3 can use acetate as the sole carbon source, the growth behavior of the strain is impaired by the presence of the C2-compound and product titers lag behind titers achieved from glucose. FBA and OptKnock are used to help understand the altered metabolism on acetate when compared to metabolizing glucose and find potential targets for strain engineering toward optimized product formation. As a basis for FBA and OptKnock, several GEMs are available for *P. putida*. The most current and complete model available is *iJN1463* (Nogales 2020). In this study, *iJN1463* was expanded to contain the synthesis and export reactions for HAA. Experimental data including growth rate, biomass yield, product yield, substrate uptake rate, as well as CO<sub>2</sub> production rate were obtained from shake flask cultivations of *P. putida* KT2440 KS3 on glucose and acetate. While the substrate uptake rate was used as input for FBA, the other data were used to compare and evaluate computationally obtained data. Internal fluxes were calculated and displayed with special interest on CO<sub>2</sub>-forming reactions. Moreover, beneficial gene deletions resulting in higher HAA yields were predicted using OptKnock in several rounds comprising one to five target reactions. This work highlights the possibilities and advantages of a combined approach of experimental and computational work.

## 2. Methods

### 2.1. Experimental methods

The bacterium *P. putida* KT2440 KS3 (Blesken 2020) was cultivated in mineral salts medium as described by (Hartmans 1989) with threefold buffer concentration when 0.17 Cmol of glucose or fourfold buffer concentration when 0.17 Cmol acetate, were used as the sole carbon source. Cultivations were performed in 500 ml shake flasks with 10 % filling volume at 250 rpm and a shaking diameter of 50 mm. Main cultures were inoculated with a defined volume of the pre-cultures to start with an optical density at 600 nm (OD<sub>600</sub>) of 0.1. Cultivations with online monitoring of CO<sub>2</sub> resulting from bacterial metabolic activity were performed with 0.13 Cmol glucose or acetate in 1 L shaking flasks with a 50 ml filling volume. Biomass formation was monitored offline by measurement of the OD<sub>600</sub>, which was converted into cell dry weight (CDW) using a correlation of 0.31 g L<sup>-1</sup>.

Concentrations of glucose and acetate were determined using HPLC as described by Blesken *et al.* (2020). HAA titers in cultivation broth were determined using an Ultimate3000 HPLC system with a dual gradient pump, connected to a Corona Veo Charged Aerosol Detector (all Thermo Scientific). An analytical and an inverse gradient set up of 0.2 % formic acid in acetonitrile and 0.2 % formic acid in ultrapure water were applied for chromatographic separation with a NUCLEODUR C18 Gravity column (Macherey-Nagel) with 150 mm length and a diameter of 3 mm.

CO<sub>2</sub> production during cultivation was monitored using BSP-CO<sub>2</sub> sensors and the BlueVIS software (BlueSens gas sensor GmbH). Yields of biomass per substrate were calculated by division of the maximal reached CDW by the applied substrate concentration. Product yields were determined by dividing maximal product concentration by applied substrate concentration. Substrate uptake rates were calculated by dividing the growth rate  $\mu$  by the biomass yield per substrate.

## 2.2. Flux balance analysis and visualization

To obtain insights into the metabolism, FBA was performed according to

$$\begin{aligned} \max_{\mathbf{v} \in \mathbb{R}^n} \quad & \mathbf{c}^T \mathbf{v} & \mathbf{v}: & \text{flux vector; } n: \text{ number of reactions} \\ \text{s. t.} \quad & \mathbf{S} \mathbf{v} = 0 & \mathbf{c}: & \text{parameter vector to choose objective flux} \\ & v_i^{lb} \leq v_i \leq v_i^{ub} \quad \forall i \in \{1, \dots, n\}, & \mathbf{S}: & \text{stoichiometric matrix from GEM} \\ & & lb: & \text{lower bound; } ub: \text{ upper bound} \end{aligned}$$

where the maximization of the biomass flux or the maximization of the HAA flux was chosen as objective function. The FBA is based on the stoichiometric matrix  $\mathbf{S}$  of a GEM. The GEM applied in this work is *iJN1463* (Nogales 2020), which contains 2,927 reactions, 2,153 metabolites and 1,462 genes. We extended the network by the gene *rhlA* and the reactions specific to the strain KS3, namely four synthesis reactions in the cytosol, one for each HAA congener, and four transport reactions from the cytosol to the extracellular space. With the extracellular HAA congeners as reactants, one exchange reaction was added that simulates the production of HAA in the congener composition that was experimentally determined. Exchange reactions represent the exchange of the cell with the environment and enable closing the mass balance. The stoichiometric factors in the exchange reactions were adjusted on each substrate to display the altered HAA composition on glucose and acetate. The software COBRAPy ([opencobra.github.io/cobrapy](https://opencobra.github.io/cobrapy)) serves to conduct the FBA and Gurobi 9.5.2 serves as solver. Substrate uptake rates determined experimentally were set as input. To visualize the fluxes through the network, the software Escher ([escher.github.io](https://escher.github.io)) was utilized.

## 2.3. Optimal knockouts

Genes encode enzymes that catalyze reactions. When knocking out a certain gene by means of genetic engineering, the associated reaction is not catalyzed anymore, *i.e.*, cannot carry flux anymore. To suggest gene knockouts, the formulation OptKnock was applied, which suggests reactions that are advantageous to block, *e.g.*, reactions towards a byproduct. OptKnock is a bilevel optimization program, where the upper level maximizes the flux of the target chemical, and the lower level maximizes the flux of biomass as follows:

$$\begin{aligned} \max_{\mathbf{y} \in \{0,1\}^r} \quad & v_{HAA} & \mathbf{y}: & \text{knockout vector} \\ \text{s. t.} \quad & \max_{\mathbf{v} \in \mathbb{R}^n} v_{biomass} & r: & \text{number of (possibly reversible) reactions} \\ & \text{s. t. } \mathbf{S} \mathbf{v} = 0 & \mathbf{B}: & \text{mapping matrix} \\ & & & (\mathbf{B}\mathbf{y})_i v_i^{lb} \leq v_i \leq (\mathbf{B}\mathbf{y})_i v_i^{ub} \quad \forall i \in \{1, \dots, n\}. \quad (r \text{ to } n) \end{aligned}$$

In this study, the HAA exchange reaction flux  $v_{HAA}$  was set as objective function of the upper level and the biomass flux  $v_{biomass}$  as objective in the lower level. For numerical reasons, the stoichiometric network with  $r$ , possibly reversible, reactions was transformed to an irreversible network with  $n$  irreversible reactions. OptKnock was implemented in our in-house software libALE (Djelassi 2020) and solved using the solver Gurobi 9.5.2.

## 3. Results and discussion

### 3.1. Cultivation on acetate is possible, but achieves lower yields than on glucose

*P. putida* KT2440 KS3 was cultivated on 0.17 Cmole glucose and acetate to determine growth rate, HAA production rate, biomass, and product yield, as well as substrate uptake rate (Figure 1). While on glucose, the strain reaches a maximal cell dry weight (CDW) of 1.6 g L<sup>-1</sup> after 9 h with a growth rate of 0.47 h<sup>-1</sup>, the strain reached a final biomass of 1 g L<sup>-1</sup> CDW after 14 h cultivation time on acetate, exhibiting a growth rate of 0.37 h<sup>-1</sup>. Thus, the biomass yield per substrate is 35 % lower on acetate than on glucose. HAA formation is threefold higher on glucose than on acetate: while on glucose, a final HAA

titer of  $270 \text{ mg L}^{-1}$  was reached after 9 h, on acetate a maximal titer of  $90 \text{ mg L}^{-1}$  was reached after 14 h. The pH increases during the course of the cultivation to a pH above 8 due to the consumption of acetic acid from the medium.

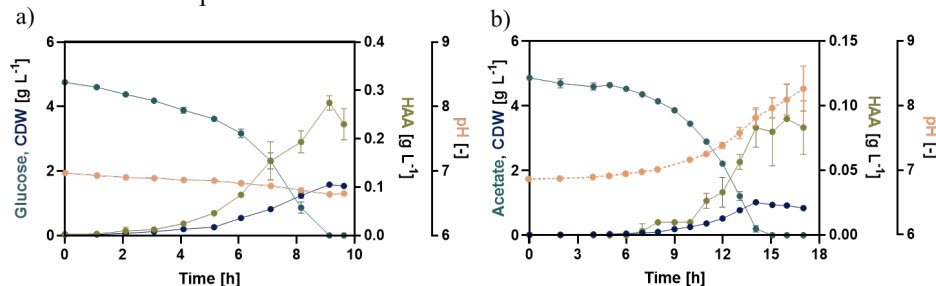

Figure 1: Biomass, HAA and substrate concentration, and pH during cultivation of *P. putida* KT2440 KS3 on a) 0.17 Cmol glucose and b) 0.17 Cmol acetate.

Measurements of the  $\text{CO}_2$  produced by the microbes during cultivation revealed a slightly higher  $\text{CO}_2$  production on acetate than on glucose. While on glucose *P. putida* KT2440 KS3 produced  $0.35 \text{ Cmol CO}_2$  per Cmol substrate, on acetate  $0.37 \text{ Cmol CO}_2$  were produced per Cmol substrate. All in all, *P. putida* KT2440 KS3 exhibits lower rates and yields on acetate than on glucose, which might result from the lower enthalpy of combustion of acetate ( $437 \text{ kJ Cmol}^{-1}$ ) compared to glucose ( $467 \text{ kJ Cmol}^{-1}$ ). However, growth as well as product formation is possible from acetate as sole carbon source. In order to elucidate acetate metabolism and calculate maximal theoretical yields, FBA was performed in a next step. For FBA, substrate uptake rates are required. These substrate uptake rates were determined on  $0.17 \text{ Cmol glucose}$  and  $0.17 \text{ Cmol acetate}$  to be  $7.8 \text{ mmol g}_{\text{CDW}}^{-1} \text{ h}^{-1}$  ( $0.04 \text{ Cmol g}_{\text{CDW}}^{-1} \text{ h}^{-1}$ ) and  $28.5 \text{ mmol g}_{\text{CDW}}^{-1} \text{ h}^{-1}$  ( $0.057 \text{ Cmol g}_{\text{CDW}}^{-1} \text{ h}^{-1}$ ), respectively.

### 3.2. Flux balance analysis gives insights into the altered metabolic configuration

FBA was used to calculate the theoretical yield of biomass and HAA per substrate. Those theoretical yields were then compared to wet lab results that were calculated from experimental data (Table 1).

Table 1: Yield of biomass and HAA on glucose and on acetate: wet lab results, i.e., calculated from experimental data, vs. dry lab results, i.e., from flux balance analysis (FBA). The errors represent the standard deviations of triplicate cultivations ( $n=3$ ). For FBA, the uptake rates were set to equal experimentally determined uptake rates. In case (a) of the FBA, the objective function is the flux of biomass; in case (b) the flux of HAA.

	Substrate	Wet lab	Dry lab
$Y_{\text{Biomass/Substrate}} [\text{g}_{\text{CDW}} \text{g}^{-1}]$	Glucose	$0.34 \pm 0.01$	0.54 (a)
	Acetate	$0.22 \pm 0.01$	0.46 (a)
$Y_{\text{HAA/Substrate}} [\text{Cmol Cmol}^{-1}]$	Glucose	$0.097 \pm 0.005$	0.68 (b)
	Acetate	$0.030 \pm 0.001$	0.59 (b)

When cultivating on glucose, the biomass yield reaches 63 % of the theoretical biomass yield, which is a small difference, when considering that the theoretical yield does not account for any product or byproduct formation. On acetate, 48 % of the theoretical biomass yield is reached experimentally, which is a larger difference. Overall, we conclude that FBA is a valid means to predict growth of *P. putida* KT2440 KS3, especially on glucose. One possible explanation for the greater deviation with acetate as a substrate is the toxic effect of the substrate (Kiefer 2021), which is not considered in the metabolic network. When looking at the HAA yields, FBA predicts values seven times higher or more, than determined experimentally for both substrates. Hence, the

experimental yield has much potential for improvement. However, the overall trend of a lower HAA yield on acetate than on glucose is predicted in the FBA.

To find a reason for this trend, in a next step, the altered tricarboxylic acid (TCA) cycle of the cell on glucose vs. on acetate was visualized in Escher maps (Figure 2). The magnitude of the fluxes in the TCA cycle gives insights into the energy demand of a cell.

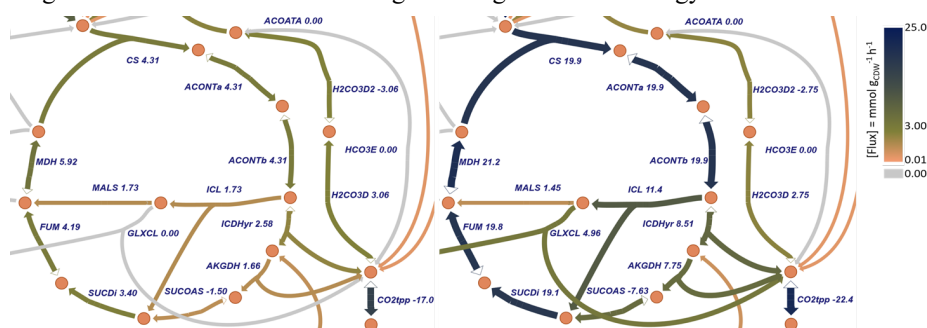

Figure 2: Visualization of the tricarboxylic acid cycle with glucose as carbon substrate (left) and acetate as carbon source (right). Biomass flux is the objective function; a substrate uptake of  $0.05 \text{ Cmol g}_{\text{CDW}}^{-1} \text{ h}^{-1}$  and a threshold of  $0.01 \text{ mmol g}_{\text{CDW}}^{-1} \text{ h}^{-1}$  on the HAA exchange reaction were set as constraints to the FBA. Reactions are labeled with BIGG ID (bigg.ucsd.edu) and the flux value. The figure was adapted from Parschau (2022).

The Escher maps reveal that the cell exhibits a different metabolic configuration on glucose than on acetate, meaning altered reaction fluxes inside the cell. The TCA cycle exhibits fluxes of  $1.5\text{-}5.9 \text{ mmol g}_{\text{CDW}}^{-1} \text{ h}^{-1}$  on glucose, whereas it displays fluxes of  $7.6\text{-}21.2 \text{ mmol g}_{\text{CDW}}^{-1} \text{ h}^{-1}$  on acetate. The higher fluxes through the TCA cycle probably result from the higher energy demand on acetate and the lower energy content of this carbon source. The  $\text{CO}_2$  data derived from FBA follow the same trend as  $\text{CO}_2$  data obtained experimentally: with acetate as substrate, more  $\text{CO}_2$  is produced than on glucose, namely  $22.4 \text{ mmol g}_{\text{CDW}}^{-1} \text{ h}^{-1}$  vs.  $17.0 \text{ mmol g}_{\text{CDW}}^{-1} \text{ h}^{-1}$  on glucose. Hence, more byproduct is formed on acetate. This may cause less HAA production on acetate than on glucose.

### 3.3. Two gene deletions may lead to improved yield

The optimization formulation OptKnock was used to suggest beneficial blocking of reactions, resulting in higher HAA yields. When only one reaction was set to be blocked, no solution was found that improved HAA yield. For two reactions, the HAA yield per substrate increases to  $0.53 \text{ Cmol Cmol}^{-1}$  while reducing the biomass production to the set threshold of  $0.08 \text{ h}^{-1}$ . The HAA yield thereby reaches 90 % of the theoretical yield (see Table 1). The suggested enzymatic reactions to be blocked are catalyzed by dihydromonapterin reductase (NADPH) and dihydromonapterin reductase (NADH). These reactions are located in the biomass synthesis pathway. Hence, by reducing the carbon flux to biomass, the carbon flux is redirected towards HAA synthesis. However, experimental experience indicates that HAA production is highly connected to biomass production. Presumably, knocking out these reactions would impede the organism. The next gene knockout suggestion addresses five reactions due to numerical problems with three and four reactions. The result for five reactions shows no improvement compared to the two knockouts. We conclude that two knockouts are sufficient to improve the HAA yield. In conclusion, the results show that there is potential for improving the yield by applying metabolic engineering. However, more advanced optimization formulations should be considered that guarantee for a minimal product yield (Tepper & Shlomi 2009) and that better represent the microorganism (Apaydin 2017) to improve the predictions.

#### 4. Conclusion

In our study, we have shown that HAA can be produced on acetate as sole carbon source by an engineered *P. putida* strain, however with a lower yield than on glucose. We have explained this by the toxicity of acetate and the altered metabolic configuration of the cell. The integration of experiments and simulations has brought confidence because both methods displayed the same trend. We found that more CO<sub>2</sub> is produced during growth on acetate, which reduces the carbon atoms available for HAA yield. To reduce the model-experiment mismatch, regulatory effects should be considered in the model formulation. We have suggested gene knockouts to improve the yield of HAA on acetate, which must be elaborated deeper by more advanced formulations and proven in the laboratory as a next step. Moreover, fermentation conditions with lower acetate concentrations can mitigate the toxicity of acetate to the cell and further improve HAA yield.

**Author Contributions:** ALZ designed the computations and MF designed the laboratory experiments. JP performed the computational and experimental laboratory work under the supervision of ALZ and MF. ALZ, MF and JP visualized, analyzed, and discussed the data. ALZ and MF wrote the manuscript draft. TT, LMB and AM conceptualized the project, discussed the data, and reviewed the draft. All authors read and approved the final manuscript.

# Machine learning models for predicting membranolytic anticancer peptides

Fatemeh Alimirzaei,<sup>a</sup> Chris A. Kieslich,<sup>a</sup>

<sup>a</sup>*Chemical Engineering Department, Auburn University, Auburn, AL 36849, USA  
cak0071@auburn.edu*

## Abstract

After heart disease, cancer is the second leading cause of death worldwide. Recently, membranolytic anticancer peptides (ACPs) have received considerable attention for their ability to target and kill cancer cells. Identification of ACPs is costly and usually time-consuming. Therefore, the development of efficient computational methods is of a great importance to aid in the identification of potential ACP candidates. In the current study, we developed multiple models using support vector machines (SVMs), gradient boosting classifiers (GB), and random forest classifiers (RF) to predict membranolytic anticancer activity given a peptide sequence. Oscillations in physiochemical properties in protein sequences have been shown to be predictive of protein structure and function, and in this work, we are taking advantage of these known periodicities to predict ACP sequences. To this end, Fourier transforms were applied to the property factor vectors to measure the amplitude of the physiochemical oscillations, which served as the features for our models. Peptides targeting breast and lung cancer cells were collected from the CancerPPD database and converted into physiochemical vectors using 10 property factors for the 20 natural amino acids. Using these datasets, cross-validation has been applied to train and tune the models based on multiple training and testing sets. Additionally, feature selection has been performed to further optimize our SVM models. To evaluate the models, performance has been quantified based on cross-validation classification accuracy. Furthermore, to try our prediction accuracy, we have also considered other sets of physiochemical features and properties of amino acids from the literature into our models.

## 1. Introduction

Cancer is the second leading cause of death worldwide, and it is anticipated the number of deaths caused by cancer will be more than 13 million by 2030 (Liscano et al. 2020). Not only are conventional cancer therapies expensive, but poor specificity often leads to devastating side effects, such as anemia, gastrointestinal mucositis, alopecia, cardiotoxicity, or osteoporosis (Manavalan et al. 2017; Gabernet et al. 2016). Moreover, cancer cells may develop resistance to chemotherapy and receptor-targeted anticancer agents (Gabernet et al. 2019). Therefore, developing innovative anticancer drugs is essential to attenuate cancer cell proliferation (Manavalan et al. 2017).

