minimum and maximum range of practical operating conditions. Then, we simulate the process in COMSOL to get cyclic steady state (CSS) and obtain purity, recovery and productivity of propylene and propane for several combinations of the variables well distributed within the chosen range. Then, we train our neuro-fuzzy model using 33 points of synthesized data. Neuro-fuzzy model is generated from a hybrid intelligent system that combines artificial neural network (ANN) and fuzzy logic using the human-inspired reasoning style of fuzzy systems (Amin et al., 2010). In this method, a layer of hidden neurons corresponds to the task of a fuzzy inference system. Jang (1993) implemented Takagi-Sugeno fuzzy rules by adaptive network-based fuzzy inference system (ANFIS). Finally, we use genetic algorithm (GA) method and our trained ANFIS structure to optimize our PSA process. The objective function that we use in this work is:

$$\max \; Productivity_{C_3H_6} - \lambda_1 \left[max(purity_{C_3H_6} - 99.0)^2 \right] - \lambda_2 \left[max(purity_{C_3H_8} - 90.0)^2 \right]$$

where productivity (mol.kg^{-1}.hr^{-1}) is amount of gas products per hour and weight of adsorbent in the PSA process, λ_1 and λ_2 are chosen as 50 and 40, respectively.

4. Optimization Results

We use ANFIS and ANN methods to model our PSA process. We check and compare the obtained results from the two models with simulation results from COMSOL. The mean square errors (MSE) of the performance of proposed PSA process for ANFIS and ANN are 2% and 10%, respectively. It seems that predictions from ANFIS are closer to COMSOL results than ANN. Therefore, we use ANFIS prediction results as the objective of our optimization. Using trained ANFIS model and GA searching method, we obtain 98.5% purity and 0.36 productivity (mol.kg^{-1}.hr^{-1}) for propylene and 90.46% purity for propane. The purity, recovery and productivity calculated by COMSOL using the optimum operating parameters for propylene are 97.6%, 92.1% and 0.31 (mol.kg^{-1}.hr^{-1}), respectively and for propane are 91.2%, 95.3% and 0.34 (mol.kg^{-1}.hr^{-1}), respectively.

In Table 2, we compare the performance of our proposed PSA process using SiCHA with the other results available in the literature for other adsorbents. We can see that our results is as good as those using 4A zeolite studied by Grande and Rodrigues (2005), where the kinetic selectivity was 811 compared to 26 in SiCHA at 353K. In 4A zeolite the propylene to propane Henry's constant and micropore diffusivity ratios are 45.3 and 321, respectively. In contract, these ratios in SiCHA are 0.36 and 5014, respectively (Grande and Rodrigues, 2005; Olson et al., 2004). Moreover, our proposed PSA process is 4-step however, Grande and Rodrigues (2005) used 5-step PSA process. Therefore, the energy consumption and cost of their process could be higher.

It may be argued that the reported literature results are not optimized and are likely to improve further. It nevertheless raises the following two important issues related to adsorbent screening for a given separation application: i) Is ideal selectivity *(= Henry's constant ratio * (diffusivity ratio)$^{0.5}$)*, calculated using uncoupled limiting equilibrium and kinetic parameters, adequate for ranking adsorbents? ii) Is it appropriate to report performance of an adsorbent without optimizing the process?

Majumdar et al. (2011) have discussed the limitation of the ideal selectivity to represent the separation factor of an adsorbent and shown that time dependent effective selectivity taking into account equilibria and diffusional interactions should be calculated for

assessing the potential of an adsorbent. We agree that the later is a better indicator than the former, but suggest that full optimization of the process is the most unambiguous way to assess an adsorbent. In this regard, our optimization approach discussed in this article provides the necessary speed and efficiency that was preventing the implementation of this route as a routine procedure.

Table 2. Purity and recovery of propylene from different adsorbents for an equimolar feed of propylene/propane.

Adsorbent	PSA process	%Purity	%Recovery
4A (Grande and Rodrigues, 2005)	5-step	99	84
SiCHA (This work)	4-step	98	92
AgNO3-SiO2 (Rege and Yang, 2002)	4-step	98	71
AlPO4-14 (Rege and Yang, 2002)	4-step	98	63
13X (F.A. Da Silva and Rodrigues 2001)	5-step	98	19

5. Conclusion

In this study, we propose the 4-step PSA process using SiCHA for propylene/propane separation. We used micropore model with concentration-dependence diffusivity to simulate the PSA process. Moreover, to realize that the proposed PSA process can produce pure propylene and propane we optimize the process using GA method. To speed up the optimization, we use ANFIS model as a black box instead of COMSOL simulation model. The objective of this optimization was to reach 99% pure propylene and 90% pure propane. This optimization could improve by minimizing the energy consumption of the PSA process in the future. Moreover, our proposed model can complement the existing and future experimental studies considerably. The resulting knowledge can then guide the design of better PSA cycles for enhancing the purity and recovery of products with lower energy consumption.

Rigorous Generation and Model-Based Selection of Future Biofuel Candidates

Manuel Hechinger, Manuel Dahmen, Juan J. Victoria Villeda, Wolfgang Marquardt

AVT – Aachener Verfahrenstechnik, Process Systems Engineering, RWTH Aachen University, 52064 Aachen, Germany

Abstract

Future liquid energy carriers should not only be synthesized sustainably from biomass, but they should also exhibit optimal properties for their application in future combustion engines. Due to the large amount of potential organic molecules, the identification of most promising fuel candidates in the entire molecular search space can only be realized by a model-supported approach. To this end, a novel fuel design framework is presented which combines a rigorous generation of molecular structures with a stepwise reduction to a set of promising candidates based on fuel-relevant properties. Predictive quantitative structure-property relations (QSPR) are employed to assess molecular structures in order to reduce necessary experiments to high potential fuel candidates. Although some of the property prediction models employed are still of limited predictive quality, the feasibility of the proposed approach is successfully shown for gasoline fuels. In particular, a significant reduction of the space of candidate fuel molecules is achieved, thus demonstrating the potential of the novel framework.

Keywords: biofuel, QSPR, property modeling, structure generation, CAMD.

1. Motivation for a model-based fuel design framework

The inevitable future depletion of fossil resources requires the premature identification of alternative value chains which are based on the renewable carbon source of biomass [1]. While often considered as a burden, this raw material shift rather represents a unique opportunity to tailor novel value chains towards pre-defined products exhibiting ideal properties with respect to their application. Identifying suitable products is thus a fundamental prerequisite for realizing optimal future value chains, and biofuels play a major role in this context. They have to replace common fossil fuels exhibiting given, but not necessarily optimal properties due to fixed crude oil composition. In contrast, the new raw material basis allows the identification of innovative, tailored biofuel structures showing superior properties with respect to both, sustainable producibility as well as clean combustion in future engines. And while these requirements ask for an integrated product and process design [2], the present contribution just focuses on product design aspects.

Obviously, the large amount of possible molecular structures renders a solely experimental search for ideal fuel compounds infeasible. This necessitates a model-supported product design approach, which could be based on one of the existing promising frameworks for chemical product design [3,4]. However, the identification of most appropriate biofuels represents a more specific product design problem which calls for a tailored framework regarding problem formulation and solution strategy. Such a frame-

work should exploit both, the well-defined atomic composition of the raw material biomass and property constraints emanating from combustion engine requirements.
The present contribution proposes a novel, fuel-specific product design framework which combines a comprehensive generation of molecular structures with critically assessed, predictive fuel property models for a stepwise reduction of the initially large molecular space towards a selection of most promising biofuel candidates. By directing experimental effort to these high-potential structures, this approach allows a targeted identification of future liquid energy carriers.

2. Fuel requirements and proposed fuel design process

The goal of a model-based fuel design is the identification of molecules with promising characteristics in all relevant aspects of a fuels' life cycle. Thus, a novel fuel should be efficiently synthesizable from biomass resources and chemically stable under ambient conditions to allow for storage and safe handling. Moreover, in order to be applicable in combustion engines, various property constraints stemming from injection, mixture formation and combustion have to be fulfilled. Focusing on these engine relevant aspects in a first step, thermophysical properties such as normal boiling point, heat of vaporization and liquid density as well as surface tension and liquid viscosity are of primary interest. Moreover the combustion kinetic characteristics like laminar burning velocity for gasoline and ignition delay time for diesel fuels have to be considered.
Model-based identification of promising fuels requires an assessment of all possible molecular structures with respect to the aforementioned properties, which results in two main questions:

1. What are all possible molecular structures and how can they be determined?
2. Which modeling approach should be used to reliably determine the fuel relevant properties of all candidates?