Recently, membranolytic anticancer peptides (ACPs) have been proposed as a potential strategy in the fight against cancer by disrupting cancer cell membranes and destroying them. ACPs are typically short peptides composed of 10–60 amino acids that can inhibit tumor cell proliferation or migration or suppress the formation of tumor blood vessels and are less likely to cause drug resistance (Xie et al. 2020). They tend to be amphipathic,

positively charged, and many of them change their structure from random to helical conformation upon associating with a preferred lipid bilayer (Queme-Pena et al. 2021). It has been hypothesized that the cationic nature leads to their selectivity for cancer with negatively charged lipid membranes (Grisoni et al. 2019). However, only a limited number of potent anticancer peptides are known to date. For instance, just 7% of the 2981 peptides annotated in the antimicrobial peptide database (APD3) (Wang et al. 2016), a group sharing physiochemical properties with ACPs, have been tested for anticancer activity (Grisoni et al. 2019), or only 53 peptides in the cancerPPD database possess low micromolar activity ( $EC_{50} < 5\mu M$ ) to be useful for cancer treatment (Grisoni et al. 2019). Furthermore, their experimental identification and development are laborious, expensive, and time-consuming (Yu et al. 2020). Last but not least, the underlying structure-activity relationship that explains the membranolytic properties of these peptides is not completely understood (Queme-Pena et al. 2021). Therefore, innovative tools like sequence-based computational methods are needed for the fast identification and design of potent ACP candidates (Manavalan et al. 2017). To identify ACPs, existing methods try to discriminate ACPs from non-ACPs and then predict their anticancer activity based on the features extracted from known ACPs which their identities are held by publicly available datasets like CancerPPD (Shoobuatong et al. 2018).

In the current study, we are developing models that predict whether a peptide will exhibit ACP activity given only an amino acid sequence of the peptide. For this purpose, we are trying to identify patterns in the physiochemical properties of ACPs by using Fourier Transform-based features that measure the oscillations of physiochemical properties along the length of peptides. Previously we have shown that oscillations in physiochemical properties in peptide sequences are predictive of antiviral peptide activity (Kieslich et al. 2021). Here we aim to take advantage of these known periodicities of amino acid properties to develop models that predict anticancer peptide activity. Furthermore, by performing feature selection, we can determine which features are the most important predicting ACP activity that have the potential of forming a design template.

## 2. Methods

In this work, Python has been used to perform all steps of our analysis, which includes the generation of physiochemical vectors for each peptide, Fourier-based feature extraction, training/validation of classification models for predicting membranolytic anticancer activity, as well as SVM-based feature selection. Below are more elaborate descriptions of how these elements were implemented in this study.

### 2.1. ACP Dataset

One of the crucial requirements for developing data-driven classification models is having access to adequately large datasets containing both amino acid sequence and function labels. Currently, there are multiple publicly available databases which hold the identities of some known anticancer peptides, including APD (Wang et al. 2004), CancerPPD (Tyagi et al. 2015), DADP (Novkovic et al. 2012), DBAASP (Pirtskhalava et al. 2021), LAMP (Zhao et al. 2013). In our study, two peptide datasets targeting breast and lung cancer were chosen owed to their relevance for human health (2.9 million cases for each cancer type in 2018) (Grisoni et al. 2019). These datasets were previously assembled and curated manually from CancerPPD (Grisoni et al. 2019), so that the final training sets contained 232 peptides targeting breast cancer cells, including 116 active and 116 nonactive ACPs, and 198 peptides targeting lung cancer cells containing 99 active and 99 nonactive ACPs.

## *2.2. Feature Extraction*

One of the prerequisites for training a machine learning-based classifier is transforming the original raw training data into a set of “features”. For this purpose, we first converted the amino acid sequences of each peptide in our raw dataset into physicochemical vectors using 10 physical properties factors of the 20 naturally occurring amino acids. These 10 physicochemical property factors were generated based on principle component analysis of a large set of amino acid physicochemical properties (Kidera et al. 1985). Kidera et al. describe the property factors as  $\alpha$ -helix or bend-structure preference-related, bulk-related, structure preference-related, hydrophobicity-related, and 5 additional property factors that represent mixtures of several physicochemical properties. Each peptide is converted into 10 physicochemical vectors (numerical vectors) based on each of the physicochemical property factors. Afterwards, we used the `fft` function in Python to apply Fourier transforms to each of the property factor vectors. It is worth mentioning, in order to make sure that the same number of frequency (Fourier) components have been generated for each property vector, we have applied zero-padding with the assumption of a maximum sequence length of 64 amino acids. The maximum ACP sequence length across both peptide datasets is 38 amino acids. In this way, the amino acid properties corresponding to positions that are longer than a given peptide were set to zero. After using zero padding and the Fourier transform, 64 Fourier coefficients are generated for each property of each peptide. However, Fourier transform spectrums are in mirror shape, and only half of the coefficients (i.e., 32) were considered in addition to the center (0). Ultimately there were 33 features for each of the ten property factors in each peptide, which means 330 features are extracted for each peptide (feature set1). In other words, each sequence was represented by 33 Fourier coefficients measuring the oscillation of the 10 property factors. We also generated two more feature sets for further evaluation of our prediction accuracies. For feature set 2, we added 10 additional features to feature set 1 based on amino acid composition. The additional features were based on the percentage of amino acid positions that fit categories of positively charged, negatively charged, aliphatic, aromatic, polar, hydrophobic, size (tiny, small, large), as well as the total charge of the peptide. The amino acid categories were based on those that have been previously proposed for a related task (Manavalan et al. 2017). For generating the feature set3, instead of 10 amino acids property factors used to create feature set1, we applied 8 newly reported properties of amino acids by Medina-Ortiz et al. that are related to  $\alpha$  structure,  $\beta$  structure, hydrophobicity, volume, energy, hydropathy, secondary structure, and other indexes (Medina-Ortiz et al. 2022).

## *2.3. Support Vector Machines and Grid-search*

In this study, all support vector machines have been trained by using the `svc` function in Python based on the radial kernel (Gaussian radial basis function (RBF)). In order to tune the cost and gamma hyperparameters of the SVM models, a grid search has been used with cost and gamma values based on powers of ten,  $10^n \forall n \in [0, \dots, 6]$  for cost values and  $10^n \forall n \in [-6, \dots, 0]$  for gamma values, where  $n$  is an integer.

## *2.4. SVM Feature Selection*

Feature selection plays a critical role in data science since it leads to the identification of the fundamental set of predictive descriptors (features). Furthermore, it can increase the robustness of the model to prevent overfitting (Kieslich et al. 2021). Previously, a feature selection algorithm has been developed based on non-linear SVM, which is common in nature and has been applied to predict faults in chemical plants (Onel et al. 2018) and HIV-1 viral entry (Kieslich et al. 2016). It is a model-based algorithm requiring first training an SVM model prior to computing a criterion quantifying the contribution

between each single feature to the SVM objective function to determine which features to eliminate. The criterion (Eq. 1) is derived in terms of sensitivity analysis of the dual formulation of SVM models.

$$crit_k = -\frac{1}{2} \sum_i \sum_j \alpha_i^* \alpha_j^* y_i y_j \left. \frac{\partial K(x_i \circ z, x_j \circ z)}{\partial z_k} \right|_{z=1} \quad (1)$$

This algorithm applies a greedy approach in order to rank the features, so that at the beginning it starts with training a model based on all of the features, computes the criteria for all features and then removes a fraction of the features with the largest criteria values. (In other words, the largest criteria values have the least importance for the model). In the current work, %33 of the remaining features has been removed after each iteration of the algorithm, and the hyperparameters have been retuned after each iteration of the algorithm. The feature ranking procedure was applied to each of the five training sets and a consensus ranking was generated based on the average rank of each feature across five training sets.

### 2.5. Cross Validation and SVM Models Accuracy

Five-fold cross-validation, based on two balanced training datasets, was applied to tune and validate the models based on the first sorting of the peptide sequences according to length, and then choose five training and testing sets with an equal number of samples for each peptide class in each peptide datasets, separately. For all datasets, model performance was evaluated based on classification accuracy which is reported as the fraction of classes (active or nonactive ACPs) that have been predicted accurately in the test sets.

### 2.6. Gradient Boosting and Random Forest Models

In this study, all gradient boosting and random forest models have been trained and evaluated using “sklearn.ensemble” and “sklearn.metrics” packages in Python. Also, like the SVM model, 5-fold cross-validation was performed to generate train/test sets for them. It is worth mentioning for both of these models, we used the default values of the parameters controlling the size of the tree publicly available on the “scikit\_learn” website ([Scikit-learn: Machine Learning in Python](https://scikit-learn.org/stable/tutorial/tutorial.html)) (Pedregosa et al. 2011).

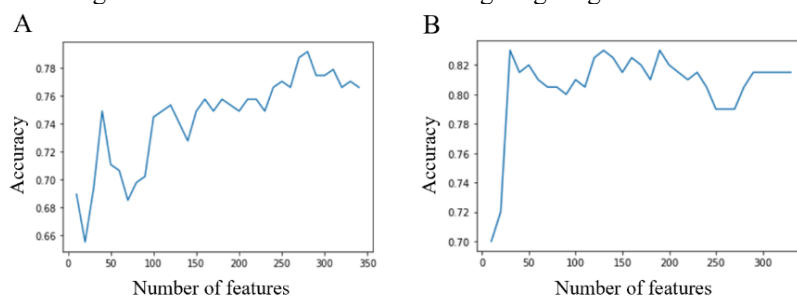

**Table 1.** Statistics of the performance of machine learning-based models predicting ACP activities.

Cancer type	Feature set/Number of features	SVM model accuracy/Minimum number of features to maintain the accuracy	Gradient Boosting model accuracy	Random Forest model accuracy
Breast	Set1/330	76%/~330	68%	68%
	Set2/340	79%/~280	59%	60%
	Set3/264	68%/~240	62%	62%
Lung	Set1/330	83%/~25	75%	72%
	Set2/340	82%/~270	74%	73%
	Set3/264	75%/~130	66%	65%

## 3. Results

Based on the proposed feature sets (3 sets in total), we developed models using SVM, Gradient Boosting, and Random Forest methods to distinguish the active and nonactive ACP peptides based on the Breast and Lung datasets. For SVM classification tasks, we performed feature selection to rank the physicochemical features. To measure the contribution of each feature to model accuracy we performed five-fold cross-validation

after adding each feature one at a time, starting with the highest-ranked feature. Also, for gradient boosting and random forest models, we have done five-fold cross-validation for all datasets and calculated the average accuracy across 5 train/test sets for each predictive model, discriminating two classes of ACPs targeting breast and lung cancer cells. A summary of obtained results of all the predictive model performances is shown in Table 1. Among them, the SVM model using feature sets2 has the highest accuracy (79%) for discriminating active and nonactive anticancer peptides targeting breast cancer cells. Also, for distinguishing between active and nonactive ACPs targeting lung cancer cells, the SVM model using feature set 1 has the highest accuracy (83%) compared to the rest of the predictive models. These reported cross-validation accuracies are the average of the classification accuracies for the five training and testing sets. As it is seen in Figure 1, the minimum number of features required to maintain those accuracies is around 280 features for the model predicting anticancer activities of the peptides targeting breast cancer cells, and approximately 25 features are needed to maintain the highest accuracy of the model predicting ACP targeting lung cancer cells. It is worth mentioning features in the x-axis on the plots are ordered based on the feature selection algorithm meaning adding more and more features. For example, those 25 features are the most important ones to distinguish active and nonactive ACPs targeting lung cancer cells.

**Figure 1.** Feature contribution to model accuracy based on feature selection ranking. A) Feature selection results for classifying active vs. nonactive anticancer peptides targeting breast cancer cells; B) Feature selection results for classifying active vs. nonactive anticancer peptides targeting lung cancer cells.

#### 4. Conclusion

In this study, we have developed a support vector machine, gradient boosting, and random forest models that distinguish between active and nonactive ACP sequences for two membranolytic ACP datasets targeting breast and lung cancer cells. To develop these models, we used different sets of amino acid property factors of naturally occurring amino acids from the literature to convert ACP sequences into property vectors that served as the input for the generation of Fourier-based features. Our results show that SVM models perform better in discriminating ACP activity. In addition, by ranking the importance of the developed Fourier-based features, we were able to train SVM models with improved accuracy and generalizability, while also starting to gain some insights into the importance of oscillations of physiochemical properties for ACP function. It can be concluded that our approach for feature extraction and model development, specifically including the SVM feature selection algorithm, has the potential for use in predicting peptide properties and functions as well as designing innovative anticancer peptides in the future. However, given the remaining challenges in discriminating between active and nonactive ACPs, more efforts are required that might need both further computational and even experimental investigations.

## Abstract

The Major Histocompatibility Complex (MHC) molecules play a major role in T-cell immunogenicity through the recognition of 'non-self' peptides derived from foreign antigens. Therefore, predicting peptides that trigger immune responses is of great interest for the general understanding of T-cell-mediated immunity and the design of peptide-based vaccines and cancer immunotherapy treatments. The presented work tests the performance of allele-specific SVM classification models in the prediction of pMHC binding. The models aim to classify MHC class II binding and non-binding peptides based on their amino acid sequences and derived features. In developing the models, we take advantage of underlying periodicities in physicochemical properties along the sequence of a peptide that has been shown to be predictive of protein structure and function. Once the physicochemical descriptors are generated, Fourier transforms are then applied to be able to encode peptide sequences of varying lengths. In training and testing the model, a comprehensive dataset of MHC class II binding peptides that includes 44 unique MHC class II alleles (molecules) with 60630 binding affinities is taken from the IEDB database. Cross-validation and hyperparameter tuning are applied across multiple train and test datasets. A feature selection algorithm is also incorporated into the model development to identify an essential set of predictive features. The blind test set prediction accuracy of the developed allele-specific models ranges from 0.58- 0.93, with an average classification accuracy of 0.73.

**Keywords:** Computational biology, data-driven, machine learning, support vector machines, Major Histocompatibility Complex, feature selection

## 1. Introduction

Understanding peptide-protein binding in T-cell immunity has potential applications in many biomedical fields, including the development of peptide-based vaccines and personalized cancer immunotherapy. Identifying T-cell epitopes first involves predicting if peptides derived from an antigen (e.g. viral protein) bind to specific Major Histocompatibility Complex (MHC) molecules since the formation of peptide-MHC (pMHC) complexes is a key determinant in the T-cell immunogenicity. Over the past years, a number of computational prediction methods have been developed to identify MHC-binding peptides as an alternative to costly and time-consuming experimental methods (Sanchez-Trincado et al. 2017). In general, the prediction of interactions between MHCs and peptides is challenging due to the highly polymorphic nature of

MHCs and also the varying length of binding peptides. Moreover, it is further compounded by non-binding residues, also known as peptide flanking regions (PFRs), which have been found to affect its binding affinity.

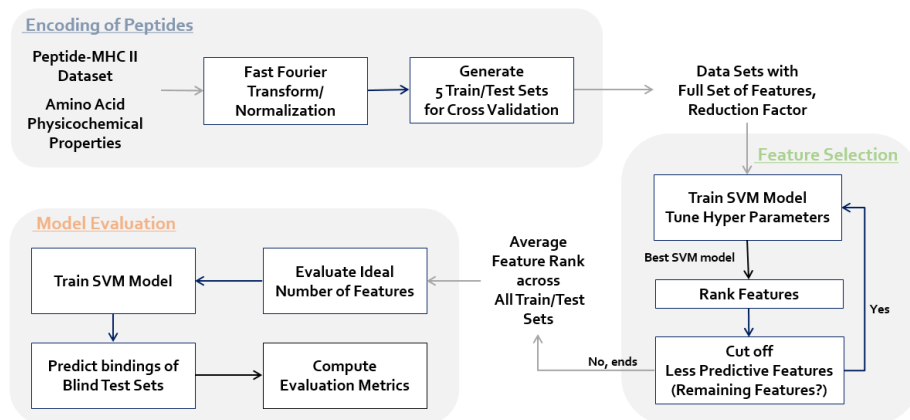

Current state-of-the-art binding prediction tools typically utilize artificial neural networks trained on sequence data with experimental binding affinity measurements. Although those sequence-based neural network models perform highly accurate predictions, they are hardly interpretable, limiting both biological insights and analysis of feature contributions. An alternative approach is machine learning methods such as support vector machine (SVM), which can be more interpretable and generalizable across peptide-MHC interactions.

One other limitation of previously developed models is that most do not incorporate information regarding the physicochemical properties of amino acids and, even when they do, they ignore the order of residues, which is known to be closely related to protein structure and function. Previously, it has been shown that families of protein structure and function can be categorized by underlying periodicities in protein or peptide physicochemical properties along the amino acid sequence (Eisenberg et al. 1984; Rackovsky 1998). Based on this observation, as well as numerical tricks such as fast Fourier transforms and zero-padding, these oscillations of physicochemical properties can be incorporated into prediction models, while also allowing the encoding of peptide sequences with varying lengths into the same number of features. A recent study on predicting antiviral peptides has shown the potential of using such Fourier-based coefficients as features for SVMs (Kieslich et al. 2021).

Here, we have developed allele-specific SVM models for the prediction of pMHC binding using the oscillations of physicochemical properties along the sequence of peptides. Our models were trained to classify binders and non-binders using supervised learning based on quantitative binding affinity experimental data. Furthermore, a previously developed feature selection algorithm was applied to rank the importance of the derived features to further optimize the developed models.

## **2. Methods**

An overview of the model development procedure used in the presented work is shown in Figure 1. All steps of model development and analysis which include data preprocessing, feature selection, training of SVMs, and model evaluation are performed using Python programming language. Each step is described in detail in the sections that follow.

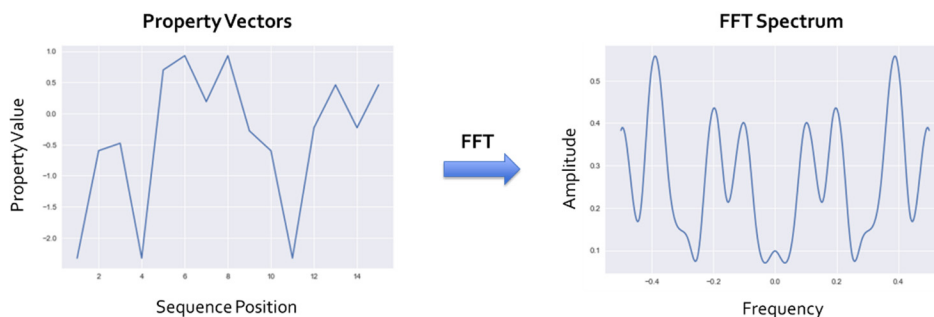

**Figure 1.** Overview of model development and evaluation procedures.

### 2.1. Peptide-MHC Class II Binding Data

The human MHC dataset was sourced from the Immune Epitope Database (IEDB) on Sep 30, 2022 (Fleri et al. 2017). Each peptide-MHC entry in the dataset consists of the peptide sequence, the MHC allele, and the measured binding affinity. For our dataset, only the quantitative type of measurements (e.g., IC<sub>50</sub>, EC<sub>50</sub>, and K<sub>D</sub>) were chosen, and entries with measurement values larger than 50000 nM were excluded from the dataset. Note that a lower value indicates higher binding affinities and vice versa. We also limited the length of peptides to range from 13 to 21 amino acids. The resulting binding affinity datasets consisted of 60630 entries with 44 unique MHC alleles and 10806 unique peptides. A binding affinity cutoff was set to 1000 nM to distinguish between binders and non-binders, which has been widely used for MHC class II binding classification. The final dataset was split into a training set and a blind test set for the evaluation of model performance with a ratio of 80:20 in a stratified sampling manner. The training set was then split again to generate 5 cross-validation sets of training/testing sets using the same approach.

### 2.2. Encoding Strategy

The first step in encoding peptide sequences is to convert them into numerical values. In this work, we adopt 10 physicochemical property factors that have been shown to describe 86% of the variance of the original 188 properties from which they were derived (Kidera et al, 1985). For each physicochemical property factor, a given peptide is converted into a corresponding physicochemical property vector (Figure 2, left), resulting in 10 physicochemical property vectors per peptide. To ensure that every peptide is represented by the same number of features, the 10 physicochemical property vectors are zero-padded assuming a maximum sequence length of 32 amino acids. Then, a Fourier transform is applied to each property vector using the Fast Fourier Transform (FFT) function of the SciPy package in Python, and we took the moduli (Figure 2, right) of the complex Fourier coefficients for frequency values between 0 and 0.5 as final features for training the SVMs which consists of 170 elements.

**Figure 2.** Fourier transform of property vectors into FFT Spectrum.

### 2.3. Support vector machines

We trained a total of 44 allele-specific binary classification SVM models based on the nonlinear radial basis kernel using the SVC function in the Python Scikit-learn package. For each SVM model, the hyper-parameters cost (C) and gamma (g) are tuned by grid-search, with values of  $10^n \forall n \in \{-3, \dots, 3\}$ , where n is an integer. In validating the SVM models, performance was assessed with 5-fold cross-validation with each training/testing set containing equal ratios of binders to non-binders. The accuracy of the SVM models was evaluated by computing classification accuracy, which is computed as to the percentage of entries in a testing set where the predictions were correct.

### 2.4. Feature selection

Feature selection, also known as variable selection, is a process by which the number of features is reduced to a subset of predictive features by eliminating redundant or irrelevant ones when developing prediction models. The process benefits machine learning tasks by decreasing the chances of over-fitting while potentially improving its accuracy and reducing training time. In this work, we have adopted a feature selection algorithm based on non-linear SVMs, which was proposed by Kieslich et al. (Kieslich et al. 2016). The algorithm has been applied to the broad area of prediction study including HIV-1 viral entry and fault detection in chemical plants (Kieslich et al. 2016, Onel et al. 2018, Onel et al. 2019).

The algorithm uses a greedy approach and ranks the features based on the criterion (Eq. 1), which characterizes the importance of feature k. The criterion was derived from the objective function of the dual formulation of the SVM model since solving the formulation, in general, is required to employ non-linear kernels for feature selection.

$$crit_k = -\frac{1}{2} \sum_i \sum_j \alpha_i^* \alpha_j^* y_i y_j \left. \frac{\partial K(x_i \circ z, x_j \circ z)}{\partial z_k} \right|_{z=1} \quad (1)$$

The algorithm initially starts with an SVM model with all of the features and computes the criteria for each feature. Then the features are ranked based on their criteria values, and given the feature reduction factor, the algorithm iteratively removes a set of features

that has the largest criteria values. The presented work used the reduction factor of 1/3, meaning 33% of the remaining features are removed after each iteration. Hyper-parameters are tuned again based on the remaining features after each iteration, and a consensus feature rank is also generated by averaging ranks across the five training sets.

**Figure 3.** Feature contribution of 44 MHC alleles obtained from feature selection.

### 3. Results

The feature selection analysis was implemented for 44 allele-specific SVMs based on the generated physicochemical features. The feature selection algorithm provided the feature rank of each MHC allele model, and the contribution of each feature was measured by training and testing individual SVMs with five-fold cross-validation after adding 10 features at a time. The validation accuracies were computed as the mean accuracy of test set prediction over cross-validation with best hyper-parameters. As can be seen in Figure 3, overall, there was a trend that the addition of features leads to a steady increase in validation accuracy across most of the MHC alleles. Those models achieve the accuracies of 0.53-0.94 only with the first 10 features, and they improve up to 0.62-0.94 as we incorporate more features. In general, maximum accuracies were achieved when almost all features are used to train each model. Meanwhile, horizontal lines are also observed for some alleles, where we can infer that the models are biased due to the limited amount of data and, for the most part, are the result of largely imbalanced classification datasets.

For each MHC allele, the optimal number of features was selected from the above feature selection analysis (Figure 3). The final allele-specific SVM classification models were trained and optimized with those features identified as minimum features required for maximum validation accuracy and then evaluated by performing prediction on the blind dataset. As shown in Figure 4, the prediction accuracy is relatively consistent across the feature-optimized allele-specific models, ranging from 0.58- 0.93 with an average of 0.73. Overall, those models exhibit sound prediction performance, indicating the use of physicochemical property-derived features enables SVMs to capture the interactions between peptides and MHC molecules.

**Figure 4.** Blind set prediction accuracy of the feature-optimized allele-specific SVM models.

#### 4. Conclusions

In this work, we have developed 44 allele-specific binary classification SVM models that were trained based on the binding affinity datasets to classify MHC binding and non-binding peptides. Features for the SVMs were derived from the physicochemical properties of amino acids and extracted from Fourier analysis, assuming the oscillation of properties along the sequence can be predictive for peptide-MHC binding. Nonlinear SVM-based feature selection analysis was also performed during the workflow to measure the contributions of features and identify an optimal list of features. As a result, the proposed approach has shown the potential of physicochemical properties derived features in the prediction of peptide-protein interactions or functions. Future work will need to investigate the generalizability and interpretability of the prediction models for a better understanding of pMHC interactions across MHC alleles. The developed models with further analysis could be used to provide a guideline for developing and designing peptide vaccines and immunotherapeutics.

## Abstract

Cancer diagnostic and treatment research continue to expand at unprecedented rates with new and promising discoveries being published regularly. However, within the realm of exciting cancer treatment improvements often lays the overlooked need for streamlined engineering systems and efficient data analytical methods. This research looks to achieve both in the framework of improving the *ex vivo* T-cell culturing environment required for Adoptive Cell Transfer (ACT) cancer immunotherapy. A unique set of Nature Inspired Solutions (Coppens, 2021) was applied to design and analyze 9600, unique, 3D Voronoi scaffolds as potential cell culturing environments. The streamlined design process involved a complex combination of computer languages and platforms and yet, was able to design and calculate various physical parameters of the 9600 scaffolds in just a few hours. To efficiently analyze and process the scaffolds, a novel systems engineering web-based networking software (the 4D Kauffman Fitness Network) was designed. This software integrates both key geometrical characteristics of the scaffolds (such as porosity, surface area and average mean curvature) and biological aspects related to the cells (such as proliferation rate). During testing, this software efficiently processed the 9600 scaffolds in under 20 s, designing a wide variety of networks which filtered the scaffolds selected for future wet lab testing. The highly adaptable and accessible nature of this software provides multiple potential applications in a wide range of scientific, data management and business sectors.

**Keywords:** Cancer Immunotherapy, Process Management, Network Design

## 1. Introduction

### 1.1. Background

There are very few people today who have not been affected by a cancer diagnosis either personally or through a loved one. Cancer can often appear as a growing, undefeatable threat. However, the portfolio of life-saving treatments continue to expand with ever increasing success rates. One of the most promising cancer immunotherapy treatments today is the Chimeric Antigen Receptor (CAR) T-cell Adoptive Cell Transfer (ACT). During this treatment, a patient's own immune-cells (T-cells) are extracted, proliferated, and activated *ex vivo*, genetically engineered to attack the specific tumour cells and then re-infused back into the patient. One of the main challenges with this treatment is the large number of activated T-cells required to proliferate (Jin et al., 2021). Currently, *ex vivo* T-cell culturing environments are often 2D, which neglect to facilitate the 3D mechanical and physical interactions required for efficient T-cell proliferation and activation (Jensen & Teng, 2020). We posit that a holistic, systems approach is essential.

By applying the Nature Inspired Solution (NIS) methodology developed at the UCL Centre for Nature-Inspired Engineering (Coppens, 2021), over 9000 unique, lymph node inspired, small-world, 3D T-cell culturing scaffolds have been designed.

A small-world network is a graph which requires a small number of steps to progress from one node to any other node within the network. This small-world feature is mathematically demonstrated through sigma ( $\sigma$ ), a combination of the path length between nodes and a clustering coefficient, where  $\sigma > 1$  shows a small-world network (Humphries et al, 2008). Examining the network topology of the fibroblastic reticular cell network (FRCN) found in the lymph nodes, Novkovic et al. demonstrated how the FRCN had  $\sigma > 1$  and a number of vertices approximated by the following equation:

$$v(6.52 * 10^{-5}) = x \quad [1]$$

where  $v$  was the volume of the design space and  $x$  was the approximate number of vertices (Novkovic et al., 2016). Therefore, a small-world network, 3D scaffold was designed. The breadth of scaffolds examined as potential cell culturing environments was then expanded upon to efficiently streamline the design and analysis process. A Voronoi pattern was chosen as the next structural type to be examined due to the similarities in network structure to the FRCN found in the lymph node.

### 1.2. Voronoi Structure and Lloyd's Algorithm

Voronoi diagrams are designed by populating a defined space (such as a square or cube) with a certain number of points. Lines are then drawn at average distances between adjacent points resulting in a collection of Voronoi cells. For this research, twenty orientations (seeds) of each of the 3D Voronoi scaffolds generated from 5-17 points were designed. Lloyd's "relaxation" algorithm was then applied to each of those scaffolds to produce a larger set of structures with differing geometric and topological parameters.

Lloyd's algorithm is a popular classification algorithm that was first designed by Stuart P. Lloyd in 1982 (Lloyd, 1982). This algorithm has since been applied in a wide variety of fields, including astronomy (Ordovás-Pascual & Sánchez Almeida, 2014) and biology (Ralf-Herwig et al., 1999). Applied to the designed Voronoi scaffolds, Lloyd's algorithm iteratively averages the volume of each Voronoi cell within the 3D structure and repositions the Voronoi generating point to the centre of the average volume. Over the course of a number of iterations, a "relaxed" state is achieved where no further iterations will shift the Voronoi's generating points. For this research, 40 iterations were selected for each Voronoi scaffold; very little change was noticed after about 15 iterations. Therefore, the combination of 12 different selections of Voronoi generating points, each with 20 different seeds, each with 40 Lloyd iterations, resulted in the 9600 Voronoi scaffolds designed.

### 1.3. The Streamlined Design Process

The process involved in designing and calculating the various geometric and topological parameters for each of the 9600 scaffolds required a combination of code written in the Grasshopper plugin of the Rhino software (McNeel, 2010), Python and R. This highly complex, multi-step procedure was efficiently streamlined to be capable of designing and calculating around 10 different geometric and topological parameters for 9600 Voronoi scaffolds in just a few hours. This process along with the specific parameters calculated will be discussed further in Section 2.

### 1.4. The 4D Kauffman Fitness Network

The pure magnitude of scaffolds being designed required an innovative computational method to analyze and process the parameters calculated for each of the scaffolds. Therefore, a novel, web-based data analytical method, inspired by Stuart Kauffman's NK fitness landscape, was designed (Kauffman, 1993). Kauffman visually demonstrated the likely evolutionary path of a series of simple proteins by stating each protein as a node in a network where edges were drawn between proteins of similar amino acid composition (Kauffman, 1993). Fitness parameters (such as the life span of the protein) were listed for each protein, such that, for any protein selected, it was possible to track the various evolutionary paths likely to occur for a protein to achieve a higher fitness and evolutionary state. Applying this methodology, where scaffolds were treated as the nodes and the various parameters calculated as the criteria by which the edges were drawn, a 4D Kauffman Fitness Network was designed. During testing, this software efficiently and successfully processed the 9600 scaffolds, designing a wide selection of networks which filtered the scaffolds selected for wet lab testing. This software, along with how it was applied, will be discussed in more detail in Section 3.

## 2. The Scaffold Design Process Journey

### 2.1. The Map

Every successful journey requires an informative map, and such was the case for these Voronoi scaffolds. Figure 1 demonstrates the various stages of the Voronoi scaffold's design and calculation process. The following sections will provide further information into the process systems required for each of the steps visualized in Figure 1.

**Figure 1:** A map of the various steps taken during the design of the Voronoi scaffolds.

### 2.2 The Design

Voronoi structures, based off varying numbers of generating points, were iterated 40 times using Lloyd's algorithm to create a collection of similar and yet unique Voronoi structures. This design code was originally written in a visual programming language (VPL). However, the VPL code included over 50 separate components and, as Table 1 demonstrates, the computational process time was considerable in view of the large number of Voronoi structures to be designed. Therefore, this code was transferred into a Python plugin component within the VPL which was subsequently parallelized. Traditionally, Grasshopper executes code on a single thread, therefore, the parallelization of the code had to be completed through a Python plugin package which was capable of multi-threading the code. Parallelizing within the Python plugin of Grasshopper initially provided a considerable challenge as the Python version within Rhino is locked in at version 2.7. It was also important to distinguish at what point the code could be parallelized as the Lloyd algorithm iterations required the Voronoi pattern from the previous iteration. However, once the code was adequately parallelized over the 64 CPU cores, this resulted in a 2- to 3-fold increase in efficiency (as shown in Table 1) which

ensured 9600 Voronoi scaffolds were designed and their parameters calculated, in just over an hour.

Coding Type	Number of Structures Generated	Time (s)	Avg. Time per Structure (s)
<b>VPL</b>	12	17.5	1.49
<b>Python (code parallelized)</b>	12	6.2	0.52
<b>VPL</b>	40	55.5	1.39
<b>Python (code parallelized)</b>	40	19.3	0.48
<b>Python (code parallelized)</b>	800	477.3	0.60

**Table 1:** The average time the computer required to complete the various parallelized and non-parallelized codes in seconds. Three trials of each calculation were completed with the average times appearing in the table above. Visual programming language has been abbreviated to VPL.

### 2.3 Mathematical Properties

In order to comprehensively understand and examine the scaffolds, a wide selection of the geometric and topological features of the Voronoi scaffolds were calculated. These included the porosity, surface area, average mean curvature, the number of generating points, the number of vertices, the number of edges, a topological parameter (the average number of edges connected to the vertices), Euler's characteristic and the minimum, maximum and average edge length. All of these were included in the Python code shown in Table 1 allowing any initial calculation errors to be easily changed and re-calculated for the thousands of scaffolds. This would also allow any future geometric, topological or physical parameters to be added to the code and efficiently calculated for all the scaffolds. In addition to this list of calculations, an adjacency matrix was also calculated for a selection of the scaffolds. This adjacency matrix was required to calculate the small-world parameter of sigma ( $\sigma$ ) for each of the scaffolds. Table 2 shows an example of the parameters calculated for one of the Voronoi scaffolds.

Points	Seed	Iteration	Min EL	Max EL	Avg. EL	SA
13	5	0	0.0263 $\mu\text{m}$	86.7 $\mu\text{m}$	31.5 $\mu\text{m}$	60600 $\mu\text{m}^2$
Vertices	Edges	Euler	Topology	Porosity	Sigma	AMC
65	126	14	3.88	83.5%	2.13	-0.0751

**Table 2:** The various topological and geometric parameters calculated for a Voronoi structure generated from 13 points before any Lloyd algorithm iterations. The abbreviated titles are edge length (EL), surface area (SA) and average mean curvature (AMC).

## 3. 4D Kauffman Fitness Network

### 3.1. The Design

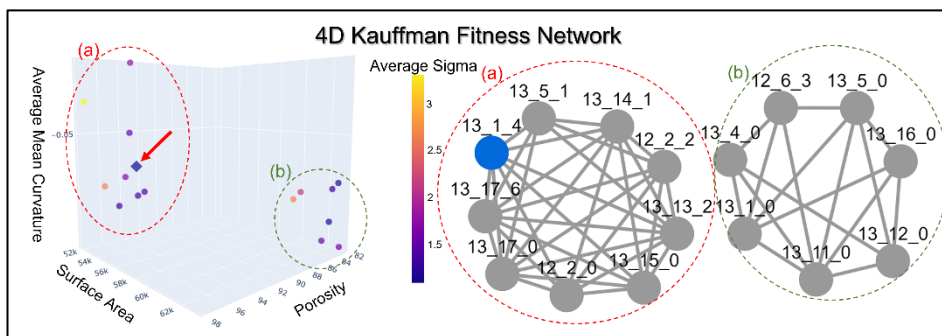

As discussed in Section 1.4, a networking software was designed to assist in analyzing and processing the 9600 Voronoi scaffolds. Designing this networking software required satisfying a variety of user and systems parameters. Firstly, the software needed to be capable of handling 9600 unique environments with around 10 separate topological characteristics. Secondly, the platform needed to allow for user integration and adaptability so networks and graphs could be re-designed based off prioritizing different geometric parameters. Thirdly, these new iterations of the networks and graphs needed to be effectively processed and displayed for user ease and efficiency. Finally, this data

needed to be easy to export in a workable format. To satisfy these various parameters, an online, web-based platform written in Python was selected. The web-based environment was chosen as this would be highly user friendly and allow the software to be easily applied in other sectors outside of computational research.

Initially the Python code, cycling through the dozen Excel files containing the 9600 scaffolds, was unable to produce an online network capable of redesigning, based off of user inputs, without crashing. It was only when each scaffold was redefined as a unique node, with its geometric and topological characteristics listed within the node's dictionary, that the software began to operate smoothly. This was likely due to each scaffold being simplified to one unit (a single node) rather than a series of 10 separate data units (1 for each of the characteristics). This node data was also highly efficient in being converted back into a data frame to produce a downloadable Excel file (something it completed in a matter of seconds).

### 3.2. The Application

Although the 4D Kauffman Fitness Network was capable of processing thousands of scaffolds, data gleaned from the graphs and networks produced, resulted in a significant filtering of the scaffolds. Of the 9600 Voronoi scaffolds designed, 952 contained  $65 \pm 2$  vertices (Equation 1) and only 73 of those had  $\sigma$  values greater than 1 (small-world networks). These 73 were further narrowed down to 36 “unique” scaffolds, as scaffolds designed from later Lloyd iterations were often indistinguishable and, therefore, the software combined them into a single node. Figure 2 demonstrates one of the generated online web-pages produced from the 4D Kauffman Fitness Network. Each node in the network on the right is a scaffold that corresponds to a point in the graph on the left. Two separate clusters can be clearly visualized in both the network and the graph demonstrating which scaffolds have similar surface area, average mean curvature and porosity. Network cluster (a) and (b) correspond to the circles (a) and (b) in the graph.

**Figure 2:** A generated 4D Kauffman Fitness Network showing 2 clusters of scaffolds in both the graph and network (indicated by the circles (a) & (b)) demonstrating the scaffolds similar in surface area, average mean curvature and porosity. The blue scaffold has been selected (“clicked-on” in the software) with its respective point highlighted as diamond, and shown with a red arrow, in the graph on the left. The labels for the nodes in the network on the right are the scaffold names (given as X\_Y\_Z) which denote the number of Voronoi generating points (X), the seed number with which the orientation of those points was saved (Y) and the number of Lloyd’s algorithm iterations (Z).

#### 4. Future Work

Future applications for both the design process and analysis software are now being explored. Firstly, the design process will be applied to other structural patterns including Lattice and Delaunay structures. Secondly, the analysis software will be utilized to select the scaffolds to be 3D printed and tested with live T-cells for cancer immunotherapy applications. Finally, the 4D Kauffman Fitness Network can be tested and applied in other scientific and business sectors where collections of similar environments or products need to be processed and graphically analyzed.

#### 5. Conclusion

The nature-inspired solution methodology applied to both the 3D T-cell culturing environments (through a lymph-node inspired scaffold design) and the software designed for the analysis of the scaffolds (inspired through Kauffman's evolutionary protein mapping) provided creative insight into the unique engineering solutions described. The computational pipeline designed and calculated 10 separate topological and geometric parameters for 9600 Voronoi scaffolds in under a few hours. These scaffolds were then filtered to 36 unique, small-world scaffolds using the novel 4D Kauffman Fitness Network with new networks and graphs being generated in a few seconds. The efficient design pipeline and analysis software provided the foundational framework to test these 3D scaffolds as *ex vivo* T-cell culturing environments for CAR ACT cancer immunotherapy. The software presented here has wider applicability for systems engineering research, beyond cancer immunotherapy.

## Abstract

During the fermentation of *Bacillus Subtilis* it is unperceivable to observe the formation of spores since, following the evolution of spores is time consuming due to various sampling and analytical procedures. Dielectric spectroscopy has shown promising results, where the measured permittivity is correlated with the cell concentration. Most of the existing works focus on determining cell concentration and not on the determination of spores. In this work, we develop a permittivity model for cells in the fermentation solution based on the Cole-Cole equations that can be used to detect the sporulation phase in future work. Utilizing the data from several fermentation runs of *Bacillus Subtilis*, a superposition hypothesis is proposed. In this hypothesis, the model equations from Cole and Cole (1941) are used and the theoretical permittivity response of the cells is calculated. As a first step, the Cole-Cole model is developed, and the modeled permittivity values are fitted to the measured data and the results are analyzed.

**Keywords:** Cole-Cole, Permittivity, Sporulation, Superposition

## 1. Introduction

*Bacillus Subtilis* is an industrially significant gram-positive spore-forming bacteria which is used in the large-scale production of various bioproducts (Abi *et al.*, 2010). The biological system along with the spore formation and evolution mechanism is complex and difficult to model. In addition, the drawbacks of offline measurement like longer and infrequent sampling make the online monitoring and detection of spores highly desirable. One of the most promising online monitoring techniques is the dielectric spectroscopy, especially in its scanning frequency mode. There have been several works where the permittivity measurements have been found to reveal information related to changes in morphological phases. Opel, Li and Amanullah (2010) and Randek and Mandenius (2020) found the influence of cell sizes on the permittivity data.