While the first question asks for a rigorous molecular structure generator, the second question concerns the development of predictive property models which are of reasonable accuracy over the diverse molecular range of generated structures. Since some of the fuel-relevant properties can be estimated easier from molecular structure than others, a proper cascading of "property filters" for a stepwise reduction of the initially large set of candidates becomes important. This insight leads to the staged approach illustrated in Figure 1.

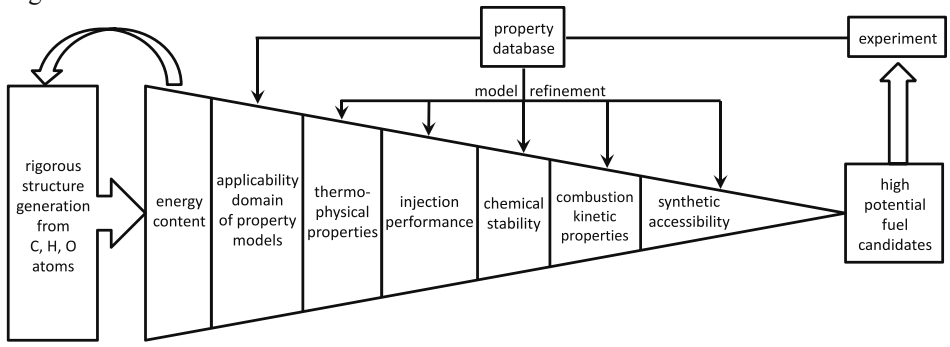

Figure 1: Workflow of model-based biofuel identification. Starting from rigorous structure generation, the molecular space is gradually decreased towards high potential fuel candidates by a combination of models and experiments.

The fuel design process starts with the rigorous generation of all possible molecular structures, where only organic molecules containing carbon (C), oxygen (O) and hydrogen (H) atoms are considered to reflect the major atomic constituents of the biomass feedstock. To this end, the software package Molgen [5] is employed, which combines valence rules with graph theory to identify all mathematically possible atomic arrangements of a given sum formula. Moreover, Molgen allows for various types of constraints on the generated structures, such as number and types of atoms and bonds.

The large number of generated fuel candidates is subsequently reduced in a stepwise fashion. In each step, a certain fuel-relevant property is predicted for all candidates first. Then, structures with a property value outside the desired range are removed from further consideration. The approach is thus similar to the one proposed by Gani et al. [3,4], who also apply property constraints to identify promising chemical compounds. However, while Gani et al. generate and assess structures based on a group contribution (GC) framework [4], the atom-based generation allows a comprehensive enumeration of all instances in the molecular space. In contrast, molecules generated from groups, i.e. molecular fragments, are constrained by the sub-graphs of each group as well as the limited number of available groups. However, the higher flexibility of an atom-based generation might lead to unrealistic structures if insufficient or inappropriate generation constraints are considered. This potential drawback is largely circumvented when only groups derived from existing molecules are employed.

This also implies that GC methods are unfavorable to assess molecules that were generated on an atomic level, as just few known groups are likely to occur in the generated molecular space. Although methods for estimating new GC parameters have been proposed [6], their general applicability is still under debate [7]. Thus, for an assessment of the molecular structures generated from atoms, quantitative structure-property relations (QSPR) [8] represent a suitable alternative as they employ molecular descriptors which can be evaluated for any molecular graph.

The cascading of the QSPR in Figure 1 is chosen such that each QSPR has the largest applicability range or confidence region possible at the respective level of structure refinement. That is, a reliable property prediction for the entire range of the very diverse molecular space of generated structures is generally not feasible, since the QSPR models are developed on the basis of available measurement data which capture only a confined molecular subspace. The resulting neglect of promising candidates due to a limited model applicability domain has to be accepted to ensure a reliable identification of final fuel candidates (see Figure 1). Obviously, their estimated properties have to be experimentally validated afterwards, and the obtained measurement data adds to the available property database, which in turn allows refining the property models and extending their applicability domains (see Figure 1). This allows gradually increasing the reliable search space, such that also the initially neglected, but promising structures will be identified correctly, however, at much lower experimental effort.

The first refinement step shown in Figure 1 is based on energy content, which is measured by the lower heating value H_u. To this end, a QSPR based on the measurement data of all 939 organic compounds in the DIPPR property database [9] showing an experimental error of less than 5% has been developed. This model explains the heating value by only two molecular descriptors with high accuracy (R^2 = 0.9994); its extrapolative capabilities have been critically assessed by cross validation. Since both descriptors can be deduced from the molecular graph, the QSPR can be translated into a constraint for the structure generation in Molgen. This way, a property-constrained generation of candidates exhibiting a minimal desired energy content is achieved (see Figure 1).

For the generated structures, property-specific applicability domains are determined by evaluating the structures' distances to database training compounds in the molecular space spanned by latent variables. These latent variables are extracted from the original descriptor database by partial least squares analysis in order to model the property under investigation. The number of significant latent variables is determined by cross-validation, and the models' predictive capabilities are further assessed by evaluating their performance on an external validation set of compounds not used during model development. Only the properties of those generated molecules sufficiently "close" to the training compounds are considered to be reliably predicted. For these molecular structures, the thermophysical properties of interest are subsequently evaluated by a combination of the empirical QSPR approach with the Peng-Robinson cubic equation of state (EoS) [10]. First, the inputs to the EoS, i.e., the critical temperature and pressure as well as the acentric factor, are estimated by QSPRs. The EoS is then evaluated for the vapor-liquid equilibrium properties. Rather than directly using QSPRs, the so-called hybrid model improves the models' physical foundation, which in turn enhances its extrapolative capabilities towards novel structures.

The next refinement step in Figure 1 comprises injection-related properties, in particular viscosity, which, however, cannot yet be predicted by means of QSPR with sufficient accuracy. The same applies for chemical stability, which cannot be predicted reliably to the authors' knowledge. While standard heat of formation has been sometimes used to predict chemical stability, our own investigations have shown that this indicator is often misguiding. More rigorous thermodynamic assessment criteria based on Gibbs free energy could provide better estimations. Moreover, stability is not only thermodynamically determined, but also influenced by combustion kinetics, which still suffer from insufficient measurement data. While a first QSPR for the laminar burning velocity has been proposed previously [11], the applicability range of those models still needs to be considerably extended in order to be included in the proposed framework. Here, optimal design of experiment techniques should be applied to achieve broad model applicability at minimum experimental cost. Finally, the synthetic accessibility [12] of the remaining structures from biomass feedstock is assessed as a first indicator of their producibility. However, the framework presented in [12] has been developed for large pharmaceutical molecules; hence, the applicability to smaller fuel molecules still has to be investigated.

Despite the fact that the latter four refinement criteria of the fuel design framework in Figure 1 still require further improvement, a first application of the framework to gasoline fuels considering only the first three criteria is presented in the following to explore the feasibility of the suggested fuel design framework.

3. Application of the fuel design framework to the gasoline fuel range

Due to the combustion process of spark ignited gasoline engines, typical gasoline fuels comprise up to eight carbon atoms. Hence, organic structures in this carbon range with up to 30 wt% oxygen have been generated and refined with respect to heating value, normal boiling point and heat of evaporation as shown in Table 1. Both, oxygen content and thermophysical property constraints stem from engine requirements [13]. Table 1 shows that the molecular search space can be reduced by more than 99% compared to the unconstrained generation if only those structures are considered which exhibit a minimum heating value and do not contain both, unstable bonds (three- and four-membered carbon rings, oxygen-oxygen single bonds) and unfavorable bonds (triple bonds, carbon bound to four other carbons). The additional refinement based on model applicability domains and property constraints leaves a final set of 122 fuel candidates

only. Although around 57 % of the generated molecules lie outside the property models' applicability domains – thus highlighting the need for further guided experiments – the strong reduction of the initial molecular space clearly illustrates the potential of the proposed framework to identify most promising fuel candidates.