In general, there are several modeling approaches applied on the permittivity data obtained from dielectric spectroscopy. Among them Konakovsky *et al.* (2015) used principal component analysis to predict the viable cell concentration (VCC). Dabros *et al.* (2009) applied Cole-Cole modeling and compared the results with linear and multivariate regression models. These works establish Cole-Cole modeling as a viable method for modeling cell concentrations from permittivity data.

Since the bacterial spores are much smaller and their presence is difficult to detect, works on the application of dielectric spectroscopy and identifying the presence of spores are rarely present. Abi *et al.* (2010) focused on the *Bacillus* species and identified the

physiological phases using the scanning frequency data. Studied parameters are capacitance, conductivity, and Cole-Cole parameters to monitor and predict the effect of operating conditions. In our study to determine the effect of spores on the permittivity data, we have applied a superposition hypothesis in conjunction with Cole-Cole modeling. This methodology is expected to result in a residual permittivity that can be indicative of the spore dynamics. This will enable the online monitoring of sporulation and to gain insight about the current fermentation phase in progress thereby reducing the time and effort required for sampling and other analytical procedures.

## 2. Theory

During the fermentation process of *Bacillus Subtilis*, the bacteria present in the culture consume the nutrients and undergo cell division. This is known as the vegetative cycle. In the initial period of fermentation, the culture broth has enough nutrients, resulting in exponential growth of bacteria. Once the nutrient depletion occurs, the cells cannot maintain the exponential growth rate. Normally this would result in a slowdown and the cells which are deprived of the nutrients will start dying. This phase is known as the stationary phase. In case of bacterial species like *Bacillus Subtilis*, a depletion of nutrients or any other adverse condition leads to a secondary cycle. This is called the sporulation cycle where a part of the population preserves its genetic material by forming dormant spores. In the last phase, a part of the vegetative cell population may convert itself into spores and the remaining cell population undergoes cell lysis. This phase is known as the death phase.

### 2.1. Dielectric spectroscopy

Over the years dielectric spectroscopy has been identified as a viable method for the online detection of cells (Teixeira *et al.*, 2009). It relies on the principle that under the influence of an electric field an exposed medium can act as an electric capacitor – in this case the cells and spores. This permittivity is measured by the probe. Since the amount of electric charge stored is related to the cell volume and the cell size this is a sufficient indicator on detecting the cells (Markx and Davey, 1999).

Dielectric spectroscopy could be conducted in two modes: 1. Dual frequency mode where a single frequency and a baseline frequency are used in parallel. 2. The scanning frequency mode where the permittivity is measured over a range of frequencies called the beta frequency (Dabros *et al.*, 2009). In the present case we use scanning frequency mode that consists of 25 frequencies ranging from 50 kHz to 20000 kHz that are scanned in one time step.

### 2.2. Experimental

*Bacillus subtilis* strain 168 (DSM 23778) was applied in this study. The inoculum was prepared in CASO-Bouillon as a pre-culture medium. Then it was inoculated into the minimal medium containing glucose as a carbon source. Batch cultivation was carried out in a 2-L stirred tank reactor with 1-L working volume. The 100 mL pre-culture was incubated at 30°C for 8 h and then it was inoculated into the bioreactor. The fermentation was run for 48 h at different temperature profiles. The bioreactor was equipped with dielectric sensor (Futura, Aber) to gain an insight of fermentation in real time. Temperature and glucose levels were changed for each experiment, with glucose levels in the range of 12.5-20 g/l and temperature levels in the range of 25 °C to 45°C. For some

experiments multiple temperature changes were carried out during the course of the fermentation process. The following data were used:

1. Spectral data – Permittivity measurement with sampling rate of around 2 per minute and spans over 25 frequencies from 50 kHz to 20000 kHz.
2. Offline data – Cell/spore count and the substrate added. About 14 samples.

Maskow *et al.* (2008) have pointed out that other intracellular products could be detected from the dielectric spectroscopy signals. We expect spores to be such products that could be detected. We hypothesize that the residual permittivity between the measured and (cell-) modeled data can provide information about the spore concentration.

$$\varepsilon_{\text{sensor}}(\omega) = \varepsilon_{\text{cells}}(\omega, N_{\text{cells}}) + \varepsilon_{\text{spores}}(\omega, N_{\text{spores}}) + u \quad (1)$$

Where  $\varepsilon$  is the total permittivity of the fermentation solution [pF/cm],  $\omega$  is the angular frequency [rad/s],  $N$  is the number density of either cells or spores [CFU/ml], and  $u$  is an unknown factor. An Illustration of the proposed superposition hypothesis is shown in Figure 1 on the left side. We propose that the sensor data can be modeled and fitted during the growth phase ideally since there is no contribution of spores to the permittivity signal. To model the permittivity of the cells we use a spherical cell model without cell size distribution. These assumptions could lead to a model error, since the cells are not ideally spherical, and their size is distributed. In order to compensate this model error, a correction factor  $\theta_0$  is introduced. We assume this linear correction factor as a first approach. The permittivity of the cells is then described as the product of the spherical cell model and the correction factor:

$$\varepsilon_{\text{cells}}(\omega) = \theta_0 \varepsilon_{\text{model}}(\omega, N_{\text{cells}}) \quad (2)$$

Using the approach from Maskow *et al.* (2008) the growth phase can be defined as the time span until the maximum of the permittivity is reached (see Figure 1). Following the equation system for Cole-Cole model present in Dabros *et al.* (2009), the permittivity equation (3) is used.

$$\varepsilon_{\text{model}}(\omega, N_{\text{cells}}) = \Delta\varepsilon \frac{1 + \left(\frac{\omega}{\omega_c}\right)^{1-\alpha} \sin\left(\frac{\pi}{2}\alpha\right)}{1 + \left(\frac{\omega}{\omega_c}\right)^{2-2\alpha} + 2\left(\frac{\omega}{\omega_c}\right)^{1-\alpha} \sin\left(\frac{\pi}{2}\alpha\right)} + \varepsilon_{\infty} \quad (3)$$

Where  $\Delta\varepsilon$  is the span in which the permittivity signal varies,  $\varepsilon_{\infty}$  is the permittivity at infinite frequency,  $\omega_c$  is the critical angular frequency where half of  $\Delta\varepsilon$  is reached and  $\alpha$  is the empirical Cole-Cole factor. The Cole-Cole  $\alpha$  for biological cells was reported to be in the range 0.1 – 0.2 (Dabros *et al.*, 2009). In the current work, a constant value throughout the batch process of 0.1 is used. The calculation of the constant  $\Delta\varepsilon$  is based on the Pauly-Schwan spherical cell model.

$$\Delta\varepsilon = \frac{3 N_{\text{cells}} \pi r_{\text{cells}}^4 C_m}{\varepsilon_0} \quad (4)$$

Where  $r_{\text{cells}}$  is the volume equivalent diameter of the cells,  $C_m$  is the membrane permittivity, and  $\varepsilon_0$  is the vacuum permittivity.  $C_m$  is assumed to 0.01 F/cm<sup>2</sup> Yardley *et al.* (2000). For the rod shaped bacteria the radius of the volume equivalent idealized sphere of 0.78  $\mu\text{m}$  was used (Errington and Aart, 2020). As suggested by Downey *et al.* (2014) an exponential growth is expected and validated with offline measurements.

$$N_{\text{cells}}(t) = N_{\text{cells},t=0} e^{kt} \quad (5)$$

### 3. Results and discussion

#### 3.1. Implementation of the Cole-Cole-model

In our approach we use the assumptions mentioned to determine the value of  $\Delta\varepsilon$ . For  $\alpha$  a value of 0.1 is assumed. As shown in Figure 1 (right), the values for  $\omega_c$  and  $\varepsilon_\infty$  are taken from the graph. For  $\varepsilon_\infty$  the permittivity value for the highest frequency is used. This procedure assumes that there is no significant change in the permittivity when the frequency is increased. To calculate  $\Delta\varepsilon$  information cell size and number are required. About 13 offline measurements were obtained during a 50-hour fermentation batch. To increase the number of the data points exponential curve fitting during the growth phase is applied.

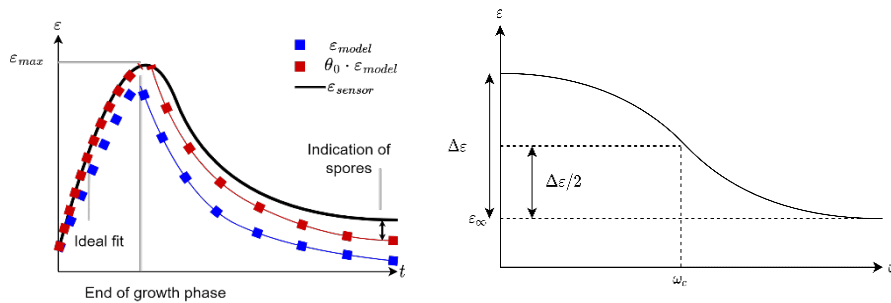

Figure 1: Illustration of the superposition hypothesis (left) and graphical representation of the Cole-Cole parameters (right).

#### 3.2. Fitting part – growth phase

Three batches KW1, KW2 and KW3 were considered for analysis. For KW1, the starting conditions were 12.5 g/l glucose and 30 °C temperature. No temperature change was made during the experiment. KW2 and KW3 included multiple temperature changes, with KW2 having a starting glucose concentration of 12.5 g/l and KW3 with 20 g/l. This ensured that each of the considered batch had differing batch conditions. The data set for the cell numbers can be increased when exponential curve fitting for equation (5) is used. Figure 2 compares the measured and the modelled permittivity during the growth phase at two frequencies for the batch number KW1. In a first step the Cole-Cole model  $\varepsilon_{model}$  without the fitting factor  $\theta_0$  is shown.

Figure 2: Permittivity data measured, model for  $g_1$  and extended model for different frequencies at KW1.

As outlined in the superposition hypothesis the model can be fitted better to the data when the factor  $\theta_0$  is introduced. It can be shown that there is a significant difference between the Cole-Cole model and the sensor data. We assume that the deviation is mostly down to either the inaccurate spherical model or the cell size assumptions. In Table 1 the corresponding values for  $\theta_0$  and the root mean square error (RMSE) before (0) and after (1) the introduction of  $\theta_0$  is shown for the fermentation batches KW1, KW2 and KW3. The proposed procedure shows that the modeled data after the introduction of  $\theta_0$  have a better fit at higher frequencies. Although all three batches had different conditions, all three achieved better fit with this method. The lowest  $RMSE_1$  and  $\theta_0$  closest to one were obtained for KW1 where no temperature variation was applied. No perfect fit for  $\epsilon_{cells}$  is achieved during the growth phase, but the mean error has been significantly reduced. The temperature change applied in the initial hours might have caused a higher  $RMSE_0$  values for KW2 and KW3. The reasons for deviations ( $RMSE_1$ ) could be due to imprecise assumptions, especially for the cell radius.

Table 1: RMSE values for the scalar factor  $\theta_0$  before and after optimization

In the following work, this approach will be extended to the remaining time periods of the fermentation batch till the end of the batch. The estimated  $\theta_0$  will be applied in equation 1 to obtain the residual permittivity that could be analyzed to establish the presence of spores.

#### 4. Conclusion

Cole-Cole modeling was identified as a suitable method that can be used to model the permittivity during the fermentation of bacteria. Using the superposition hypothesis and Cole-Cole modeling, an alternate model to describe the fermentation process of *Bacillus subtilis* was developed and the various components that contribute towards the total permittivity of the system were outlined. The linear correction parameter  $\theta_0$  has been used in this first approach to compensate for the inaccuracies in the cell model. It is observed that the modelled permittivity is in better agreement with the sensor data for higher frequencies. This work will be extended in the next stage to calculate the residual permittivity which might provide information on the development of spores, especially after the growth phase. Further work with increased number of offline measurements would provide a better fit with the current model. This model could be extended to determine the cell radius of the species more precisely. Since *Bacillus subtilis* is ellipsoidal in nature, models other than the spherical shell model could be used to improve the model fit.

## Abstract

Multiple QSAR models of mutagenicity were created and compared, using knowledge graph approaches to train and test multi-layer perceptron classifiers, following dimensionality reduction from several thousand dimensions to hundreds of dimensions via principal component analysis. Such knowledge graphs were built in one case using molecular fingerprint based structural similarities, while in another case using molecular fragments found via application of the Girvan-Newman algorithm. A simple hybrid model was also explored. However, both competing QSAR models performed with comparable accuracies, with both sensitivity and specificity scores for each occurring within range of 70%. The predictions of both models were in agreement in an average of 71% of cases, meaning that each could offer a related yet notably different perspective of toxicological space; hence a simple hybrid model was trialed, which only output predictions agreed between both constituent models, which averaged at 78% accuracy.

## 1. Introduction

Food and drink products contain a variety of chemicals, of which some are intentionally present (e.g. preservatives) while others are unintentionally present (e.g. environmental contaminants) [1]. The possible risks posed by consumption of food and drink chemicals to human and animal health, are ideally evaluated via chemical risk assessments (CRAs) carried out by regulatory bodies [1]. Current CRA frameworks are overly reliant on *in-vivo* studies on live animals [1], which pose significant ethical, scientific relevancy, and scalability-based concerns for the future of this space. New Approach Methodologies (NAMs), such as Quantitative Structure-Activity Relationship (QSAR) modelling, may be used to address some of these limitations and contribute to future frameworks that regulatory bodies may utilise [2].

QSAR modelling is an *in-silico* approach which relies on the premise that molecular structures are correlated with corresponding biological activities [2]; hence, in a toxicological context, QSAR models quantify relationships between toxicological properties of molecules and quantitative metrics concerning molecular structures. There is no universally agreed upon metric for reliably quantifying molecular structures [2],

however a variety of different approaches exist, such as structural similarity coefficients (SCs – which quantify structural similarities between pairs of molecules via techniques such as molecular fingerprinting [2] or alternatively applications of graph theory), as well as molecular fragmentation (of which numerous algorithms exist in order to split a molecular structure into smaller substructures, which may then be correlated with certain toxicological properties). QSAR models frequently use machine learning (ML) to construct models; in a toxicological context, this typically entails regression algorithms that can predict continuous metrics [3] (e.g. benchmark doses, for hazard assessments), however classification algorithms are more appropriate for certain endpoints that are thresholded and hence associated with discrete predictions [3] – e.g. mutagenicity is a thresholded endpoint where molecules may be assessed into discrete classes: A (strongly mutagenic), B (weakly mutagenic) and C (non-mutagenic) [4].

QSAR models of mutagenicity were compared as part of the 2014 Ames/QSAR International Challenge Project, involving a variety of rule-based QSAR frameworks such as SARpy and Toxtree, as well as statistical QSAR frameworks such as CEASAR and AMBIT. Sensitivity and specificity scores varied, however none were able to consistently surpass accuracy scores of 80% (considering both sensitivities and specificities), furthermore with many displaying imbalance across classes [4]. Neural networks (NNs) are a popular ML technique, using layers of artificial neurons with weights that may be optimised to form complex models. A 2021 study used feed-forward NNs to build a QSAR model of mutagenicity which was 84% accurate [5], while a separate 2021 study used graph convolutional NNs (GCNs) in order to obtain sensitivity scores that were consistently matching or below 70% and specificity scores that were consistently above 90% [6].

The aim of this study was to use NNs to construct and optimize novel QSAR models of mutagenicity, using data from *in-vitro* Ames mutagenicity studies. While *in-vitro* methods are NAMs that are frequently used in studies concerning mutagenicity, with certain advantages over *in-vivo* studies [2], they nonetheless continue to be limited in terms of efficiency and scalability, which *in-silico* techniques such as QSAR modelling may help address [2], as part of a potential future ecosystem of NAMs used in CRA. Furthermore, mutagenicity is a comparatively more thoroughly covered endpoint, in terms of data available in open source, as well as with literature concerning competing QSAR models [4], when compared to comparatively lesser covered endpoints such as neurotoxicity and cardiotoxicity; hence mutagenicity may serve as a more intuitive starting endpoint, for the construction and optimisation of novel QSAR models that may eventually be adapted and applied to more challenging endpoints in future.

## 2. Methods

### 2.1. SC-Based QSAR Model

The first QSAR model constructed used SCs (via molecular fingerprinting) to build a knowledge graph encoding similarities between constituent molecules of a dataset, which was then reduced in dimensionality via principal component analysis (PCA) and subsequently used to train and test a multi-layer perceptron (MLP) model.

Six SC algorithms that used molecular fingerprinting were separately used to create competing SC-based QSAR models; these were the Cosine, Tanimoto, Dice, Kulczynski, McConnaughey and Rogot-Goldberg SCs, each with their own unique methodology.

Each SC algorithm first required molecular fingerprints to be generated for each molecule, for which Morgan fingerprints were used. The Morgan fingerprinting algorithm was used as a function of the open-source cheminformatics Python library RDKit, with a specified radius of 3 and maximum number of 2048 bits. Following obtention of Morgan fingerprints for all possible pairs of molecules, the six algorithms were each used to calculate SCs between all Morgan fingerprint pairs.

The dataset of molecules used was that associated with the 2014 Ames/QSAR International Challenge Project, with Ames mutagenicity data collected from a variety of different studies, for a variety of organic molecules provided in canonical SMILES (simplified molecular-input line-entry) notation. Following data curation measures (such as excluding molecules with inconsistencies in descriptors, or with incomplete mutagenicity data), the final dataset used in this study contained 11,268 molecules. The occurrences of A, B and C classes in the data were imbalanced, which was alleviated via combining classes A and B into a single “mutagenic” class, while assigning class C as a “non-mutagenic” class (an approach similar to those used in past studies [4]). The two classes nonetheless remained imbalanced, hence further balancing was carried out via assignment of training and testing data.

The 11,268 molecules were split into approximately 80% training data and 20% testing data, using random sampling via pseudorandom numbers, with each molecule treated as a sample to be used in an MLP classifier model. Knowledge graphs for training data were constructed, using individual molecules as nodes, connected via edges to every present node (including to themselves) and weighted according to SCs between corresponding molecule pairs. Feature vectors for each training sample molecule were derived from the weightings of edges in the knowledge graph connected to the corresponding node. Feature vectors for training data similarly contained calculated edge data to the existing nodes in the knowledge graph, effectively describing how each test sample molecule would be positioned in the knowledge graph, if included.

Each feature vector was naturally of several thousand dimensions, which would have proven problematic for training effective models with simple architectures. PCA was implemented via the Python-based ML package scikit-learn, to reduce dimensionality, while conserving as much information contained within the multidimensional data as possible. Final dimensionalities were varied between 2-220 (see Figure 2), for the sake of finding an optimal dimensionality.

The NNs used were MLP classifiers, also implemented via scikit-learn in Python, with two hidden layers containing 500 artificial neurons, while using the rectified linear unit (ReLU) activation function, along with the Adam optimisation algorithm (a stochastic gradient-based algorithm, which is typically suitable for larger datasets) for weight optimisation. The strength of the L2 regularization term was set to  $1 \times 10^{-5}$ , while the number of epochs was set to 1,000. All other parameters remained as default.

## 2.2. Fragmentation-Based QSAR Model

Figure 1: schematic diagram demonstrating how (A) an input molecule [7] would be (B) fragmented before (C) being placed in a graph of mutagenic/non-mutagenic molecules that shared substructures. (D) A feature vector would then be derived, based on connections.

A second QSAR model was constructed and applied to the same dataset, using knowledge graphs, PCA and MLP classifiers in an identical nature to that of the SC-based QSAR model, but instead using molecular fragmentation to construct knowledge graphs.

Fragments of molecules were obtained via consideration of canonical SMILES descriptors as molecular graphs, using graph theory (the Python library `pysmiles` was used to convert between canonical SMILES and Python Graph objects). Fragmentation was treated as a community detection problem, with communities of each molecular graph identified and regarded as molecular fragments via the Girvan-Newman algorithm; a widely used hierarchical community detection method available as a function of the `NetworkX` library of Python. The algorithm required a specified number of communities to be identified, hence a separate algorithm output ascending values for each new molecule, until all fragments found by the Girvan-Newman algorithm were within a specified size range in terms of constituent atoms (excluding hydrogen atoms). Three different size ranges were considered: 2-7, 3-12 and 3-15.

Once lists of fragments for every molecule were obtained, knowledge graphs were constructed (see Figure 1). Training and testing data assignment, as well as subsequent PCA and use of MLP classifiers, were identical to as described in Section 2.1.

### 2.3. Hybrid QSAR Model

Following training and testing of the QSAR models described in Sections 2.1 and 2.2, a simple hybrid model was explored via testing both models in parallel (with the same training data for each) and only outputting predictions that were agreed by both models. Within the hybrid model, the SC-based QSAR model used the cosine similarity, whereas the fragmentation-based QSAR model used a size range of 3-12 atoms for finding fragments. Both constituent models also used reduced dimensionalities of 100.

## 3. Results and Analysis

### 3.1. Individual QSAR Model Results

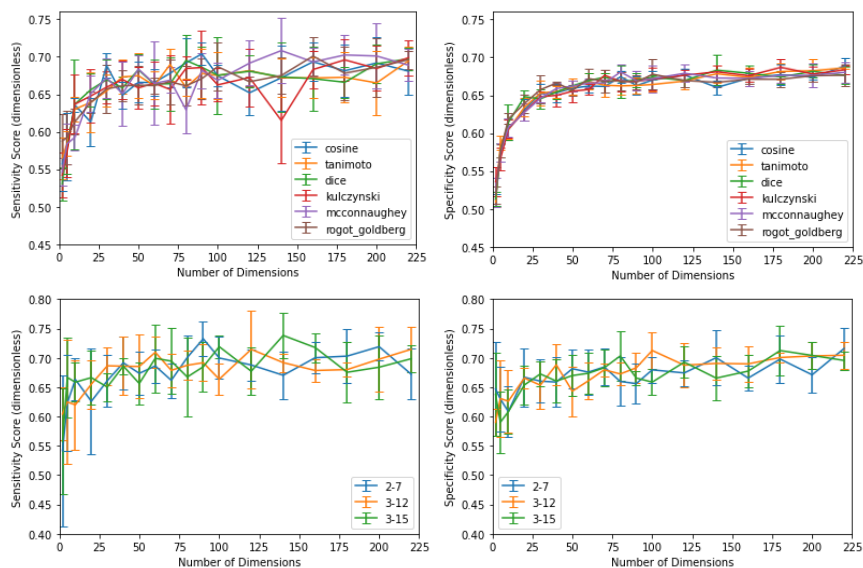

Figure 2: sensitivity (for correctly classified mutagenic molecules) and specificity (for correctly classified non-mutagenic molecules) scores, for the SC-based QSAR model (top row) and the fragmentation-based QSAR model (bottom row).

As observed from Figure 2, increased dimensionalities initially improved accuracy scores, as higher dimensionalities of data from knowledge graphs were presumably necessary for sufficiently conserving information regarding a complex toxicological space. For the SC-based model, convergence within range of 70% accuracy was apparent from approximately 100 dimensions onwards, as sufficient dimensionality was reached and inclusion of further dimensions contributed comparatively less to describing the complex toxicological space. Convergence for the fragmentation-based model appeared to have occurred less extremely and at lower dimensionalities. No consistent differences in performance were visible, concerning different SC algorithms or fragment size ranges (the latter may indicate that smaller substructures could have been responsible for causing mutagenic/non-mutagenic effects), however it should be noted that higher variances were generally present for sensitivity scores than for specificity scores; this is deemed to be due to the data equalisation measures that were performed, which successfully equalised the average sensitivity and specificity scores, but however caused greater numbers of non-mutagenic test samples to give rise to greater certainty in specificity scores than for sensitivity scores. The fragmentation-based model displayed marginally higher converged accuracy scores, than for the SC-based QSAR model, however the two models are overall deemed as closely comparable in performance.

### 3.2. Hybrid QSAR Model Results

Figure 3: percentage agreements between constituent models, along with overall hybrid model performance, over 70 repeat runs.

Figure 3 demonstrates that an average of  $71\% \pm 1\%$  of predictions were agreed by constituent models, which gave rise to a hybrid model with an average accuracy score of  $78\% \pm 2\%$ . It was furthermore found that percentage agreement between the models was strongly positively correlated with percentage accuracy of the resulting hybrid model, with a Pearson correlation coefficient calculated at 0.8.

### 4. Conclusions

Our results suggested that the novel QSAR approaches explored were effective in modelling mutagenicity. Dimensionality reduction via PCA was a critical step for improving accuracy scores, via better enabling MLP classifiers to navigate a multidimensional toxicological space. Explored parameters such as individual SC algorithms, along with searched fragment sizes, were found to be less relevant for improving accuracy scores. Compared to existing QSAR models in this space, the two

individual QSAR models underperformed, however the hybrid model formed by both outperformed certain studies and matched others in average accuracy score [4-6]. Accuracy scores may be further improved by developing additional constituent QSAR models for the final hybrid model, as well as exploring parameter optimization for the NNs involved, alongside novel NN architectures and potentially more advanced and specialised NNs than MLPs. Exploration of differing dimensionality reduction algorithms may also prove beneficial, especially non-linear techniques such as autoencoders and locally linear embedding, which may perform better in preserving any complex multidimensional decision boundaries between classes that may potentially exist in higher dimensional toxicological space.

## Abstract

Cardiomyocytes (CMs) are heart cells responsible for heart contraction and relaxation. CMs can be derived from human induced pluripotent stem cells (hiPSCs) with high yield and purity. Mature CMs can potentially replace dead and dysfunctional cardiac tissue and be used for screening cardiac drugs and toxins. However, hiPSCs-derived CMs (hiPSC-CMs) are immature, which limits their utilization. Therefore, it is crucial to understand how experimental variables, especially tunable ones, of hiPSC expansion and differentiation phases affect the hiPSC-CM maturity stage. This study applied clustering algorithms to day 30 cardiac differentiation data to investigate if any maturity-related cell features could be related to the experimental variables. The best models were obtained using k-means and Gaussian mixture model clustering algorithms based on the evaluation metrics. They grouped the cells based on eccentricity and elongation. The cosine similarity between the clustering results and the experimental parameters revealed that the Gaussian mixture model results have strong similarities of 0.88, 0.94, and 0.93 with axial ratio, diameter, and cell concentration.

## 1. Introduction

Cardiovascular disease (CVD) is the leading cause of death worldwide (Ahmed et al., 2020). A heart attack can cause the loss of more than one billion heart cells, initiating blood flow overload and overstretching on viable cardiac cells, potentially leading to death. Because the human heart has limited regenerative capacity, it cannot replace damaged cells. Engineered heart tissue is a potential alternative for heart failure due to the difficulties associated with Cardiac Implantable Electronic devices (CIEDs) and heart transplants, two available therapies (Kempf et al., 2016). Human-induced pluripotent stem cells (hiPSCs) can be differentiated into CMs with the potential to produce therapeutic CMs (Tani et al., 2022). However, CMs produced by current differentiation protocols are immature. Immature CMs differ substantially from mature ones. For example, immature CMs have underdeveloped mitochondria, limited fatty acid oxidation capacity, less elongated cells, and disorganized sarcomeres and myofibrils. Research is ongoing to develop protocols that lead to mature hiPSC-CMs (Hamledari et al., 2022). This paper applied clustering algorithms to group hiPSC-CMs based on maturity-relevant features and investigated the relationship between clustering results and tunable experimental variables of the differentiation protocol with the aim of identifying variables that produce more matured CMs. Clustering, instead of classification, was employed

because the hiPSC-CMs cannot be labeled to train a classifier. The CMs were produced through hiPSC hydrogel encapsulation and direct differentiation within a 3D-engineered tissue microenvironment (Chang et al., 2020). The unbiased data were collected from 17 different batches, with each batch having different experimental variables, such as axial ratio (AR), cell concentration, PEG-fibrinogen (PF) concentration, and microspheroid size (i.e., diameter). Eight clustering algorithms from Scikit-learn (Fabian Pedregosa) were applied to day 30 cardiac differentiation data. The maturity-relevant features considered for clustering were cell area, cell circularity, eccentricity, elongation, sarcomere length, sarcomere organization score, and orientation index. The k-means and Gaussian mixture clustering algorithms yielded the best clusters based on evaluation metrics.

## 2. Experimental Procedure for hiPSC-CM Production and Data Collection

### 2.1. HiPSC Culture, Encapsulation, and Cardiomyocyte Differentiation

Un-Arc 16 Facs II (Shinnawi et al., 2015) was cultured on Geltrex (Gibco) with E8 media. The hiPSCs were resuspended in PF precursor solution at 30-60 million cells/mL and encapsulated within PF by using a novel microfluidic system as described previously (Finklea et al., 2021). Microspheroids with different sizes and ARs were produced (Seeto et al., 2019). The D-optimal experimental design was used, assuming Gaussian process model. Microspheroids were cultured for an additional 2 days in E8 media with daily media changes (days -2 and -1). To analyze the initial size and AR of the microspheroids, the autofluorescence of the photoinitiator Eosin Y in PF was captured using the FITC filter on the Nikon Eclipse Ti fluorescence microscope at low magnification. Standard plugins in ImageJ were used for quantification. To initiate cardiac differentiation on day 0, microspheroids were transferred to chemically defined cardiac differentiation media (CDM3) supplemented with CHIR99021 (5 – 7.5  $\mu$ M, STEMCELL Technologies). Exactly 24 h later, the media was exchanged for CDM3 supplemented with 5  $\mu$ M IWP2 (STEMCELL Technologies). Fresh CDM3 was added on days 3, 5, 7, and 10; following day 10, microspheroids were cultured in RPMI/B27 (Gibco). The differentiation outcomes were assessed using flow cytometry on day 10 using the primary antibodies, such as cTnT (Invitrogen) and MF20 (DSHB), and secondary antibody (1:300, AlexaFluor 647 goat anti-mouse IgG (ThermoFisher)).

### 2.2. Microspheroid dissociation and replating

Microspheroids on day 30 of differentiation were dissociated by incubating in a Collagenase-B (1 mg/mL, Roche) supplemented by DNase (0.05 mg/mL, Worthington) in PBS dissociation solution at 37 °C for about 8 minutes. The cells were plated on a Matrigel-coated coverslip in RPMI 20 medium (RPMI 1640 medium with 20% FBS, Atlanta Biologicals) supplemented with 5 $\mu$ M RI for 2 days before starting staining. After fixation, the cells were washed with PBS, permeabilized with PBS-T containing 0.2% Triton X-100 in PBS for 30 minutes, and blocked with 10% FBS in PBS blocking buffer for 45 minutes at room temperature. Cells were incubated in primary antibody (aSA) overnight at 4 °C. After washing, cells were incubated in the secondary antibody (Alexa Fluor 568, 1:200), and nuclei stained with Bisbenzimidazole Hoechst 33342 (MilliporeSigma) for 1 hour at room temperature. All samples were visualized with Nikon Eclipse TE2000 Inverted Microscopes equipped with a Nikon A1 plus Confocal Microscope System. To assess hiPSC-CMs cell morphology and sarcomere structure, SarcOmere Texture Analysis (Sutcliffe et al., 2018) was used for immunofluorescent confocal images.

### 3. Clustering Algorithms

#### 3.1. K-means Clustering

Given the number of clusters ( $|C|$ ), the algorithm (Likas et al., 2003) randomly initializes  $|C|$  cluster centroids ( $\mu_j, j = 1, 2, \dots, |C|$ ) and assigns a class membership to each point ( $x_i, i = 1, 2, \dots, n$ ) based on its closest centroid. Then, the centroids are reestimated using Eq. (1). Each point is reassigned a new class membership based on the new centroids. The steps are repeated until class memberships stop changing.

$$\sum_{i=0}^n \min_{\mu_j \in C} (||x_i - \mu_j||^2) \quad (1)$$

#### 3.2. Gaussian Mixture Model Clustering

The Gaussian mixture model (Yang et al., 2012) assumes that all data points come from a finite number of Gaussian distributions with unknown parameters. The distribution parameters are estimated by the expectation maximization (EM) algorithm. The EM algorithm first assigns the mean and variance of the distributions either randomly or based on the centroids of k-means clustering results. The probability of a point belonging to a cluster is calculated using the distribution parameters. Cluster means and variances are improved by maximizing the likelihood of the data given those parameters, and the procedure is repeated until the mean and variance of each distribution stop changing.

#### 3.3. Agglomerative Clustering

Agglomerative clustering (Murtagh & Legendre, 2014) is a hierarchical algorithm that uses a bottom-up approach. Each data point is initially considered a “cluster.” The algorithm proceeds by successively merging clusters using a selected linkage criterion. Criterion using ward, complete, average, and single linkage minimizes the sum of squared distances within all clusters, the maximum distance between observations of pairs of clusters, the average of the distances between all observations of pairs of clusters, and the distance between the closest observations of pairs of clusters, respectively.

### 4. Metrics Used for Evaluating Clustering Results

The three evaluation metrics used to assess the cluster results were Silhouette score, Calinski-Harabasz index (CH), and the Davies-Bouldin index (DB). Based on the results of these metrics, the best three cluster models were selected. Silhouette score (Shahapure & Nicholas) for a data point,  $s$ , is calculated using the distance between that point and all other points in the same and nearest clusters. The average silhouette score of all the data points gives the Silhouette score for the clusters. Silhouette score is between -1 and 1, with 1 indicating that the clusters are well separated. The CH (Maulik & Bandyopadhyay, 2002) is the ratio of the sum of dispersion between and within clusters for all clusters. The CH is higher for dense and separated clusters. The DB (Maulik & Bandyopadhyay, 2002) is defined as the average similarity between each cluster  $C_a$  and its most similar one  $C_b$ . The similarity score,  $R_{ab}$ , given in Eq. (2), is calculated between cluster  $a$  and  $b$ ,  $d_a$  is the average distance between each point in cluster  $a$  and its centroid, and  $D_{ab}$  is the distance between cluster centroids  $a$  and  $b$ . The DB is calculated by Eq. (3). Values closer to zero indicate better clustering.

$$R_{ab} = \frac{d_a + d_b}{D_{ab}} \quad (2)$$

$$DB = \frac{1}{k} \sum_{i=1}^k \max_{i \neq j} R_{ab} \quad (3)$$

## 5. Results and Discussion

### 5.1. Clustering Results

Five hundred thirteen (513) hiPSC-CMs from 17 batches were analyzed to obtain cell morphological features, such as cell area, eccentricity, circularity, elongation, and sarcomere properties, such as sarcomere length, orientation index, and organization score. Only k-means, Gaussian mixture model, and agglomerative clustering algorithms were found to be applicable to the dataset. The agglomerative clustering algorithm grouped almost all hiPSC-CMs in one cluster. These clustering results were not further analyzed. Because this study aims to investigate the relationship between mature and immature hiPSC-CMs and experimental variables, the number of clusters was set to two.

Based on the evaluation metrics, k-means clustering yielded the best model with a Silhouette score of 0.17, CH of 107, and DB of 1.99. Gaussian mixture model clustering with spherical, full, and diagonal covariance yielded the following models in that order. The evaluation metrics for these models were similar to those for the k-means algorithm. Analyzing the two clusters yielded by the k-means and Gaussian mixture model algorithms revealed that the hiPSC-CMs were clustered based on eccentricity and elongation. Mature CMs typically have an elliptical shape with larger eccentricity and elongation values (Karbassi et al., 2020).

The k-means algorithm grouped hiPSC-CMs with eccentricity values between 0.7 and 1 and elongation between 2 and 10 in one cluster, which we named the “Mature” cluster, and the remaining cells in another, we named the “Immature” cluster. The Gaussian mixture model algorithms yielded clusters with the same cell property ranges. The overall clustering results suggest that eccentricity and elongation were significant features for separating mature hiPSC-CMs from immature cells by unsupervised learning.

### 5.2. Relationship between hiPSC-CM Maturity and Tunable Experimental Variables

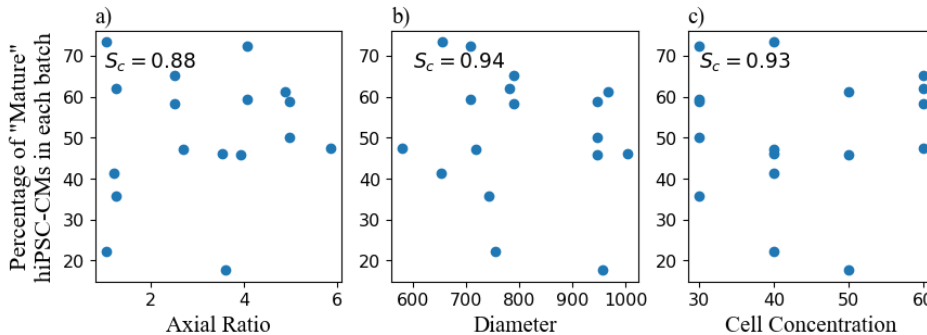

To investigate the potential relationship between hiPSC-CM maturity and tunable experimental variables, we calculated the percentage of hiPSC-CMs clustered as “Mature” in each of the 17 batches. A set of tunable experimental variables, namely AR, diameter, cell concentration PEG concentration, and PF concentration, were used in each batch. Then, the Cosine similarity (Xia et al., 2015) between this percentage and each tunable experimental variable for each clustering result was calculated. Cosine similarity is a measure of similarity between two vectors. Using cosine similarity, we quantify how similar the percentage of mature CMs to the experimental variables. The resulting similarity values are plotted in Figure 1. The PEG and PF concentration results were not considered because there were only three values for these variables. Figure 1 illustrates that the strongest similarity metric values were observed for the results obtained using the Gaussian mixture model clustering, with a cosine similarity of 0.88 with AR, 0.94 with diameter, and 0.93 with the cell concentration. The cosine similarity values for the results obtained with the k-means algorithm are similar, with a cosine similarity of 0.86 with AR, 0.92 with diameter, and 0.91 with cell concentration.

Figure 2 plots the percentage of “Mature” hiPSC-CMs in each batch calculated using Gaussian mixture model clustering results versus AR (Figure 2(a)), diameter (Figure 2(b)), and cell concentration (Figure 2(c)). Figures 2(a), 2(b), and 2(c) suggest that there is a relationship between the percentage of “Mature” hiPSC-CMs and AR, diameter, and cell concentration. Three of the five batches with ARs less than two have less than 45 % of hiPSC-CMs clustered as “Mature”. In contrast, batches with an AR greater than two have at least 45% hiPSC-CMs clustered as “Mature”, except for one. Figure 2(c) shows that when the concentration is equal to 60 million cells/mL, the percentage of mature cells is greater than 50%. These observations suggest the existence of non-linear and

potentially complex relationships between the mature hiPSC-CMs and the ARs, diameters, and cell concentration, which should be further investigated.

**Figure 1** – Cosine similarity between the percentage of “Mature” hiPSC-CMs in batches based on the clustering results and the experimental parameters. K\_Means – k-means clustering, GMM\_Diag, GMM\_Full, and GMM\_Sp – Gaussian mixture model with diagonal, full, and spherical covariance function.

**Figure 2** - Percentage of mature hiPSC-CMs clustered by k means clustering vs. (a) AR (b) Diameter (c) Cell concentration.  $S_c$  – Cosine similarity between the percentage of mature CMs and each experimental parameter.

## 6. Conclusions and Future Directions

Using day 30 cardiac differentiation data, we identified eccentricity and elongation as the significant features for clustering hiPSC-CMs into two groups via k-means and Gaussian mixture model clustering algorithms. The results of the Gaussian mixture and k-means models suggested that there is a concurrent relationship between ARs, diameter, and cell concentration, all experimentally tunable variables, and hiPSC-CMs with higher eccentricity and elongation, which are associated with maturity. Future work will investigate using different clustering approaches that relax the compact set assumption for determining better “Mature” cell cluster boundaries. Then, the relationships between the experimental variables and mature hiPSC-CMs will be modeled to aid in directing hiPSC differentiation towards mature CMs.