Table 1: Size of generated and refined organic molecular space, C_1 - C_8

	constraint	C_1-C_6	C_7	C_8	search space
unconstrained generation	-	340,088	28,402,888	153,690,076	100.00 %
constrained generation	H_u > 30 MJ/kg[1]	2,262	15,083	172,528	0.104 %
normal boiling point	< 100 °C	492	615	533	0.000899 %
heat of vaporization	< 60 kJ/kg air[2]	13	27	82	0.000067 %

[1] and exclusion of structures with unfavorable/unstable bonds; [2] at stoichiometric fuel to air ratio

4. Conclusions

A novel framework for the identification of future biofuels is presented, which combines rigorous structure generation on an atomic level with a stepwise reduction of the fuel candidates by prediction and assessment of fuel-relevant properties. To this end, quantitative structure-property relations (QSPR) are developed and their validity range is critically evaluated before fuel properties are predicted. While the majority of building blocks for the complete framework already exist, reliable prediction methods of some remaining fuel properties still have to be established and refined in ongoing work. However, the successful demonstration of the framework in this work clearly illustrates its potential for a reliable identification of future liquid energy carriers.

Abstract

This work presents a mixed integer nonlinear programming method for the design of energy efficient multistage adsorption dryers within product temperature and moisture constraints. The aim is to find the adsorbent type and properties that minimize specific energy consumption. The results show that the adsorbents chosen in each stage have highest sorption capacities for corresponding drying air conditions. Heat requirements are matched so, zero utility energy is spent regenerating the second stage adsorbent. The adsorbent flow speeds are such that the first stage is optimized for dehumidification and the second for heat recovery. Overall, the optimal system reduces specific energy consumption by about 64% compared to a conventional system at the same drying temperature. Also, drying capacity is improved which permits the use of smaller dryers.

Keywords: Multistage adsorption drying, Mixed integer nonlinear programing, Energy

1. Introduction

Drying is a major industrial energy consumer. Hence, reduction of drying energy consumption remains important in view of the cost and environmental implications. One major method of reducing energy consumption in convective drying is heat recovery. Apart from using heat exchangers and heat pumps, heat recovery can be accomplished by multistage and adsorption drying. In multistage drying, sensible and latent heat in the exhaust air from the earlier drying stages is regained by reusing the air for drying in latter stages. Reheating is necessary to regain drying capacity lost due to moisture uptake. In adsorption drying, moisture is removed from ambient air so latent heat is recovered while sensible heat is gained by adsorption heat release. The high drying capacity air so derived is used for drying. When optimized (for one-stage zeolite systems without exchanger heat recovery), energy consumption reduces by about 20% (Atuonwu et al., 2011). Multistage adsorption drying combines the advantages of both methods as the sensible and latent heat of both inlet and exhaust air of the drying stages are recovered by passing them through adsorbent stages with no need for reheating. Previous studies on this type of drying have focused on the use of a single adsorbent in all stages. To extend the energy efficiency it is important to explore several adsorbent options. In this work, an energy optimization problem is formulated in which adsorbent choice per-stage is a superstructure of alternatives. Specific adsorbents are not defined but the discrete variable of adsorbent choice is specified by isotherm type. Properties like sorption capacity, sorption heat and other isotherm model parameters constitute continuous optimization variables with constraints specified to avoid situations where some parameters become unrealistically high or low (compared to literature values).

2. Process description, superstructure modeling and optimization

In the adsorption drying process (Fig. 1) an adsorbent-coated rotary wheel with adsorption and regeneration sections (A and R respectively) is an add-on to the basic conventional dryer. Ambient air is dehumidified in the adsorber and used in the dryer for drying the wet product. The dehumidification is accompanied by the release of adsorption heat. The dryer exhaust air is passed through a second-stage adsorber and reused in drying. The product flow direction could be co- or counter-current to the airflow direction and the number of stages can be greater than two. Meanwhile, for each stage, there is regeneration of spent adsorbent by hot air. The mass and energy balances describing each stage of the system are available in Atuonwu et al. (2011). In that work, zeolite was considered in a one-stage system and so, the adsorption isotherm and all other constitutive equations were based on zeolite. In this work, all adsorbent constitutive equations are lumped into a superstructure model derived based on a general adsorbent isotherm structure. The dehumidification performance, ease of regeneration, sorption heat and other adsorbent properties that determine adsorption dryer energy performance depend on the nature of the adsorbent-water vapour sorption isotherm. For practical purposes, these isotherms, regardless of the particular adsorbent involved have been classified into types 1 to 5 (Brunauer, et al., 1940). The type 1 isotherm is largely described by the Langmuir equation while the types 2 and 3 are well-fitted by the BET equation (Thibodeux, 1996). Similarly, the types 4 and 5 are well-described by the Dubinin-Astakhov equation (Stoeckli, 1998). Hence, in this work, all isotherms are categorized in three as shown in the superstructure (Fig. 2). Category 1 corresponds to type 1; category 2 to types 2 and 3; and category 3, to types 4 and 5.

Let $I=\{i:i=1...M\}$ and $J=\{j:j=1...N\}$ be the set of adsorbent categories i and drying stages, j, then, we formulate the energy consumption minimization problem as

$$\min Q_{in}(x_{ij}, y_{ij}) = \sum_{i=1}^{i=M}\sum_{j=1}^{j=N} y_{ij} F_{aRj}\left(C_{pa} + Y_{aRin\,j} C_{pv}\right)\left(T_{aRinij} - T_{aRout_{j-1}}\right)\ i \in I, j \in J, T_{aRout0} = T_{amb} \quad (1)$$

subject to constitutive, coupling equations (Atuonwu et al., 2011) and the constraints:

$$x_{ij} = \left[X_{01ij} \quad X_{02ij} \quad X_{03ij} \quad X_{04ij} \quad b_{0ij} \quad E_{ij} \quad F_{ij} \quad G_{ij} \quad H_{ij} \quad n_{ij}\right] \quad i \in I \quad j \in J \quad (2)$$

$$y_{ij} \in \{0,1\} \qquad i \in I \quad j \in J \quad (3)$$

$$X_{ads} = \left[X_{01} bP/1+bP \quad X_{02} Fw/\left[(1-w)(1+(F-1)w)\right] \quad X_{03}\exp(-A/G)^n + X_{04}\exp(-A/H)^n\right] \quad (4)$$

$$b = b_{0ij}\exp(-E_{ij}/RT_{ij}) \quad (5)$$

$$w = P/P_{sat} \quad (6)$$

$$A = RT\ln(P_{sat}/P) \quad (7)$$

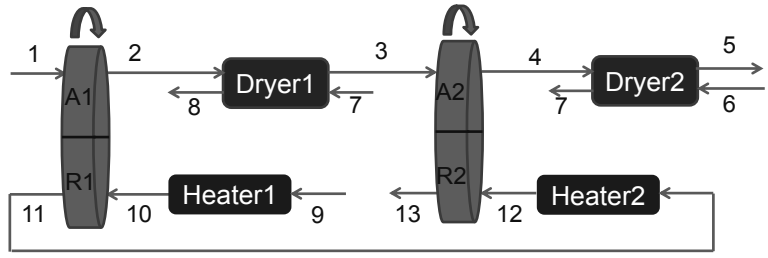

Fig. 1. Two-stage adsorption drying process

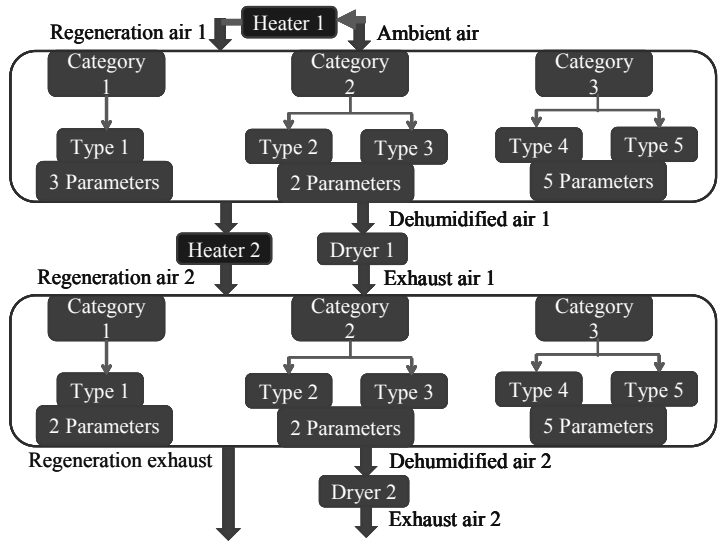

Fig. 2. Superstructure model of a two-stage adsorption drying process

$$H_{ads} = -RT^2\left(\partial \ln P/\partial T\right)_{X_{ads}\ \ constant} \tag{8}$$

$$\sum_{i=1}^{i=M} y_{ij} = 1 \qquad j \in J \tag{9}$$

$$L_j = \sum_{i=1}^{i=M} y_{ij} L_{ij} \qquad j \in J \tag{10}$$

$$Y_{outij} = Y_{inij} - \frac{F_{Sij}}{F_a}\left(X_{Soutij} - X_{Sinj}\right) \tag{11}$$

$$T_{outij} = \frac{F_{aij}\left(\left(C_{pa} + Y_{anij}C_{pv}\right)T_{ainij} + \left(\Delta H_v + H_{ads}\right)\left(Y_{ainij} - Y_{aoutij}\right)\right) + F_{Sij}\left(\left(C_{pSij} + X_{Sinij}C_{pw}\right)T_{Sinij}\right)}{F_{aij}\left(C_{pa} + Y_{aoutij}C_{pv}\right) + F_{Sij}\left(C_{pSij} + X_{Soutij}C_{pw}\right)} \tag{12}$$