## Abstract

This paper is part of a general effort to integrate disjoint stages of the Design-Build-Test-Learn cycle that addresses the simultaneous design of biocatalysts with process engineering. Engineering kinetics are currently based on regression studies based on experimental data with limited reference to the underlying reaction pathways. Instead, the ORACLE framework offers an attractive environment to generate populations of large-scale (curated) dynamics and a platform for in-silico kinetic models to check for physiological relevance and stability. Stability checks have reported low rates of success and the paper explains a systematic approach that combines deterministic methods and data analytics to accelerate realizable kinetics that could be set a basis to connect the dynamics of the cell with the dynamics of the process. The work is demonstrated with the production of muconic from *S. cerevisiae* which is achieved by shunting the shikimic pathway. The ORACLE framework consists of two reduction stages where the first one ensures that the generated kinetic models are physiologically relevant and the second one checks the model's stability. The conventional method produced 370 physiologically relevant models out of which 70 were stable (19.2%) whereas our approach increased uptake of acceptable solutions to 97.7%.

**Keywords:** metabolic engineering; machine learning; rule extraction; *S.Cerevisiae*; muconic acid;

## 1. Introduction

The typical design process towards a sustainable bio-production of chemicals follows the iterative Design-Build-Test-Learn (DBTL) cycle. The design involves the selection of the platform organism and the heterologous reactions that need to be expressed to produce the desired chemicals as well as strategies (enzyme upregulations or downregulations) to enhance product yield. The build module involves the genetic transformation and gene editing of the platform organism in accordance to the strategies of the design step. The test module we gather information on the cloning results, omics data and help comprehend cellular behavior. Small batch experiments showcase the developed strain's desired product yield as well as some key metabolites secretion rates. The learn module takes into account the generated information from the test step and incorporates it into new metabolic strategies to further optimize and increase the desired flux.

Optimization and Risk Analysis of Complex Living Entities (ORACLE) is an attractive methodology to formalize development stages and set a basis for the development of large-scale kinetics. The approach combines mathematical optimization and data analytics. The ORACLE framework is a venue to connect genome-scale models with process engineering. Thermodynamic Flux Analysis is used to predict potential fluxes at steady states; reduction methods and parameter sampling can be applied to produce candidates for observable dynamics. Pruning tests and stability checks can be applied to determine candidates for large-scale kinetic models. Such models are valuable in scale-up studies, in the design and optimization of bioreactors, also to manipulate pathways as required to increase yields and selectivity. The screening of candidates and the analysis of uncertainty are critical issues in the current methodology that currently embraces hypotheses and heuristics to tackle the large size and complexity of the problem. The challenges offer room for systems methods to add rigor, automate the analysis, and improve the quality and relevance of the high-throughput experiments. The paper explains the application of a systems approach to tackle stability of curated kinetics demonstrating significant improvements in the quality of the results.

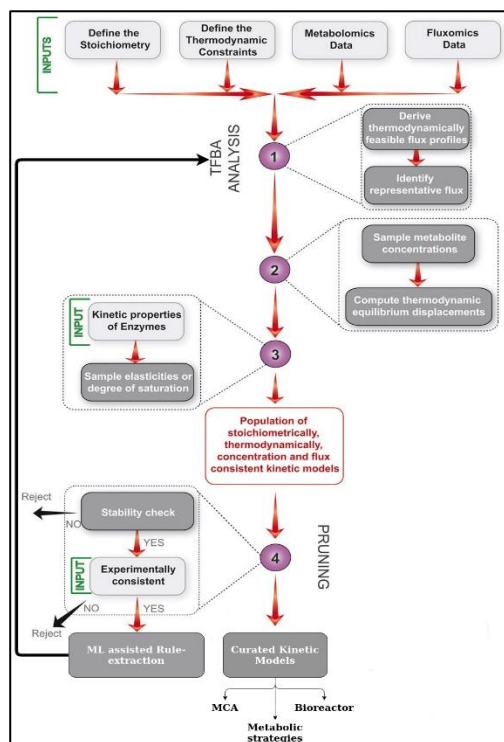

Figure 1. ORACLE methodology pipeline

## 2. Pilot study: Muonic acid production from *S.cerevisiae*

The pilot study involves a Genome-Scale model produced for the mutant strain of *S. Cerevisiae* that produces muonic acid via the shunting of shikimic pathways. The model is thermodynamically curated and reduced in order to generate kinetic models through the ORACLE framework. A total of 23500 kinetic models was generated; 370 of them remained within physiological bounds. Only 70 out of 370 models showed great stability to random initial metabolite concentration. Due to the small percentage of stable models, we deployed a decision tree classifier to extract rules on key kinetic parameters that affect the system stability. The decision tree's input kinetic parameters were the enzyme saturation ( $\sigma$ ) and thermodynamic displacement

Figure 2. Muonic acid pathway

The decision tree's input kinetic parameters were the enzyme saturation ( $\sigma$ ) and thermodynamic displacement

(gamma) parameters. The differences in the development of decision trees motivated the remaining analysis where we explored different rule extraction approaches.

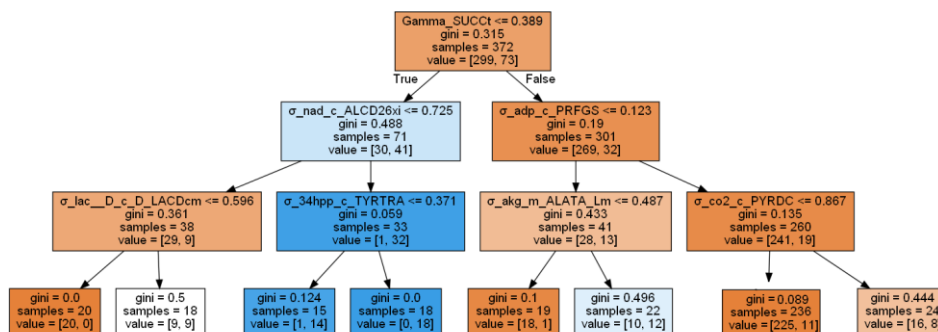

Figure 3. Decision tree of kinetic parameters

### 3. Methods and Materials

#### 3.1. Parameter classification problem

The parameter classification problem is the identification of a subspace in the parameter space wherein the parameters satisfy a given property (GP). Let us consider an  $n$ -dimensional space of parameters  $p_1, p_2, \dots, p_n$ , and assume that the GP is satisfied provided a function of these parameters satisfies  $f(p_1, p_2, \dots, p_n) > 0$ . The task is to find ranges of  $p_1, p_2, \dots, p_n$ , for which the GP is satisfied without any knowledge of the exact functional form of  $f(p_1, p_2, \dots, p_n)$ . As applied in the population of the curated kinetic models, the parameters  $p_1, p_2, \dots, p_n$  account for the saturation and thermodynamic displacement parameters of the kinetic model; GP would be satisfied if the referred kinetic model passes the stability tests.

#### 3.2. Learning-based Rule-extraction Algorithms

Rule-extraction is important to understand how the system functions. Rule extraction methods are typically used in conjunction with learning algorithms that feature an inherent explanation capability (surrogate model). In our case several ML methods (black-box models) are trained using saturation and thermodynamic displacement parameters of curated kinetic models to predict whether the curated kinetic model is stable or not. Then, a CART decision tree (surrogate model) was trained to approximate predictions of the black box models.

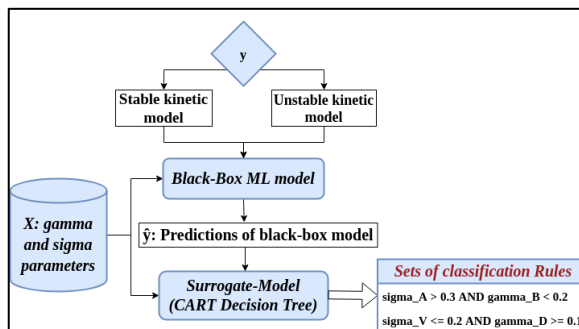

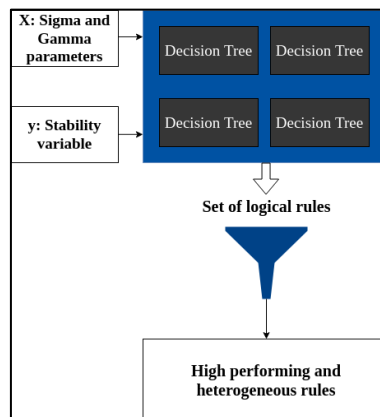

Figure 4. Pipeline to obtain a surrogate model

### 3.3. Skope-Rules

*Skope-Rule* extraction is a rule-based interpretable model that allocates logical rules with high precision to fuse them. The difference from other rule-extraction methods stands in that decision rules are actual inputs. Rules are extracted from tree ensembles; similar or duplicated rules are removed based on similarity thresholds. A fitted tree defines a set of rules; rules are then tested selecting and merging rules with higher precision. In our case, the Skope-Rules algorithm is implemented on training tree ensemble models on saturation and thermodynamic displacement parameters. They algorithm is used to predict if a given kinetic model is stable or not.

**Figure 5.** Skope-Rules pipeline

## 4. Methodology

The adopted rules-extraction procedure is outlined in the following steps:

**Step 1a.** The physiologically relevant generated kinetic models are used to define a *dataset* that consists of an *input* ( $X$ ) and an *answer set* ( $y$ ). The *input set* contained all the *gamma* (thermodynamic displacement) and *saturation* (*sigma*) parameters for each kinetic model; the *answer set* answers if the model is stable or not.

**Step 1b.** The dataset was split into a *training set* and a *validation set* in an 80:20 ratio. The *training set* was then used to train and extract the rules from the machine learning models, while the *validation set* was used to validate the accuracy of the extracted rules. We computed the *Stability Index* (SI) as the ratio between the number of kinetic parameters sets that passed the *stability check*.

**Step 2.** Several machine learning classifiers (“black-box” models) were built using this *training set*. Then, these models were used to predict the labels, i.e. the *answer set*, for the *input set* mentioned in *Step 1*. The employed machine learning algorithms used as “black-box” models were; Logistic Regression and Support Vector Machines.

**Step 3.** A decision tree (*surrogate model*) was built on the *input set* of the training data and the *predictions* of the black-box model. The rules generated from the decision tree represented the generalization behavior of the black-box model. We ranked the classification rules based on the number of training samples (kinetic parameter sets) that they enclose and we selected the rule enclosing the most samples.

**Step 4.** From the *validation set*, we selected only the kinetic models that satisfied the extracted rules and computed the SI over these sampled models. If the obtained SI is improved, the extracted rules and the general methodology as well are valid.

**Step 5.** Finally, we generated new populations of kinetic models based on the inferred rules from *Step 3* independently of the training set. We calculated the SI obtained and compared it with the one from the *training set*. If the SI and the number of feasible kinetic models are improved, the rules extracted from the black-box model are valid and the uncertainty in kinetic parameters is reduced.

## 5. Results and Discussion

Different sets of rules were extracted from each black-box model and the rule enclosing the most training examples was finally selected for each model. These inferred rules

constrained the saturations and the corresponding kinetic parameters of some critical enzymes, reducing the sampling space and, as a result, the uncertainty in the model analysis. The critical parameters that affect the stability of the generated kinetic models and the inferred rules according to every black-box model are presented in *Table 1*.

Black Box Model	Rules
Logistic Regression	Gamma_GLUDC ≤ 6.27e-09 Sigma_[chor_c]_CHORS ≤ 0.126
Decision Tree	Gamma_HCO3E > 0.856 Sigma_[nad_c] ≤ 0.524
SVM	Gamma_GLUDC ≤ 6.27e-09 Sigma_[2oxoadp_m] ≤ 0.646 Sigma_[g6p_c] ≤ 0.522 Sigma_[gmp_c] ≤ 0.999
Skope rules	Gamma_FBA ≤ 0.527 Sigma_[nad_m] > 0.484 Sigma_[glu_L_m] ≤ 0.862

**Table 1.** Rules extracted from each machine learning algorithm

Reaction Name	Reaction Stoichiometry
GLUDC	glu_L_c + h_c ⇌ 4abut_c + co2_c
CHORS	3psme_c → chor_c + pi_c
H3COE	co2_c + h2o_c ⇌ h_c + hco3_c
GAPD	g3p_c + nad_c + pi_c ⇌ 13dpg_c + h_c + nadh_c
2OXOADPTm	2oxoadp_m + akg_c ⇌ 2oxoadp_c + akg_m
LMPD biomass	Biomass reaction
GK1	atp_c + gmp_c ⇌ adp_c + gdp_c
FBA	fdp_c ⇌ dhap_c + g3p_c
ALCD26xi	h_c + nadh_c + id3acald_c ⇌ nad_c + ind3eth_c
ASPTA	akg_c + asp_L_c ⇌ glu_L_c + oaa_c

**Table 2.** List of reactions that came up during the Machine Learning analysis

In order to quickly validate the accuracy of the extracted rules, we sampled from the *validation set* (as described in paragraph 2.4) only the kinetic models that satisfied these rules and computed the Stability Index over them. The obtained SI for every implemented machine learning algorithm was improved over the SI computed on the training test, meaning that our method is able to determine and constrain the critical kinetic parameters that lead to more feasible kinetic models. We proceeded with the generation of new kinetic models implementing the extracted rules for the parameters that seem to affect stability. A total of 200 physiologically relevant kinetic models were produced for every different set of rules. In addition, we implemented all the rules combined and generated again 200 physiologically relevant models. The generated models underwent the ORACLE stability check where 100 random concentration perturbations were performed using a wide range ( $0.5[X_{ref}] \leq [X] \leq 2[X_{ref}]$ ) of initial values. We deemed a kinetic model stable if 95/100 times the metabolite concentrations returned to steady state. The results obtained are presented on *Figure 6*.

**Figure 6.** Stability Index obtained from extracted rules for every machine learning model. *Validation Set:* SI is computed on samples following extracted rules on validation set. *New Models:* SI is computed on new kinetic models, generated based on extracted rules. *Original Models:* SI is computed on kinetic models generated originally, with no inferred rules.

## 6. Conclusion

The production of large scale metabolic kinetic models is hindered by the uncertainty of predicting the kinetic parameters and producing physiologically relevant and robust kinetic models. Using the ORACLE framework, we are able to generate large populations of kinetic models but the biggest percentage of them are not stable. In this work the uncertainty in the model analysis is reduced through the use of machine learning principles. Using machine learning classification and explainability techniques we were able to raise the stability index of the generated models. We were able to reach up to 97.7% stability on our generated models implementing simultaneously all the extracted rules which leads to postulate that it is better to constrain such systems as much as possible to get more feasible results.

## Abstract

In this work, the design of the conventional process to produce bioethanol from lignocellulosic biomass is developed. The conventional process consists of pretreatment, hydrolysis, and fermentation of the biomass to obtain bioethanol and other bioproducts. The bioethanol is purified up to 99% through extractive distillation. Different options for intensification are proposed to improve such conventional process. The analysis of the developed production schemes is performed by simulation in the software Aspen Plus V.11. The first intensified scheme (I-1) consisted in the elimination of the glycerol purification column. The second intensified scheme (I-2) consisted in the elimination of the column that purifies the ethanol-ammonia mixture, by means of the implementation of a side stream. Scheme I-2 reduces the thermal load by 2.36%, which is associated with a lower capital cost.

**Keywords:** bioethanol, lignocellulosic biomass, process intensification, process simulation.

## 1. Introduction

Fossil fuels contributed with 79.7 % of the total energy used in the world in 2015 (Banco Mundial, 2022). In addition, the U.S. Energy Information Administration (EIA) estimated that in 2021, the consumption of gasoline in the U.S. transportation sector resulted in the emission of about 1,018 million metric tons (MMmt) of carbon dioxide (CO<sub>2</sub>) (Energy Information Administration, 2022). To reduce the dependence on fossil fuels and their environmental impact, the use of biofuels has been proposed as a viable solution. Those biofuels are obtained from renewable biomass and are considered one of the most feasible options to reduce CO<sub>2</sub> emissions in the transportation sector (Alam and Tanveer, 2020). Bioethanol stands out among the fuels that can be obtained from lignocellulosic biomass. This alcohol is used in blends of 10 vol% with gasoline (Costagliola et al., 2016) and can be used to partially replace the use of gasoline.

Biomass is renewable organic feedstock that can be obtained from plants and animals. The composition of the plant biomass generally comprises cellulose, hemicellulose, and lignin; referred to as lignocellulosic biomass. By 2020, the production of agricultural residues in the world has been reported as  $2.14 \times 10^9$  tons (FAO, 2022), with a high contribution of residues from corn, sorghum, wheat, and barley crops. Sorghum is

important at national level since Mexico is its main producer in Central America. To be economically feasible, the conversion of biomass into biofuels must take place in a biorefinery scheme. A biorefinery is a facility that integrates biomass conversion processes and equipment to produce fuels, energy, and chemicals. In the biorefinery scheme based on lignocellulosic materials, it is necessary to break down the lignin structure on the feedstock, then obtaining fermentable sugars from cellulose and hemicellulose. The initial lignin removal requires a pretreatment stage. In the literature there are several studies related to the production of lignocellulosic bioethanol, such as the work developed by Conde-Mejía et al. (2012), in which different types of pretreatments as well as different conversion technologies were analyzed to find the best configuration of this process in economic and environmental terms. Similarly, Duque et al. (2020) analyzed the production of ethanol from barley straw combining a soda and enzyme-catalyzed extrusion pretreatment, reporting a production of 15.8 g ethanol/100 g raw barley straw. In these studies, several types of biomass and different conversion pathways were analyzed, with the major objective of obtaining feasible pathways with high yields. Nevertheless, biofuels must also be economically competitive with their fossil counterparts; this implies that the biofuels production costs must be reduced. In this context, process intensification (PI) plays a key role, since it can help to generate compact, energy-efficient, safer, and more environmentally friendly processes. Therefore, in this work, the design of the conventional process to produce bioethanol from lignocellulosic biomass is developed. Areas of opportunity are detected for the conventional process, proposing and evaluating intensification alternatives, such as thermally coupled columns and columns with side streams, aiming to the improvement of the energetic performance of the conventional process.

## 2. Case Study

The case study is based on the work of Conde-Mejía et al. (2013), considering 87,539 kg/h of sorghum residues as feedstock. Data in Table 1 show the composition of the lignocellulosic material. The carbohydrates profile of the feedstock is shown in Table 2.

**Table 1.** Composition of lignocellulosic biomass (Conde-Mejía et al., 2013).

Component	% wt.	Formula
Cellulose	27.56	$C_6H_{10}O_5$
Hemicellulose	15.37	$C_5H_8O_4$
Lignin	14.11	$C_{7.3}H_{13.9}O_{1.3}$
Carbohydrates	42.93	

**Table 2.** Carbohydrates profile (Conde-Mejía, et al., 2013).

Component	% wt.	Formula
Galactan	9.41	$C_6H_{10}O_5$
Manan	3.62	$C_6H_{10}O_5$
Arabinan	29.90	$C_5H_8O_4$

The pretreatment is carried out with dilute acid, due to the low sulfuric acid prices and the high yields of the treatment. Table 3 shows the reactions occurring in the pretreatment reactor, as well as their yields. In this reactor, 0.49 wt% of  $H_2SO_4$  is used at 160 °C and 1 atm. On the other hand, acid hydrolysis is carried out in a reactor at 220 °C and 1 atm. The hydrolysis reactions are presented in Table 4. As a next step, fermentation is carried

out using urea (CH<sub>4</sub>N<sub>2</sub>O) in a CH<sub>4</sub>N<sub>2</sub>O/sorghum residues mass ratio of 1:32.18, at 34°C and 1 atm. Fermentation reactions are presented in Table 5.

$H_2SO_4 + 2NH_3 \rightarrow N_2H_8SO_4$	1	Sulfuric Acid	(33)

Through these conversion steps, it is possible to obtain 15,482.61 kg/h of ethanol; however, the fermentation effluent still requires a purification process. The description of

the strategy used to simulate and design the whole process will be presented in the following section.