The symbols are designated as follows: Q_{in} is the regeneration air heat input (kJ/s), C_p is specific heat capacity (kJ/kgK), x represents continuous optimization parameters of which X_{01}-X_{04} are sorption capacities, E-H, energy constants, n is the heterogeneity parameter, y, the adsorbent choices, Y, air absolute humidity (kg/kg), T, temperature (K), F, flowrates (kg/s), P is vapour pressure (Pa), w is water activity. X_{ads} is the equilibrium adsorbent loading vector (kg/kg), R, gas constant (J/molK), P_{sat}, saturation pressure (Pa), H_{ads}, the adsorption heat, ΔH_v, water latent heat of vaporization (kJ/kg) and L, is a general lumped variable for the air flow in and out of the sorption system (e.g. temperature, humidity). For the subscripts, *amb* represents the ambient, *in*, the inlet, *out*, the outlet, *w* for water, *a* for air, *R* for regenerator and *S* for solid (adsorbent or dried product). Equation (1) minimizes the total regeneration energy which approximates the net system energy input for low-temperature drying. Equation (2) contains the continuous optimization variables while (3) defines the discrete variables. (4) is a vector containing the three categories of equations defining the superstructure of sorption isotherms; (5), (6) & (7) are definitions of variables within (4); while (8) is the Claussius-Clapeyron equation which defines the adsorption heat which appears in the

energy balance (12). (9) ensures that only one adsorbent is chosen per-stage, (10) states that the state variable (temperature, humidity, loading, etc) of the air and solid outputs of each sorbent system is a binary-weighted sum of all the possibilities. (11) is the mass balance. (11) and (12) apply to both the adsorption and regeneration sections of the wheel. They also apply to the dryer except that the sorption heat term in the energy balance is negligible. The product is at a dry mass flowrate of 72kg/h, initial moisture content of 10kg water/kg dry matter. The outlet moisture content is constrained to be 0.05kg/kg while the product temperature is less than 50°C. For comparison, a 2-stage conventional dryer is also optimized. Here, the wheels in Fig. 1 are replaced by heaters that heat up the air to the same dryer inlet temperatures as the optimal adsorption dryer.

3. Results and Discussion

A sensitivity analysis shows that the optimal adsorbent choices depend strongly on the parameter (x) upper and lower bound constraints. The active sets are: $\{b_0, n\}$ for the lower bound and $\{X_{01}, X_{02}, X_{03}, X_{04}, E, F, G, H\}$ for the upper bound constraints. Thus, in choosing among adsorbents of known isotherm parameters for drying applications, the lower the values of $\{b_0, n\}$ and the higher the values of $\{X_{01}, X_{02}, X_{03}, X_{04}, E, F, G, H\}$, the more suitable the adsorbent. When the upper and lower bound constraints are set to within ±50% of typical values for adsorbents as reported in the literature (Atuonwu et al., 2011; Mihoubi and Bellagi, 2006; Moore and Serbezov, 2005), the optimal choice of adsorbents is as shown in Fig. 3. Ambient air dehumidification which occurs in the first stage requires a type 1 adsorbent (example, zeolite) while exhaust air dehumidification in the second uses a type 4 or 5 isotherm-based adsorbent (example, silica-gel). The following is observed: first, sorption capacity-vapour pressure matching. The adsorbent chosen for ambient air dehumidification has a higher sorption capacity at lower drying air vapour pressures while for the moister higher vapour pressure 1st stage dryer exhaust air, another adsorbent of higher sorption capacity is chosen. Second, there is heat requirement matching. The optimal operating conditions (Table 1) shows the required regeneration air temperature for the second stage adsorbent equals the first stage regenerator exhaust air temperature (streams 11 & 12). Thus, Heater2, Fig. 1 is redundant. Third, the flowrate (speed) of the second-stage adsorbent is 3701 kg/h which is much higher than that of the first stage which is returned as 2139 kg/h. This implies the second-stage wheel behaviour is optimized for dryer and regenerator exhaust heat recovery while the first stage is optimized for air dehumidification. Overall, these effects ensure a highly energy-efficient system that improves further with heat recovery.

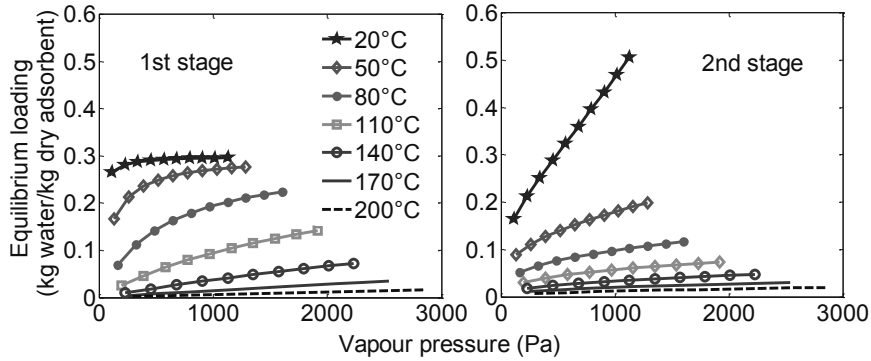

Fig. 3. Adsorbent-water vapour sorption isotherms for optimal adsorbent choices per stage showing type 1 in first stage and type 4 (or 5) in second stage

Table 1. Process variables for optimal adsorption dryer

No.	*Flow(kg/h)*	*Temp.(°C)*	*Humidity(kg/kg)*	*No.*	*Flow(kg/h)*	*Temp.(°C)*	*Humidity(kg/kg)*
1	54000	25	0.0100	8	72	46	0.0500
2	54000	46	0.0020	9	3794	25	0.0100
3	54000	24	0.0109	10	3794	400	0.0100
4	54000	34	0.0061	11	3794	229	0.1232
5	54000	23	0.0105	12	3794	229	0.1232
6	72	23	10.0000	13	3794	130	0.1918
7	72	34	6.6765				

Table 2. Process variables for conventional dryer

No.	*Flow(kg/h)*	*Temp.(°C)*	*Humidity(kg/kg)*	*No.*	*Flow(kg/h)*	*Temp.(°C)*	*Humidity(kg/kg)*
1	71067	10	0.0100	5	71067	28	0.0141
2	71067	46	0.0100	6	72	10	10.0000
3	71067	29	0.0108	7	72	29	3.2894
4	71067	36	0.0108	8	72	28	0.0500

The specific energy consumption of the system is 2040 kJ/kg of water evaporated. With heat recovery where stream 13 is used to preheat stream 9, it becomes 1565 kJ/kg. For a conventional two-stage dryer at the same drying air temperatures, the operating conditions when energy consumption is optimized are shown in Table 2. The drying capacity is much less and so, the required air flowrate is much higher (Compare stream 1, Tables 1 & 2). The energy required to heat this high air flow increases and the scope for heat recovery is very low as the exhaust air (stream 5) temperature is very close to ambient. The specific energy consumption is 4310 kJ/kg. In comparison therefore, the optimal adsorption drying system reduces energy consumption by about 64%.

4. Conclusion

Adsorbent property and operational optimization ensures matching of system needs with adsorbent material properties and operating conditions thus yielding significant energy savings. Improved drying capacity is observed. Based on the optimal adsorbent properties, the use of zeolite in the first stage and silica gel in the second is proposed.

Abstract

As protein drugs become increasing popular therapeutic approaches, formulations must be developed to ensure stability of the final drug product. Lyophilization, or freeze-drying, is an approach commonly used to produce stable protein drugs, yet protein aggregation may still occur in lyophilized formulations. Excipients in the formulation may be selected to reduce the propensity of a protein to aggregate through interaction with aggregation prone regions. In the following work, molecular docking simulations were used to predict the regions on a protein where different excipients were most likely to interact. Simulation results compared variably with experimental hydrogen/deuterium exchange experiments used to determine regions of protein-excipient interactions. The results were used to design formulations for lyophilized calmodulin (PID #1CLL). Sugar and surfactant pairs were selected that would maximize protection of different aggregation prone regions through direct interactions.

Keywords: protein aggregation, lyophilization, formulation design.

1. Introduction

Protein aggregation is an active problem in the development of protein drug formulations. Aggregation can occur either from unfolding of proteins leading to interaction or surface interactions between hydrophobic regions on proteins. Lyophilization, or freeze-drying, is used to improve stability but aggregation can still occur (Costantino*, et al.*, 1995). Stabilizing additives, or excipients, are often included in lyophilized formulations to reduce aggregation.

Nonionic surfactants have been shown to bind with weak affinity to proteins (McNally and Hastedt, 2008). Such binding could interact with hydrophobic regions on the protein and limit access to aggregation prone “hot spots”. Nonionic surfactants such as Tween 80 have been shown to decrease aggregation in lyophilized protein formulations (Kerwin, 2008). However, use of surfactants can cause difficulty during the lyophilization process due to the low glass transition temperatures exhibited by surfactants (McNally and Hastedt, 2008). A successful formulation using surfactants requires the presence of glass formers, such as sugars or polymers.

Sugars are widely used as protein stabilizers in lyophilized products. Sugars usually have high glass transition temperatures which lead to stable glass formation during freezing and subsequent drying. Sugar molecules have also been shown to exhibit site-specific effects on proteins during lyophilization through use of hydrogen-deuterium exchange mass spectroscopy (Li*, et al.*, 2008), indicating that interaction between sugars and proteins occur in the lyophilized state. Such interactions can be exploited to provide better coverage of aggregation prone "hot spots" on the protein.

By selecting excipients that interact preferably with aggregation prone regions, a lyophilized formulation can be developed to reduce aggregation. In this work, a sugar and surfactant pair is selected to optimally provide the most interaction with an aggregation prone region on the protein calmodulin (PID #1CLL). By choosing a formulation with maximal protein-excipient interactions, the potential for aggregation is reduced. While surfactants may interact more than sugars on a per molecule basis, a sugar was included to ensure that a stable glass could be formed.

2. Methods

2.1. Determination of Protein-Excipient Interactions

To predict the amino acids of calmodulin most likely to interact with a given excipient, molecular docking simulations were performed using Autodock (http://autodock.scripps.edu/). Each simulation provided ten docking conformations that provided the lowest free energy. Five simulations were done for each excipient with calmodulin, providing fifty docking conformations total for each excipient. Each conformation was analyzed to determine which resides were in contact, either through van der Waals forces or hydrogen bonding, with the excipient molecule.

The computation results from Autodock were compared to experimental hydrogen-deuterium exchange (HDX) mass spectroscopy experiments using lyophilized formulations of calmodulin and either trehalose, sucrose, raffinose, or mannitol (Li*, et al.*, 2008). Regions of the protein that are able to freely exchange hydrogen for deuterium are exposed and are not protected by protein-excipient interactions. Experimentally, protein-excipient interactions are indicated by low deuterium uptake.

2.2. Optimal Selection of Excipients

Contact information provided by the docking simulations was used to optimally select excipients that have the highest number of interactions with aggregation prone "hot spots". The hot spots were predicted using Aggrescan (Conchillo-Sole*, et al.*, 2007).

For each hot spot, a sugar and a surfactant molecule were chosen to maximize protein-excipient interactions. For selection purposes, whichever excipient had the most interactions with a particular residue was chosen as the best candidate. It was assumed that the molecule with the most interactions with a residue would have the dominant effect and thus contribute the most to the protection of the residue of interest. At each residue in the hot spot, the best sugar candidate and the best surfactant candidate were compared. Whichever excipient had the most interactions was selected and the process was repeated for the entire hot spot sequence. The sugar-surfactant pair that provided the maximum number of interactions was selected as the optimal drug formulation. The formulation of the optimization problem is given in Equation (1). The problem is

formulated as a MINLP and was solved using the DICOPT solver in GAMS (http://www.gams.com/).

$$\max \sum_{i}^{n} \text{interaction score}(i) \tag{1}$$

s.t.

$$\text{interaction score}(i) = y_{sugar}(i) \cdot \text{sugar score}(i) + y_{surfactant}(i) \cdot \text{surfactant score}(i)$$

$$\text{sugar score}(i) = \sum_{j=1}^{4} y_j \cdot score_j(i)$$

$$\text{surfactant score}(i) = \sum_{k=1}^{3} y_k \cdot score_k(i)$$

$$y_{sugar}(i) \le \frac{\text{sugar score}(i)}{\text{surfactant score}(i)}$$

$$y_{surfactant}(i) \le \frac{\text{surfactant score}(i)}{\text{sugar score}(i)}$$

$$y_{sugar}(i) + y_{surfactant}(i) = 1$$

$$\sum_{j=1}^{4} y_j = 1$$

$$\sum_{k=1}^{3} y_k = 1$$

$$y_{sugar}, y_{surfactant}, y_j, y_k = \{0,1\}$$

Where i is a residue location, n is the number of residues in the hot spot of interest, j is a specific sugar, and k is a specific surfactant. The $score_j(i)$ and $score_k(i)$ are input as parameters based on the results from molecular docking. The scores are integer values, but are not explicitly defined as such in GAMS. The constraints ensure that the highest interaction score between a sugar and a surfactant is chosen for each residue. The constraints provide an interaction score that is summarized below, without the need for disjunctive programming:

$$\text{interaction score}(i) = \begin{cases} \text{sugar score}(i) & \text{if sugar score}(i) \ge \text{surfactant score}(i) \\ \text{surfactant score}(i) & \text{if surfactant score}(i) > \text{sugar score}(i) \end{cases} \tag{2}$$

3. Results and Discussion

3.1. Docking Simulation Results

Docking simulations providing fifty conformations were performed individually for mannitol, trehalose, sucrose, raffinose, octyl glucoside, tween 40, and tween 80 with the protein calmodulin. The results for the sugars were compared to experimental HDX results. Overall, the docking results compared favorably with the HDX results. Regions of high interactions in the docking simulations corresponded to regions that were protected from hydrogen/deuterium exchange. The histogram of interactions versus residue location is provided in Figure 1 for trehalose. Residues that interacted frequently with trehalose match well with the shaded regions indicating protection from hydrogen/deuterium exchange.

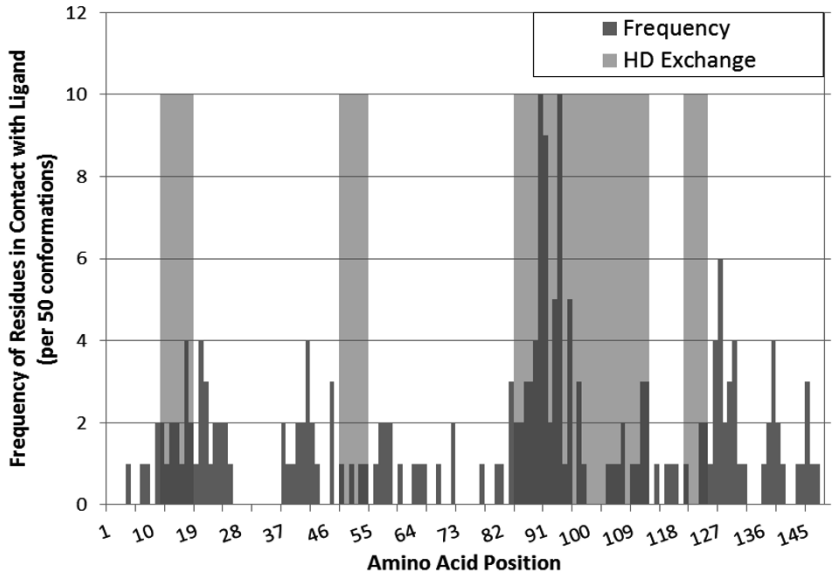

Figure 1. Frequency of amino acid residues of calmodulin in contact with trehalose. Results are given for 50 docking conformations. The shaded regions indicate amino acids that were protected by trehalose in the lyophilized state, as determined by HDX experiments (Li*, et al.*, 2008).