### 3. Methodology

Bibliographical research was carried out to determine the parameters required for the simulation of the solid components present in the biomass, *i.e.* cellulose, hemicellulose and lignin; these data has been obtained from the database of the National Renewable Energy Lab (1996). NRTL was used as the thermodynamic model, due to the complexity of the involved mixtures and the operating conditions (Conde-Mejía et al., 2013). Case study was simulated in the software Aspen Plus V.11 using RYield reactors. Process flow diagram is shown in Figure 1. In the purification section, C-1 is the distillation column for the separation of CO<sub>2</sub> as top product with a purity of 95% mass, with heavy components at the bottom. The bottoms stream is fed to a rectifier (C-2) with partial condenser, for the removal of by-products. This is followed by an extractive distillation column (C-3), using glycerol as extractant agent with a mass ratio of 1:1 with relation to the amount of ethanol in the stream. A column is used for the extraction of the ammonia present (C-4) in the stream, obtaining ethanol with a purity of 0.99. Finally, a column for the purification of glycerol (C-5) is required, aiming to a 99% recovery. Operating conditions are shown in Table 6.

**Figure 1:** Conventional process.

**Table 6.** Feed conditions for the columns of the conventional process.

Unit	Temperature (°C)	Pressure (bar)
C-1	34	1
C-2	100.46	1.33
C-3	57.51	1
C-4	41.73	1.01
C-5	170.76	1.70

Following the simulation of the conventional process, two schemes are proposed for the intensification of the ethanol distillation sequence, aiming to reduce the number of equipment and the thermal load. Figure 1 highlights the area to be intensified in red. Characteristics of the schemes are obtained by recursive simulation and sensitivity

analysis to determine the configuration with the lowest heat duty, while maintaining the specified ethanol purity.

#### 4. Results

The first scheme (I-1) consists of replacing C-5 by a side rectifier, intending to reduce the heat duty while reducing the number of units. Figure 2 shows the scheme. The ethanol-water mixture leaving the column C-2 is fed into the thermally coupled extractive column C-3. The design consists of 30 stages, where glycerol is feed at stage 2 and the BE<sub>2</sub> stream is fed at stage 10. Interconnecting flows are located at stage 29.

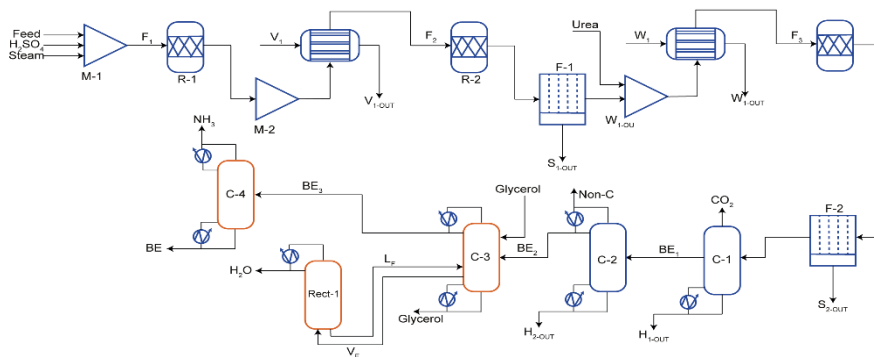

Figure 2: Intensified scheme 1 (I-1).

The second intensified scheme (I-2) involves replacing column C-4 by a side stream where ethanol is concentrated, as shown in Figure 3. In this scheme, the ammonia present in the mixture is obtained as top product in C-3. The column C-3 has 30 stages, where the glycerol enters in stage 10 and the stream BE<sub>2</sub> is fed at stage 25. The side stream is obtained from stage 4. Operating conditions of both schemes are shown in Table 7.

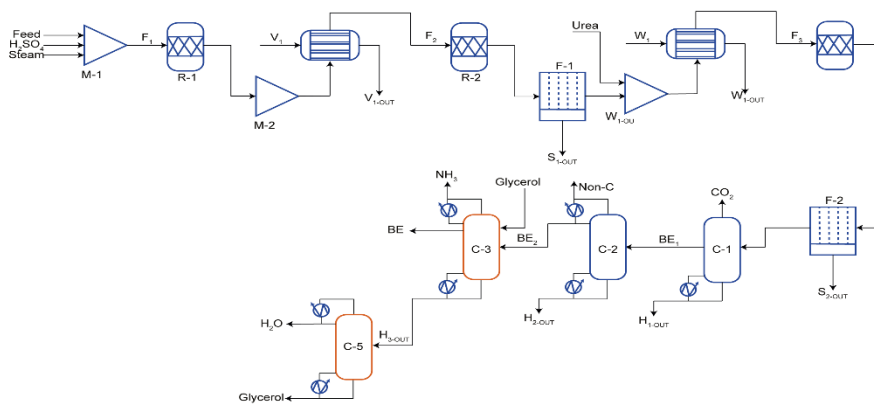

Figure 3: Intensified scheme 2 (I-2).

Table 7. Feed conditions to the columns of the intensified schemes.

Scheme, unit	Temperature (°C)	Pressure (bar)
I-1, C-4	42.01	1
I-2, C-5	192.02	2.18

Table 8 shows that I-1 consumes 2.36 % less energy than the conventional scheme. Meanwhile, I-2 has an energy reduction of 1.82 %. In both intensified schemes, 99% of the available bioethanol and 99% of the glycerol are recovered, being the heat duty in the reboilers the representative variable of these implementations.

**Table 8.** Comparison of schemes

Variable	Scheme	Conventional	I-1	I-2
Q (kW)		150,200.63	146,654.3	147,463.47
Bioethanol Recovery (kg/h)		14,472.67	14,435.15	14,431.04
Glycerol Recovery (kg/h)		14,540.74	14,542.23	14,536.96

## 5. Conclusions

The design of the conventional bioethanol production process from sorghum residues has been carried out. Two intensification alternatives have been proposed for the purification stage, with the goal of reducing the number of units and the thermal duty without compromising the recovery of the biofuel and the solvent. Scheme I-1 achieves a reduction of 3,546.33 kW as well as the incorporation of the glycerol recovery in a thermally coupled system. The recovery of bioethanol and glycerol is maintained at the target values of 99%. Finally, it is important to mention that the implementation of a rigorous optimization algorithm can achieve lower thermal duties with higher recoveries for the proposed schemes.

## Abstract

Carbon capture and storage is one option for reducing industrial CO<sub>2</sub> emissions. Ship CO<sub>2</sub> transport is gaining interest due to its potential competitive cost, lower risk, and higher flexibility with respect to pipelines. This work focusses on the cost of ship CO<sub>2</sub> transport chains in the European context. The objective is to develop an economic model of CO<sub>2</sub> transport via ship, including the chain stages: liquefaction, buffer storage, loading, ship, conditioning, and unloading. An optimisation model is proposed to determine the minimum transport cost from Southern European ports to permanent geological storage in the North Sea. The minimum cost is found around 26 €/t of CO<sub>2</sub> for a total transported CO<sub>2</sub> of 103 Mt/y, which may be cost-competitive with pipelines for long distance routes via large vessels (greater than 50 kt).

**Keywords:** Carbon capture and storage; CO<sub>2</sub> ship transport; chain logistics; optimisation; mixed integer linear programming.

## 1. Introduction

Energy and industry carbon dioxide (CO<sub>2</sub>) sources generate more than half of the annual worldwide CO<sub>2</sub> emissions (IEA, 2022). Carbon capture and storage (CCS) consists in a range of technologies that can separate the CO<sub>2</sub> from these concentrated sources, to avoid its release to the atmosphere (Bui et al., 2018). Then, the CO<sub>2</sub> is compressed, purified, transported, and permanently stored in geological sequestration sites (IPCC, 2005).

Europe has significant potential for CO<sub>2</sub> geological sequestration, especially in the offshore area of the North Sea (Holler and Biebahn, 2011) where different CCS research projects are in an advanced phase of implementation (e.g., Northern Lights, 2022), while storage basins identified in the Mediterranean area (e.g., in the Adriatic Sea and off the coasts of Greece) currently exhibit an early-stage degree of investigation and limited capacity (Donda et al., 2011; Koukouzas et al., 2021). Ship CO<sub>2</sub> transport could foster the development of CCS projects in European regions that are far from the North Sea (e.g., the Mediterranean), and such marine alternative to pipelines may be key due to its potentially competitive cost (Weihs et al., 2014), greater flexibility (Neele et al., 2014), and lower risk (Kjarstad et al., 2016).

A ship-based CO<sub>2</sub> transport chain is constituted by multiple stages: liquefaction, intermediate storage, naval shipping, conditioning, and unloading (IEAGHG, 2020); each stage comprises several options in terms of process parameters (e.g., the transport pressure, Roussanaly et al., 2021) and chain design alternatives (e.g., the unloading strategy, Roussanaly et al., 2013; 2014). This leads to the necessity of addressing such combinatorial complexity from a systems perspective. The objective of this work is to provide a detailed economic model of CO<sub>2</sub> transport by ship; the economic model is exploited for the development of a mixed integer linear programming (MILP)

optimisation framework, to minimise the total cost of a European ship-based CO<sub>2</sub> transport chain. This optimisation model is tested on a transport chain including the most significant industrial CO<sub>2</sub> emission points in southern Europe located in the vicinity of strategic CO<sub>2</sub> collection ports, and geological sequestration in the North Sea. Different unloading scenarios and carbon reduction targets are investigated. The resulting minimum unitary transport cost is 26 €/t, for transporting more than 103 Mt/y of CO<sub>2</sub>, which may be competitive with pipeline transport for very long-distance routes.

## 2. Modelling framework

A ship-based CO<sub>2</sub> transport chain is constituted by several sequential stages  $i = \{liq, stor, load, ship, cond, unload, pipe\}$  (Figure 1). This study assumes that the CO<sub>2</sub> arrives from the capture plant as a pressurised gas at pressure  $P_{in}$ . In the liquefaction plant (*liq*) the CO<sub>2</sub> is liquefied through compression at its transport pressure  $P_t$ . This work is based on a low  $P_t$  design (7 barg, -50°C), as low  $P_t$  benefits from lower costs with respect to medium  $P_t$ , if considering the whole transport chain (IEAGHG, 2020; Roussanaly et al., 2021). Then, the CO<sub>2</sub> is stored (*stor*) in buffer tanks to ensure continuous operation, to be subsequently loaded (*load*) onto ships (*ship*). This study considers vessel capacities  $C_{ship}$  [t] from 10 kt to 100 kt per ship. The transport stages downstream ship transport depend on the unloading strategy (*unload*): (S1: port-to-port) the CO<sub>2</sub> is unloaded onshore, stored in an unloading buffer storage facility, then sent to offshore sequestration via an offshore pipeline (*pipe*); (S2: port-to-FSI) the CO<sub>2</sub> is unloaded, through equipment onboard vessels, to a floating storage and injection (FSI) platform with intermediate storage tanks; and (S3: port-to-direct injection) the CO<sub>2</sub> is directly injected to the offshore basin without any unloading buffer storage hence, lower capital investment than S1 and S2, but higher risk in operation due to batch-wise unloading. The final stage is conditioning (*cond*), which increases the CO<sub>2</sub> pressure and temperature for injection.

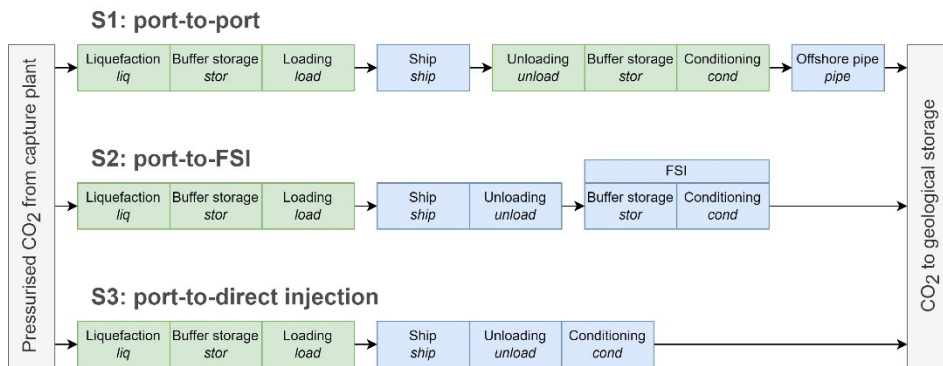

Figure 1. Schematic representation of a ship-based CO<sub>2</sub> transport chain.

## 3. Mathematical formulation

This study optimises a ship-based CO<sub>2</sub> transport chain at a European-scale. It is assumed that the CO<sub>2</sub> is captured from large-scale industrial emitters located in Southern Europe: 5 steel plants for a total emission of 26.5 Mt/y (17 % of sectorial European CO<sub>2</sub>), 25 refineries for a total of 43.8 Mt/y (33 % of sectorial European CO<sub>2</sub>), and 42 cement plants for a total of 33.1 Mt/y (23 % of sectorial European CO<sub>2</sub>) (d'Amore et al., 2021). The spatially-explicit features are described by means of nodes  $n$ , comprising ports and geological sequestration in the North Sea. The CO<sub>2</sub> collection ports are chosen among

large-scale harbours located in the vicinity of selected CO<sub>2</sub> emission points, and the port of Stavanger (Norway) is chosen as a CO<sub>2</sub>-to-storage hub for unloading S1 (Figure 2).

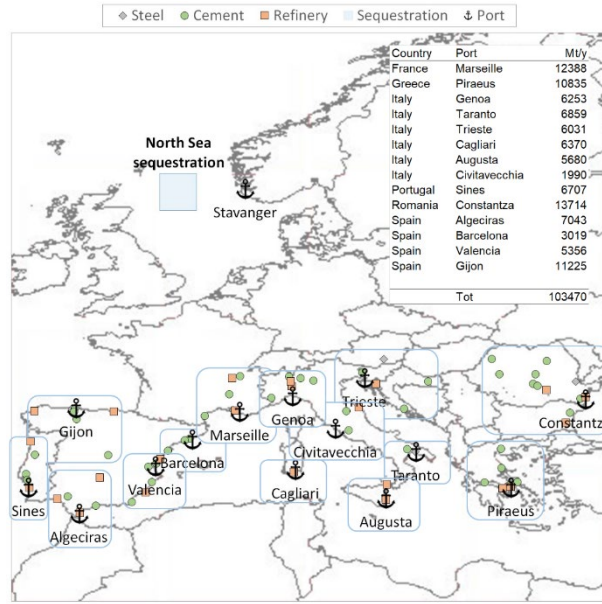

Figure 2. Geographic location of CO<sub>2</sub> emission clusters and collection ports, and yearly CO<sub>2</sub> emissions available at each port for ship transport.

The objective is to minimise the total annual cost  $TC$  [€/y] of the ship transport chain:

$$objective = \min(TC) \quad (1)$$

$$TC = \sum_i TC_i = \sum_i \left( \frac{CAPEX_i}{lifetime} + OPEX_i \right) \quad \forall i \quad (2)$$

being  $TC_i$  [€/y] given by the investment cost ( $CAPEX_i$  [€/y], scaled over a 20 years' *lifetime*) and operational expenditure ( $OPEX_i$  [€/y]) of the stages  $i$  of the transport chain. Costs of stages  $i$  are based on data from IEAGHG (2020) and the methodology is reported in d'Amore et al. (2023). The operational design input parameters are the inlet pressure  $P_{in}$ , the transport pressure  $P_t$ , the vessel capacity  $C_{ship,n,n'}$ , the number of ships  $N_{ship,n,n'}$ , the sailing distance  $d_{n,n'}$  [km], and the operational transit speed  $v_{ship}$  [km/h], to determine the amount of CO<sub>2</sub> transported  $\dot{Q}_{ship,n,n'}$  [t/y] through vessel  $ship$  from  $n$  to  $n'$ , which depends on  $C_{ship,n,n'}$ ,  $N_{ship,n,n'}$ , on the number of roundtrips per year  $N_{ship,n,n'}^{rtrip}$  [ $y^{-1}$ ], and on the maximum vessel filling  $\eta_{tank}$  (set at 95 %):

$$\dot{Q}_{ship,n,n'} = C_{ship,n,n'} \cdot N_{ship,n,n'} \cdot N_{ship,n,n'}^{rtrip} \cdot \eta_{tank} \quad \forall ship, n, n' \quad (3)$$

The total yearly amount of CO<sub>2</sub> transported via ships from  $n$  to  $n'$  is equal to:

$$\dot{Q}_{n,n'} = \sum_{ship} \dot{Q}_{ship,n,n'} \quad \forall n, n' \quad (4)$$

Considering the yearly amount of CO<sub>2</sub> transported  $\dot{Q}_n^{tr}$  [t/y] from port  $n$  and that sequestered  $\dot{Q}_n^{seq}$  [t/y] in node  $n$ , it is possible to impose the mass balance at each port  $n$ :

$$\dot{Q}_n^{tr} + \sum_{n'} \dot{Q}_{n',n} = \sum_{n'} \dot{Q}_{n,n'} + \dot{Q}_n^{seq} \quad \forall n \quad (5)$$

where  $\dot{Q}_n^{tr}$  is bounded by the amount of CO<sub>2</sub> available  $\dot{Q}_n^{capt}$  [t/y] at port  $n$  (Figure 2). The final aim is to sequester a fraction  $\alpha$  [%] of the total CO<sub>2</sub> from capture plants:

$$\sum_n \dot{Q}_n^{tr} = \alpha \cdot \sum_n \dot{Q}_n^{capt} \quad (6)$$

#### 4. Results

The MILP problem was optimised on a 3.0 GHz computer (32 GB RAM), by using GAMS software and CPLEX solver (optimality gap lower than 2 %). It emerges that liquefaction and ship represent about 10 % and 40 %, respectively, of the total investment, independently from the analysed unloading scenario. Other significant contributions to capital expenditures were found to be case-specific: namely offshore pipelines in S1 (up to 39 % of the total investment), FSI unit in the S2 option (comparable with the cost of ships), and conditioning in S3. Variable costs are dominated by ships operation and by liquefaction. Direct unloading (S3) emerges as the most cost-effective scenario. In fact, the results show that the unitary cost for transporting via ship 103 Mt/y of CO<sub>2</sub> is equal to: 26.1 €/t (S1), 26.4 €/t (S2), and 25.6 €/t (S3, though it could be an unfavourable design due to discontinuous injection) (Figure 3). As  $\alpha$  increases the selected ports and distances increase as well, so the unitary cost rises because: (i) more ports determine the installation of more onshore infrastructure; and (ii) more ships are needed as each journey takes longer. In fact, the optimal chain design avoids as much as possible (i.e., for low values of  $\alpha$ ) ports far from Stavanger, to minimise ship transport costs. For instance (Figure 4), the optimal chain for S3 involves the use of few but large ships from Spain and Portugal for  $\alpha=30$  %, while the network expands to more ships and ports located in Mediterranean France and Italy for  $\alpha=60$  %, and towards Greece and the Black Sea for  $\alpha=100$  %.

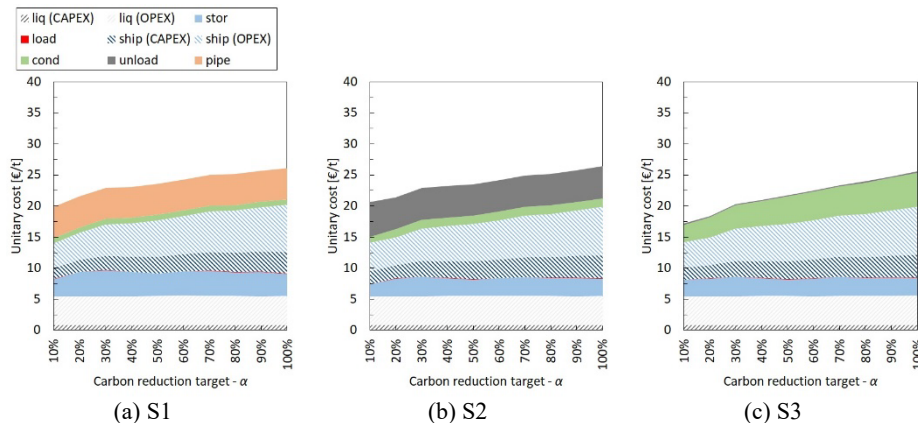

Figure 3. Unitary cost [€/t] depending on unloading scenario and carbon reduction target  $\alpha$ .

Ships investment cost depends on the choice in the vessel size: a decrease in the maximum size from 100 kt to 50 kt produces a +38 % increase in the investment for ships, though with limited effect on the overall cost of the transport chain (+10 %). Differently, deploying small vessels (10 kt) would double the chain cost. At the same time, optimised ship CO<sub>2</sub> transport through large-scale vessels (over 50 kt) is cost competitive with pipelines for long-distance routes, e.g., to connect Greece with the North Sea (Figure 5).