Figure 2 provides a visual comparison of the regions with high interaction and the regions protected from exchange for the trehalose-calmodulin system. From the comparison of the computational and experimental results, the docking simulations provide a reasonable prediction of the residues involved in protein-excipient interactions and provide a useful tool for selecting excipients for lyophilized protein formulations.

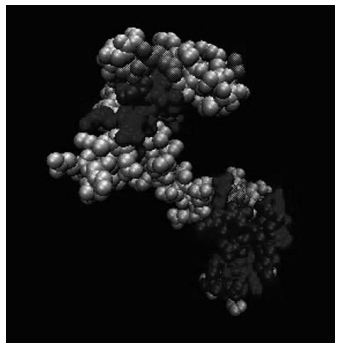

Figure 2. Trehalose interaction regions mapped to the surface of calmodulin. Blue regions indicate residues that interacted with trehalose in more than three conformations. Red regions indicate regions that were protected by trehalose in the lyophilized state, as determined by HDX experiments. Purple regions are the intersect of the computationally predicted high interaction regions and the experimentally determined protected regions.

3.2 Formulation Selection for Maximizing Protein-Excipient Interactions

Using the docking simulation results and the previously described optimization problem formulation, sugar-surfactant pairs were selected for each hot spot region on calmodulin. The hot spots were predicted using Aggrescan (Conchillo-Sole*, et al.*, 2007). Due to the proximity of hot spots 4 and 5, a formulation was also selected for the combined region. The results are given in Table 1. The interaction scores provided correspond to the number of interactions exhibited in the docking simulations.

Table 1. Sugar-surfactant formulations selected for maximum interaction with hot spot regions.

Hot Spot	*Amino Acids*	*Sugar*	*Surfactant*	*Combined Interaction Score*	*Sugar Interaction Score*	*Surfactant Interaction Score*
1	15-19	Trehalose	Tween 40	24	10	24
2	33-38	Mannitol	Tween 40	13	10	7
3	67-73	Sucrose	Tween 40	17	9	15
4	99-103	Raffinose	Octyl Glucoside	10	7	8
5	106-111	Raffinose	Tween 80	17	11	13
6	141-145	Raffinose	Octyl Glucoside	26	15	26
4 & 5	99-111	Raffinose	Octyl Glucoside	29	18	22

The results show that the excipients providing maximal interactions vary from hot spot to hot spot. All available excipients were selected at least once. The addition of a sugar provided no additional interactions for the formulations selected for hot spots 1 and 6 and thus was not beneficial from a protein-excipient interaction standpoint. A sugar would be necessary to ensure a stable glass was formed during the lyophilization.

The procedure outlined above could be used for any number of excipients and proteins to predict formulations with maximal protein-excipient interactions. By maximizing protein-excipient interactions, the aggregation propensity is reduced and a safer, more effective drug product is produced. The fact that the sugar-surfactant pair providing maximal interactions differed between hotspots speaks to the complexity of selecting beneficial excipients for a lyophilized protein formulation.

Abstract

The reverse problem formulation is a technique used for the solution of integrated process and product design problems from a properties perspective. In this work, an algorithm has been introduced for reverse problem formulations using property operators based on molecular signature descriptors. Current molecular design algorithms are applicable only in non-reactive systems. Here, a general framework is introduced for integrated design of systems where chemical reactions are taking place.

Keywords: Signature Descriptors, Reactive Systems, Molecular Design.

1. Theoretical background

1.1. Reverse problem formulation (RPF) technique and property operators

In most design problems, it is important to consider the aspects of process and molecular designs simultaneously because of their mutual relationships. However, some model equations are non-linear in nature which makes integrated problems computationally challenging. The reverse problem formulation (RPF) is a technique used to reduce the complexity of such integrated problems [1]. In RPF, the integrated problem is decomposed into two reverse problems. The first reverse problem identifies the property targets to achieve optimum process performance and the second reverse problem generates the molecular structures that meet the identified property targets. To track properties, property operators are used which are functions of the original properties tailored to obey linear mixing rules. The normalized property operator, Ω_{js} is obtained by dividing it by a reference value [2]. If $\psi_j(P_{js})$ is the property operator of the j^{th} property P_{js} of stream s, x_s is the fractional contribution, N_s is the number of streams:

$$\Omega_{js} = \frac{\sum_{s=1}^{Ns} x_s \psi_j\left(P_{js}\right)}{\psi_j^{ref}} \tag{1}$$

1.2. Molecular signatures

Molecular signature is a descriptor used for representing the atoms in a molecule using extended valencies of atoms to a pre-defined height [3]. If G is a molecular graph and x is an atom of G, the atomic signature of height h of x is a canonical representation of the subgraph of G containing all atoms that are at a distance h from x. Faulon *et al.* identified the relationship between TIs and signatures [4]. If k is a constant, ${}^h\alpha_G$ is the vector of occurrences of atomic signature of height h and TI (root (${}^h\Sigma$)) is the vector of TI values calculated for each root of atomic signature:

$$TI(G) = k.{}^h\alpha_G.TI\left(root\left({}^h\Sigma\right)\right) \tag{2}$$

2. Signature descriptors for molecular design

There are a number of property models that make use of different topological indices for predicting properties from molecular structures. These relationships are known as quantitative structure activity/property relationships (QSAR/QSPR). Algorithms have been developed that make use of molecular signature descriptors to represent topological indices for the molecular design [5]. Since many existing QSPR expressions can be reformulated in terms of signatures, algorithms based on signatures will be able to track a wide variety of property targets.

2.1. Signature descriptors for reactive systems

Most computer-aided molecular design algorithms can be applied only to systems where no chemical reactions take place. However, the clustering technique has been shown to have the ability to track the properties for stoichiometric conversion reactors [6]. The normalized property operator of the outlet stream of a stoichiometric conversion reactor, Ω_{j2} can be calculated using eq. (3):

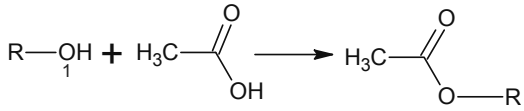
$$\Omega_{j2} = \frac{F_1}{F_2} \cdot \left(\Omega_{j1} + X.y_{Key1} \cdot \sum_{i=1}^{NC} \theta_i \cdot \Omega_{ji}^{*} \right) \tag{3}$$

Where F_1 and F_2 are the flowrates of inlet and outlet steams respectively, θ_i is the stoichiometric coefficient, X is the conversion, Ω_{ji}^{*} is the property operator corresponding to the individual components. To track the same set of target properties, the signature of a reaction, $\sigma(R)$ can be defined as shown in eqs. (4) and (5):

$${}^{h}\sigma(R) = f(\sigma(A)\sigma(B)) \tag{4}$$

$$\Delta\Omega_{f2} = f({}^{h}\sigma(R)) \tag{5}$$

Where $\sigma(A)$ and $\sigma(B)$ are the signatures corresponding to the reactants and products. During a reaction, one or more of the molecular groups in the compound will be replaced by a new group(s). The change in groups results in changes in the molecular signatures. The height of the signature considered for tracking the target property will determine the signatures from the original molecular groups that will be repeated in the product as well. For instance, consider the esterification of alcohols with acetic acid:



According to eq. (2), the signatures of atoms originating from the last two groups in 'R' will be changed because of the esterification reaction. Therefore, the change in property function will be represented as the changes in atomic signatures of the atoms that are at a height 2 from the signature marked as '1'. In general, the difference in property contributions of different signatures can be represented using eq. (6):

$$\Delta\Omega = \Delta\left[\left(\sum {}^{h}\alpha_{h-k} \right)_{reactant} - \left(\sum {}^{h}\alpha_{h-k} \right)_{products} \right] \tag{6}$$

where, $({}^{h}\alpha_{h\text{-}k})_{\text{reactants}}$ is the sum of property operators for the signatures of the atoms that are at height '*h*-*k*' from the group that would be replaced, $({}^{h}\alpha_{h\text{-}k})_{\text{products}}$ is the sum of

property operators for the signatures of the atoms that are at height '*h-k*' from the group that is formed after the reaction and $\Delta\Omega$ is the difference in property operator value as a result of the reaction. Since the atomic signatures of molecular building blocks that are farther from height '*h-k*' will be the same even after the reaction, the property operators will be same for the rest of the molecule. Now, the property operator corresponding to the molecule formed after a specific type of chemical reaction can be estimated:

$$\Omega_{reaction} = \Delta\Omega + \Omega(P) \tag{7}$$

where, $\Omega_{reaction}$ is the property operator corresponding to the final molecule when the initial compound used has a property operator value of $\Omega(P)$.