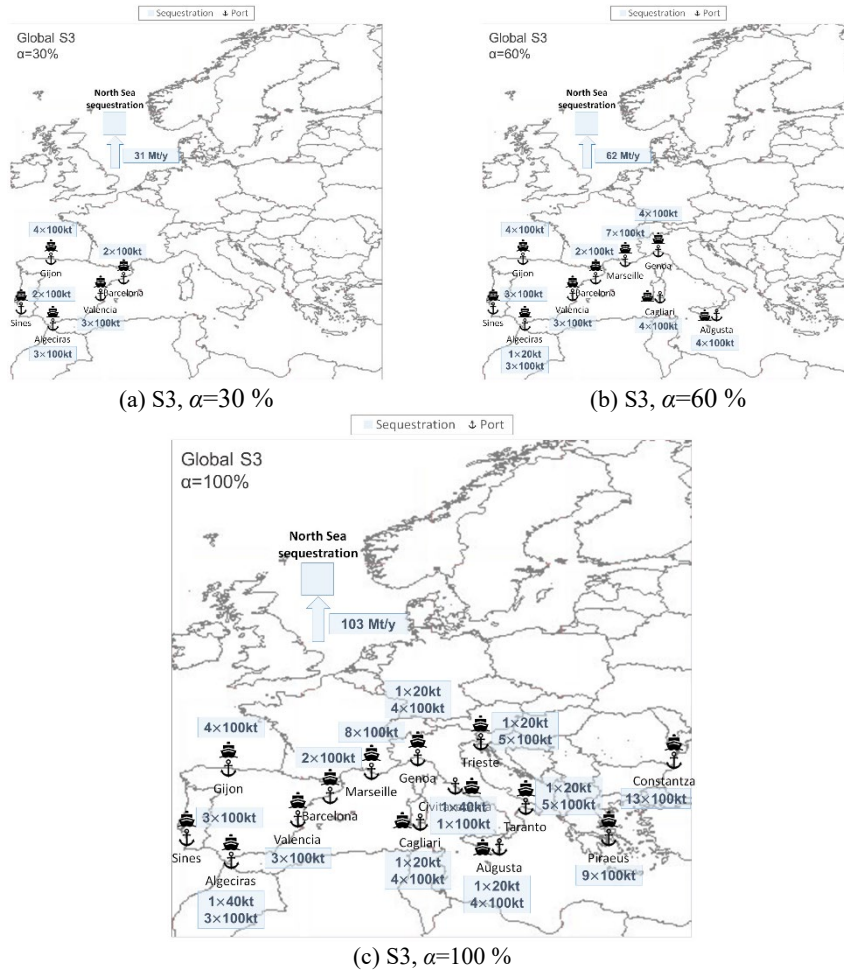

Figure 4. Optimal ship transport chains for S3 under increasing carbon reduction target  $\alpha$ .

Figure 5. Ship vs. pipeline long-distance CO<sub>2</sub> transport from Greece (Piraeus) to North Sea storage. Unitary transport costs for pipelines are computed from d'Amore et al. (2021).

## 5. Conclusions

This study proposed a modelling tool for the economic and logistic optimisation of ship CO<sub>2</sub> transport chains from large-scale Southern Europe emitters to the North Sea offshore

storage. Depending on the unloading strategy, we found that the minimum unitary cost for transporting via ship 103 Mt/y of CO<sub>2</sub> is equal to 26.1 €/t (port-to-port), 26.4 €/t (port-to-floating storage and injection), and 25.6 €/t (port-to-direct injection), though this latter does not comprise a buffer storage prior to injection and is designed as a batch-wise process. Importantly, it was demonstrated that an optimal design of ship transport via large-scale vessels (50-100 kt) can be cost competitive with pipeline transport for very long distance routes (e.g., from Greece to the North Sea), while the use of small ships (10 kt) results in twice the cost of pipelines.

## Abstract

Heat integration can reduce the consumption of external utilities in batch processes. Batch processes often include process steps with dynamic temperature progression, such as heating in vessels. During heat integration between those process steps, the temperature difference decreases over time. Exploiting the thermodynamic potential for heat integration can, therefore, lead to long process durations. Hence, there is a trade-off between the total cost of heat integration and the process duration. A method is missing to map this trade-off while considering the dynamic temperature progression. We introduce the DynHeat optimization method for heat exchanger network design in dynamic batch processes based on dynamic optimization. We apply the DynHeat method to a case study and perform a multi-objective optimization regarding the process duration and the total cost. We find that the DynHeat method can propose a suitable heat exchanger network design and operation mode for the regarded case study.

**Keywords:** Energy Efficiency, Heat Integration, Pinch Method, Logarithmic Mean Temperature Difference, Dynamic Processes

## 1. Introduction: Heat Integration in Batch Processes

Meeting thermal energy demands in industrial processes by external utilities is economically and environmentally expensive. Heat integration can reduce the consumption of external utilities by reusing waste heat. For heat integration, a heat exchanger network needs to be built. To obtain cost-optimal heat exchanger networks, the total cost should be considered, comprising operational costs for utility consumption and investment costs for heat-exchangers.

Common existing approaches for heat exchanger network design, based on the Pinch Method (Linnhoff and Flower, 1978) or the superstructure model by Yee and Grossmann (1990) and most of their extensions, reviewed by Klemeš and Kravanja (2013), assume stationary process streams. In practice, many industries work with instationary batch processes. In batch processes, the products are often cooled down or heated up in vessels, which leads to temperatures changing over time. When using heat integration in such processes, the transferred heat between two products decreases over time as the temperature difference between those products decreases. Thus, exploiting the full thermodynamic potential for heat integration between two products leads to long process durations. Hence, heat integration in dynamic batch processes causes a trade-off between process

duration and total cost for heat integration. This trade-off needs to be considered when designing heat exchanger networks for dynamic batch processes. A suitable method for heat exchanger network design for dynamic batch processes should, thus, represent the dynamic temperature profiles accurately to determine both the amount of integrated heat and the process duration.

In practice, the Pinch Method is commonly used for estimating the thermodynamic potential for heat integration of a process. The Pinch Method can be adapted to varying thermal demands by averaging the demands over time (time-average model) or by dividing the time horizon into several time slices (time-slice model) (Kemp and Lim, 2020). However, both approaches still assume temporary stationary process streams. Vaselenak et al. (1986) propose a heuristic method to handle different types of temperature progression of batch products in tanks in heat integration problems. Dowidat et al. (2014) extend the time-slice model to dynamic temperature progression by introducing additional time slices. However, both approaches do not explicitly design a heat exchanger network. In Dowidat et al. (2016), the authors introduce a match ranking matrix for the design of economically efficient heat exchanger networks. However, the approach relies on heuristic rules instead of considering the actual costs. Furthermore, in all the approaches mentioned above, the timing of the processes needs to be known in advance, and the trade-off between process duration and total costs, is not taken into account. Castro et al. (2015) introduce an optimization model for combined heat integration and scheduling in order to optimize the makespan of the process. However, in their approach, matches between process streams can be derived but no design optimization is included.

In conclusion, no optimization method exists that can represent the trade-off between process duration and total cost for thermal energy supply in heat integrated dynamic batch processes. In this contribution, we bridge this gap by developing the DynHeat optimization method for heat exchanger network design of dynamic batch processes while taking the trade-off between total cost and the process duration into account.

## 2. The DynHeat Method

The aim of the DynHeat method is to design a heat exchanger network for dynamic batch processes while taking the trade-off between total cost, comprising operational costs and investment costs, and the process duration into account. In the corresponding DynHeat optimization model, we model products that either need to be heated or cooled in vessels. The thermal demands can be provided by external utilities or via heat integration. For heat integration, there is the option of building an external heat exchanger between every two vessels. A scheme of the DynHeat model is shown in *Figure 1*.

To address the trade-off between cost and duration, we perform a multi-objective optimization with the total cost  $C^{total}$  of one process run as one objective function and the process duration  $\tau^{final}$  as the other objective function. The total cost  $C^{total}$  for one process run are composed of the investment cost for the heat exchangers and operational cost for external utility:

$$C^{total} = \left( \sum_{h \in H} (A_h^{cu} + A_h^{HI}) + \sum_{c \in C} (A_c^{hu} + A_c^{HI}) + \sum_{h \in H} \sum_{c \in C} A_{h,c}^{HE} \right) c^A + \sum_{h \in H} Q_h^{cu} c_h^{cu} + \sum_{c \in C} Q_c^{hu} c_c^{hu} \quad (1)$$

With the surface areas of the heat exchangers for hot utility ( $A_h^{cu}$ ), cold utility ( $A_c^{hu}$ ), hot product to heat transfer media (HTM) ( $A_h^{HI}$ ) and cold product to HTM ( $A_c^{HI}$ ) and the

external heat exchanger ( $A_{h,c}^{HE}$ ). The cost factor  $c^A$  refers to the specific investment costs for the heat exchanger surface areas scaled down to one process run. The operational costs comprise the amount of heat supplied by the cold utility  $Q_h^{cu}$  and hot utility  $Q_c^{hu}$  and the specific price for cold utility  $c^{cu}$  and hot utility  $c^{hu}$ .

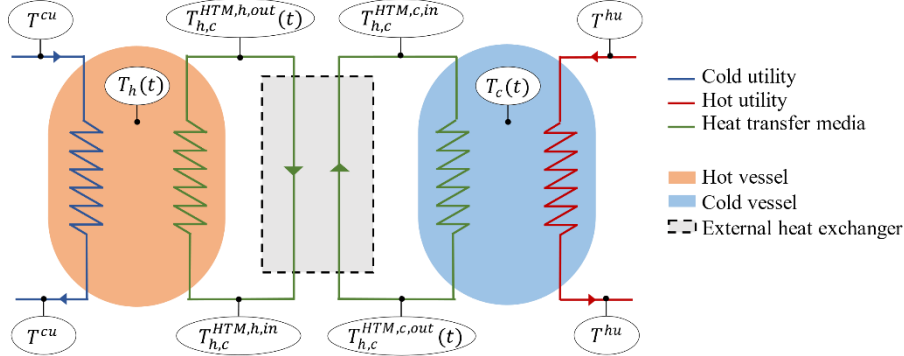

Figure 1: Exemplary scheme of the DynHeat model for one hot and one cold product. The left vessel (orange) contains the hot product of the temperature  $T_h(t)$  which can be cooled down by cold utility of the temperature  $T^{cu}$  (dark blue). Analogously the cold product in the right vessel (light blue) of the temperature  $T_c(t)$  can be heated up by hot utility (red) of the temperature  $T^{hu}$ . Both vessels can be connected by an external heat exchanger (grey) with heat transfer media (HTM) (green line). The temperature of the HTM at the inlet of the vessels  $T_{h,c}^{HTM,h,in}$  and  $T_{h,c}^{HTM,c,in}$ , is constant.

In the DynHeat model, we make the following assumptions: The vessels are perfectly mixed, and no heat losses occur. The external heat exchangers are counter-flow heat exchangers. All heat capacities, heat transfer coefficients, and the temperature of the utilities are constant. The HTM is not allowed to function as a storage, i.e., the total integrated heat flow must be transferred from the hot product to the cold product immediately, and the temperature of the HTM at the inlets of the vessels  $T_{h,c}^{HTM,c,in}$  and  $T_{h,c}^{HTM,h,in}$  is constant. The HTM between a hot and a cold product has the same heat capacity rate on both sides of the external heat exchanger, i.e., the temperature difference along the external heat exchanger  $(T_{h,c}^{HTM,h,in} - T_{h,c}^{HTM,h,in}(t)) = (T_{h,c}^{HTM,h,out}(t) - T_{h,c}^{HTM,c,in})$  is constant along the heat exchanger surface area.

In the following, we describe the DynHeat model in detail. The most important equations are given for hot products that need cooling. The equivalent equations for cold products that need heating can be derived analogously.

The temperature profile  $T_h(t)$  of a hot product  $h$  with the mass  $m_h$  and heat capacity  $c_{p,h}$  changes due to heat transferred to cold utility  $\dot{Q}_h^{cu}(t)$  or by heat integration with a cold product  $\dot{Q}_{h,c}^{HI}(t)$ :

$$\frac{dT_h(t)}{dt} = - \frac{(\sum_{c \in C} \dot{Q}_{h,c}^{HI}(t)) + \dot{Q}_h^{cu}(t)}{m_h \cdot c_{p,h}} \quad \forall h \in H \quad (2)$$

The heat flow from a hot product to the HTM  $\dot{Q}_{h,c}^{HI}(t)$  is defined by

$$\dot{Q}_{h,c}^{HI}(t) = \dot{m}_{h,c}^{HTM} c_p^{HTM} (T_{h,c}^{HTM,h,out}(t) - T_{h,c}^{HTM,h,in}) \quad \forall h \in H, \forall c \in C \quad (3)$$

, where  $\dot{m}_{h,c}^{HTM}$  is the given mass flow of the HTM between hot vessel  $h$  and cold vessel  $c$  and  $c_p^{HTM}$  is the given constant heat capacity of the HTM.

The temperature of the HTM at the outlet of the hot vessel  $T_{h,c}^{HTM,h,out}(t)$  is defined by

the temperature progression along the heat exchanger between the hot product and the HTM (Glück, 2017):

$$T_{h,c}^{HTM,h,out}(t) = T_{h,c}^{HTM,h,in}(t) \cdot e^{-\frac{k A_{h,c}^{HTM,h}}{\dot{m}_{h,c}^{HTM} c_p^{HTM}}} + T_h(t) \cdot \left(1 - e^{-\frac{k A_{h,c}^{HTM,h}}{\dot{m}_{h,c}^{HTM} c_p^{HTM}}}\right) \quad \forall h \in H, \forall c \in C \quad (4)$$

, where  $A_{h,c}^{HTM,h}$  is the surface area of the heat exchanger between the hot product and the HTM, and  $k$  is the constant heat transfer coefficient of the heat exchanger.

Finally, the required surface area of the external heat exchanger  $A_{h,c}^{HE}$  can be derived by the transferred heat and the temperatures of the heat transfer medium by

$$\dot{Q}_{h,c}^{HI}(t) \geq k A_{h,c}^{HE} \Delta T_{h,c}^{HTM}(t) \quad \forall h \in H, \forall c \in C \quad (5)$$

, where the temperature difference  $\Delta T_{h,c}^{HTM}(t)$  describes the temperature difference in the external heat exchanger. As in Verheyen and Zhang (2006), we assume that the biggest surface area needed at any time is installed and that all other operation modes can be realized by bypassing a part of the streams. The heat exchanger surface area for utility supply can be derived analogously. We assume a sequential process, meaning that external utilities are only used after heat integration is complete. Logical big-M constraints denote the beginning and end of utility supply and heat integration.

To solve the resulting dynamic-algebraic optimization problem, we discretize the time by orthogonal collocation on finite elements using `pyomo.dae` (Nicholson et al., 2018). Through the collocation, the discretized problem is a fully algebraic mixed-integer nonlinear optimization problem (MINLP) (Biegler, 2010).

### 3. Application to a Case Study

We apply the DynHeat method to a case study with one hot and one cold product. We adapt our process parameters to a milk pasteurization process, where fresh milk is first heated to a certain temperature and, afterwards, is cooled down to its final storing temperature. We assume that the heating of one batch and the cooling of another batch take place simultaneously. We adapt the process parameters from a case study in Fellows (2017).

We compute the case study on an Intel(R) Xeon(R) CPU E5-1660 v4 with 3.30GHz running on Microsoft Windows Server 2016 Standard with kernel version 10.0.14393. We use python 3.7 as a modeling language. As a solver, we use baron version 20.4.14 (Kılınç and Sahinidis, 2018). We apply eight threads. The relative gap is set to 1E-8. For the collocation method, we choose seven finite elements and 3 collocation points per element. We set a limit of 1000 *sec* to the time horizon to facilitate the solution of the problem.

With the DynHeat model, we perform a multi-objective optimization of the given case study, minimizing the process duration and the total cost of one process run. Figure 2 (left) shows the resulting Pareto front for the selected case study. The Pareto front visualizes the trade-off between the total cost for one process run and the process duration.

In the left anchor point, the total cost is minimal. Heat integration takes place as long as possible, such that the smallest possible amount of utility is used. However, thereby the maximal allowed time horizon of 1000 *sec* is required. In contrast, the right anchor point shows the results for minimal process duration. For minimal process duration, the thermal demands are covered by utility only. By the increased use of external utility, the total cost increase by almost 60% compared to the minimal total cost. Accordingly, heat integration can significantly reduce the total cost in the regarded case study.

Furthermore, there is one solution point between the two anchor points, representing a compromise between process duration and total cost. Figure 2 (right) shows the temperature profiles and the heat flows for the compromise solution. The heat integration is stopped before the temperature of the hot and the cold product reach the same level. Instead, a temperature difference of 19.02 K remains and utility is used to cover the remaining demands. This compromise increases the total cost only slightly, while reducing the process duration by almost 600 sec compared to the left anchor point.

All in all, the Pareto front shows that heat integration can reduce the total cost significantly in the regarded case study. However, heat integration extends the process duration notably. Given this trade-off, the DynHeat method also offers solutions with a finite process duration that still significantly benefit from heat integration.

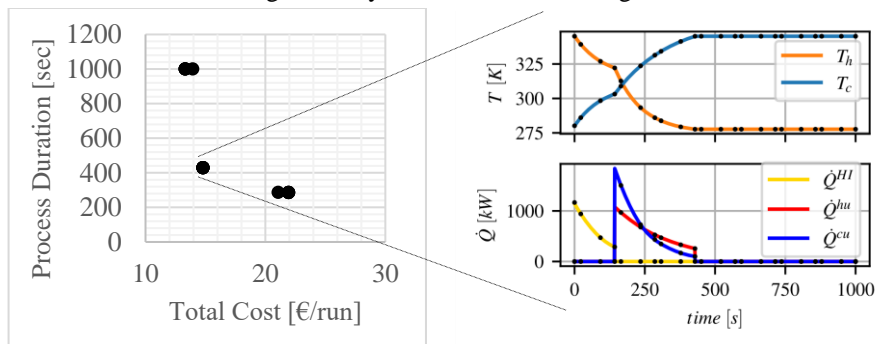

Figure 2: Left: Resulting Pareto front of the DynHeat method for the selected case study. Right: Process operation for one middle point on the Pareto front. The upper diagram shows the temperature progression of the hot product  $T_h(t)$  (orange) and the cold product  $T_c(t)$  (blue) over time. The lower diagram shows the corresponding heat flows (heat integration  $\dot{Q}_{h,c}^{HI}(t)$  (yellow), cold utility  $\dot{Q}_h^{cu}(t)$  (blue) and hot utility  $\dot{Q}_c^{hu}(t)$  (red)).

While the orthogonal collocation in the DynHeat method allows for a more accurate representation of the dynamic temperature profiles than existing approaches, it still leads to some discretization errors. The dynamic profiles are not represented exactly but approximated by polynomials. In our case, the DynHeat method leads to a discretization error concerning the integrated heat of 1.1 %. Thus, we conclude that the chosen settings are sufficient for accurate representation of the temperature profiles. Furthermore, due to the discretization, the process can only switch from heat integration to utility supply, and also finish the utility supply, at the boundaries of a finite element of the discretized time horizon. Consequently, the obtained solutions highly depend on the number of finite elements. The discretization, thus, restricts the solution space, but all solutions of the discretized problem are feasible to the original problem.

With the chosen settings, we find that the DynHeat model does not terminate to global optimality within the allowed computing time of 3000 sec for all points on the pareto front. Thus, further research on the model complexity and solvability needs to be done. However, the results show that the DynHeat model can propose reasonable solutions for heat integration in batch processes while considering dynamic temperature changes.

#### 4. Conclusion

In this contribution, we introduce the DynHeat method for heat exchanger network design in dynamic batch processes. We model the temperature dynamics of the batch process and discretize the problem by orthogonal collocation to a fully algebraic MINLP. To the

best of our knowledge, the DynHeat method is the first optimization method that meets the trade-off between process duration and total cost for heat integration in dynamic batch processes while taking design decisions for heat exchangers into account. We find that the DynHeat method enables us to find solutions that offer a compromise between total cost and process duration.