2.2. General problem statement

Design the molecules with the best dominant property that satisfy a set of property constraints identified during the process design when the molecule is formed after a chemical reaction.

2.3. Problem formulation

The property operator of a property P is a function, θ, of the actual property which obeys linear mixing rules [5]:

$$\theta = f(TI) \tag{8}$$

$$TI = \sum_{i=1}^{N} {}^{h}\alpha_i \cdot TI(root({}^{h}\Sigma)) = \sum_{i=1}^{N} {}^{h}\alpha_i L_i \tag{9}$$

$$\Omega(P) = \sum_{i=1}^{N} x_i L_i \tag{10}$$

$$\left(\Omega_{reaction}\right)_j = \Delta\Omega + \Omega(P) \tag{11}$$

This problem can be formulated as a bilevel optimization problem. The first level is to identify the right sets of atomic signatures that change after the reaction and the second level is to identify the right combination of those atomic signatures along with the atoms whose signatures would not change with the reaction. To solve the first level, the groups can be represented as a set of binary variables:

$$\Phi = \sum {}^{h}\alpha_{h-k}.e_i \tag{12}$$

where e_i is the number of appearances of each signature that will change because of the reaction. Φ will be optimized to get the optimum value of Ω_j. The components of $\Delta\Omega$ can be estimated corresponding to the type of reaction. Since the difference is restricted to the atoms that are at height *h-k* from the group on which the reaction can take place, this modification will add only a small number of additional parameters in the final problem formulation. The dominant property, which is expressed in terms of the occurrences of atomic signatures, can be optimized subject to the property constraints. If Ω_j is the property operator corresponding to the dominant property and Ω_{ij} is the normalized property operator of molecule *i*, an optimization problem can be formulated as follows:

$$Max / Min \ \ \Omega_j \tag{13}$$

$$\Omega_j^{\min} \le \Omega_j \le \Omega_j^{\max} \tag{14}$$

The principles of graph theory are applied to ensure that the signatures connect together to form feasible molecules [7]. To do that, a number of structural constraints that ensure the consistency of signatures are introduced in terms of the number of appearances of atomic signatures [5].

2.4. Stepwise procedure

- The property targets for the input molecules to provide the optimum process performance will be calculated using eq. (1).
- Identify the QSAR/QSPR/group contribution models that predict the properties corresponding to the optimum performance.
- Identify heights of molecular signatures corresponding to the TIs used in QSPR
- Estimate the property operators corresponding to the changes possible on the molecular groups because of the reaction.
- Estimate the property operator values corresponding to potential types of reactions.
- Based on the structural constraints and transformation techniques explained in section 2.4, identify the signatures and generate candidate molecules using the algorithm by Faulon *et al*. [8].

3. Proof of Concept Example

In this case study, the target is to identify an alcohol that produces an ester with a given set of properties. The property targets for the ester are given in Table 1, while the property models that are used to predict the target properties are given in Table 2.

Table 1. Property Constraints

Property	Upper Bound	Lower Bound
Boiling Point, *BP* (°C)	170	110
log(*TLC*) (ppm)	-	1
log(K_{oc})	Minimum	

Table 2. Property Models

Property	Property Model
log(K_{oc}) [9]	$\log(K_{oc}) = 0.53({}^1\chi) - 1.25(\Delta^1\chi^v) - 0.72(\Delta^0\chi^v) + 0.66$
Boiling Point, *BP* [10]	$T_b = t_{b0}.\ln\left[\sum_{g=1}^{n_g} n_i t_{b1} + \sum_{s=1}^{N_s} n_s t_{b2} + \sum_{t=1}^{N_t} n_t t_{b3}\right]$
log(*TLC*) [11]	$\log(TLC) = 4.066 - 0.9915({}^1\chi^v)$

The molecular descriptors used in the equations presented in Table 2 are transformed into the corresponding molecular signatures. The maximum signature height appearing

in this case is 2. The following signatures (and the similar signatures from the C4 root) have the potential to form a different signature because of the reaction:

O1(C2(OC)),O1(C3(OCC) O1(C4(OCCC)) C2(O1(C)C2(CC)) C2(O1(C)C3(CCC)) C3(O1(C)C1(C)C2(CC)) C3(O1(C)C2(CC)C2(CC)) C3(O1(C)C3(CCC)C2(CC)) C3(O1(C)C3(CCC)C3(CCC))

An optimization problem has been set up using eqs. (8)-(14) and relevant structural constraints and solved for the minimum value of soil sorption coefficient. The best three candidates along with their predicted property are given in Table 3:

Table 3. Final molecules

Molecule	*BP* (K)	log *TLC* (ppm)	log K_{oc} (ppm)
$(CH_3)_2CH(CH_3)CHOH$	114	1.762	1.892
$(CH_3)_2CH(CH_2)CH_2OH$	125	1.707	1.921
$CH_3CH_2CH(CH_3)CH_2OH$	125	1.609	1.941

4. Conclusions

An algorithm has been developed for solving property based product design problems when chemical reactions are involved during the process. The algorithm is formulated to track the changes in the properties during different types of reactions. The developed algorithm focuses on the changes in the reaction sites of the molecules to design the components involved.

Abstract

The property integration framework is combined with multivariate statistical techniques and applied in a reverse problem formulation on chemical product design problems by systematic and insightful use of past data describing the properties of the raw materials, their blend ratios, and the process conditions during the production of a range of product grades to achieve new and improved products. The method is illustrated using a polymer blending problem.

Keywords: Mixture Design, PCA, PLS, Property Clustering, Reverse Problems.

1. Introduction

Correlation is inherent in the data of chemical processes which requires the use of multivariate statistical tools for visualization and identification of important relationships in the data. The product formulation design problem in industrial research and development is one such area where the analysis of mixture data is a common problem, especially in pharmaceutics, cosmetics, oil, and biotechnology. Such mixture design problems are traditionally formulated as *mixed integer non-linear programs* (MINLPs) which can be difficult to formulate and solve.

2. Methodology

Projection methods like principal component analysis (PCA) and partial least squares (PLS) are employed to extract and utilize the necessary information from three degrees of freedom that are available to control the properties of any product manufactured in blending operations. This information forms the basis for models that can be used to simultaneously explore the effects of the raw material properties data (**X**), their blend ratios (**R**), and process conditions (**Z**) on the product quality (**Y**). These methods capture information about the variance and correlation structure within predictor and quality variables that were present during the production of previous grades and that are important for the consistency of the desired process conditions with past operating procedures.

The empirical models are used in a reverse problem formulation to ensure that a complete set of candidate materials and their mixtures are found which match the design target subject to the predictive power of the model. Mapping the design problem onto the lower dimension cluster space utilizing the property clustering algorithm facilitates simultaneous visualization and solution of the problem and also avoids combinatorial explosion when dealing with multi-component mixtures [1]. The solution methodology can be summarized as follows:

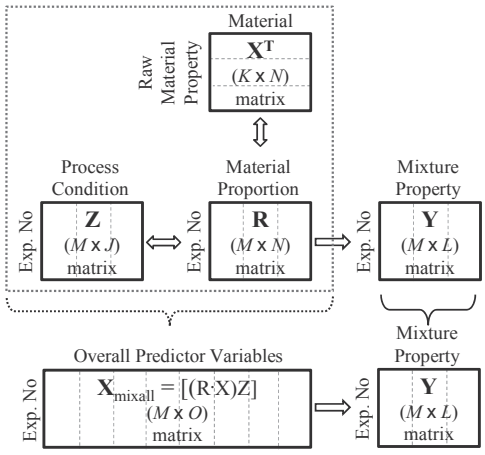

Figure 1. Data structure for three predictor variable matrices and a quality matrix. (The dotted lines in the blocks indicate the mean centering and scaling direction.)

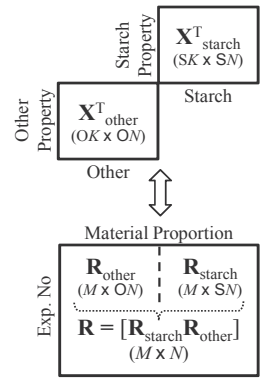

Figure 2. Data structure of **X** and **R** Matrix for the polymer blend problem.

1. Acquire original training data matrix generally available on mixture design. The structure of the raw material properties matrix, $\mathbf{X}_{NxK}$, consists of N available raw materials with K number of properties. The blend ratio matrix, $\mathbf{R}_{MxN}$, consists of M number of blends of N materials used in the blend formulation such that $\sum_{i=1}^{N} r_i = 1$, where $r_i \geq 0 \; \forall \; \mathrm{i} = 1,2,\ldots,N$. The process conditions matrix $\mathbf{Z}_{MxJ}$, consists of J process conditions. The response or product quality matrix $\mathbf{Y}_{MxL}$, consists of L properties measured on the final product. Using ideal mixing rules the raw material properties matrix (**X**) and the blend ratios matrix (**R**) can be combined in order to relate all (**Z**, **R**, $\mathbf{X}^T$) to the **Y** matrix with a common dimension M [2]. The model to relate **Y** with all three **Z**, **R** and $\mathbf{X}_{mix\ all}$ variables can be of the form:

$$\mathbf{Y}_{M\times L} = f(\mathbf{X}_{mix\ all\ M\times O}) + \varepsilon \qquad \text{where, } \mathbf{X}_{mix\ all} = \left[\mathbf{X}_{mix}\mathbf{Z}\right] = \left[\left(\mathbf{R}\cdot\mathbf{X}\right)\mathbf{Z}\right] \tag{1}$$

$\mathbf{X}_{mix\ all}$ is a matrix combining $\mathbf{X}_{mix}$ and **Z** in parallel and contains O (=K+J) number of predictor variables. This simplifies the analysis and design by not having to differentiate between mixture and process variables and not having to assume independence of the factors [3]. This data structure illustrated in Fig. 1.

2. Mean centre and unit variance scale $\mathbf{X}_{mix\ all}$ and **Y** variables.
3. Perform PCA to achieve a qualitative analysis of the data and PLS to develop the calibration model. Using PCA, a large number of correlated variables can be transformed into a smaller number of uncorrelated variables called *principal components* (PCs). Choose A number of PCs based on cumulative percentage variance explained. The PLS projection to lower dimensional subspace gives:

$$\mathbf{X}_{mix\ all,M\times O} = \sum_{i=1}^{A} t_i \cdot p_i^T + \mathbf{E}_{M\times O} = \mathbf{T}_{M\times A}\cdot\mathbf{P}_{A\times O}^T + \mathbf{E}_{M\times O} \qquad \text{where, } \mathbf{T} = \mathbf{X}_{mix\ all}\cdot\mathbf{W}^* \tag{2}$$

In this way, the data matrix $\mathbf{X}_{mix\ all}$, containing O highly correlated predictive variables is transformed into the *score* matrix, **T**, containing only A (where, A<K) independent *latent variables* (LVs), which are linear combinations of the original

manipulated variables. Thus, further design work can be conducted in the reduced subspace. The prediction of **Y** can be obtained from the PLS model as:

$$\hat{\mathbf{Y}}_{M\times L} = \sum_{i=1}^{A} t_i \cdot q_i^T = \mathbf{T}_{M\times A} \cdot \mathbf{Q}_{A\times L}^T = \mathbf{X}_{mix\ all,M\times O} \cdot \mathbf{W}_{O\times A} \cdot \mathbf{Q}_{A\times L}^T = \mathbf{X}_{mix\ all,M\times O} \cdot \hat{\mathbf{B}}_{O\times L} \tag{3}$$

P, **W*** and **Q** are the *loading* matrices, **E** is a *residual* matrix, and **B** is the regression coefficient matrix. The scores from PCA can also be used for a development of a regression model (PCR) as:

$$\hat{\mathbf{Y}}_{M\times L} = f\left(\mathbf{T}_{M\times A}\right) \qquad \text{where, } \mathbf{T} = \mathbf{X}_{mix\ all} \cdot \mathbf{P} \tag{4}$$

If new raw material properties, x^T_{new}, have to be predicted from the desired product quality specifications, y^T_{des}, then the inversion of the latent variable model gives:

$$\hat{x}^T_{new,1\times K} = \hat{y}^T_{des,1\times K} \cdot (\hat{\mathbf{B}}^T \cdot \hat{\mathbf{B}})^{-1} \cdot \hat{\mathbf{B}}^T_{L\times A} \cdot \mathbf{P}^T_{A\times K} \tag{5}$$

where, $(\hat{\mathbf{B}}^T \cdot \hat{\mathbf{B}})^{-1} \cdot \hat{\mathbf{B}}^T$ is the generalized inverse or pseudo-inverse of $\hat{\mathbf{B}}$.

Note: It is important to check and remove outliers prior to the calibration of a model. *Hotelling's* T^2 is a powerful measure of a multidimensional outlier.

4. Convert all the physico-chemical attribute properties of interest to *principal properties* (PP) [4] by using the regression coefficients from the calibration model as

$$\mathbf{T}_{M\times A} = \mathbf{Y}_{M\times L} \cdot \mathbf{B}^T_{L\times O} \tag{6}$$

5. In order to utilize the LVs in the property clustering algorithm, it is important that the LV structures follow a linear mixing rule. This can be achieved by standardizing the data structure to obtain a new $\mathbf{Q}_{MxA}$ matrix [4].

$$\mathbf{Q}_{M\times A} = \left(\sum_{i=1}^{M} \mathbf{S}^T_{O\times M}\right)^{-1} \cdot T_{M\times A} \qquad \text{where, } \mathbf{S}_{M\times O} = \mathbf{T}_{M\times A} \cdot \mathbf{P}^T_{A\times O} \tag{7}$$

6. Using the property clustering algorithm, map the problem from conserved principal property domain to the conserved componentless cluster domain [5].

$$\Psi_l\left(y_l\right)_{mix} = \sum_{u=1}^{U} x_u \cdot \Psi_l\left(y_l\right)_u \qquad \text{where, } \Psi_l\left(y_l\right)_u = Q_u \tag{8}$$

where, $\Psi_l(y_l)_u$ is an operator on the *j*'th property of stream/material, *u,* involved in the mixing. For systems of up to three properties, each vertex in a ternary diagram represents a pure latent property cluster.

7. Apply the property integration solution approach within the cluster domain by formulating and solving two reverse problems, one for identification of the synthesis/design feasibility target region (reverse of simulation problem) and another for identification of materials, blends, or plant operation conditions that match the target values identified earlier (reverse of property prediction problem) [1,5].
8. Compute the performance index based on cost, environmental impact, solubility, etc. for all feasible solutions from step 7 and rank to determine the optimal solution.

Following the above steps, one can avoid the difficulties involved with formulating and solving mixed integer non-linear programming (MINLP) problems.

3. Proof of Concept Example – Polymer Blending

The development of thermo-plastic from a mixture of starches, lactic acids and additives using latent variables in cluster space is presented as a case study to illustrate the method and concept described in this paper. The data consists of properties of starch (**X**), blend ratios of starch and other materials (**R**), molding temperature (**Z**) and final product properties (**Y**) for 28 blends. Fig. 2 represents a more complex extension of the data structure for the **X** and **R** matrixes involved in this problem than shown in Fig. 1. More details can be found in Muteki [2]. Using PCA, the first three PCs obtained captured about 87% of the total variance of the mean centered and unit variance scaled $\mathbf{X}_{mix\ all}$ [=($\mathbf{R}_{starch}$:$\mathbf{X}_{starch}$)$\mathbf{R}_{other}$**Z**] data. Latent variable models were developed stepwise by minimizing the *Bayesian Criterion* (BIC) using the PCs obtained from PCA to predict three product properties: tensile strength (TS), elongation at break (EB) and density (Rho). The general form of the model is

$$\hat{y} = \beta_0 + \sum_{i=1}^{3} \beta_i t_i + \sum_{i<j}^{3} \sum_{j>i}^{3} \beta_{ij} t_i t_j + \sum_{i=1}^{3} \beta_{ii} t_i^2 \tag{9}$$

It is desirable to cover a wide range of product properties with a minimum number of products, thus the desired product properties could be independently selected in the *cluster space* (Fig. 4 (left)) as well as in the *score space* (Fig. 4 (right)) that spans the desired property space. A mixture feasibility region in cluster space also ensures that the products within its boundary are physically feasible, consistent with past operating strategies and expected to yield the desired product qualities. LV models can be inverted to obtain mixture conditions that give the desired product quality after selecting an appropriate point or region in cluster space. Table 1 shows the calculated mixture conditions that yield the desired product properties for a target blend point that was not part of an existing product grade. Fig. 3 shows how the starch properties, the polylactic acid, the additives and the molding temperature influence the final product properties.

Table 1. Target product properties and mixture conditions

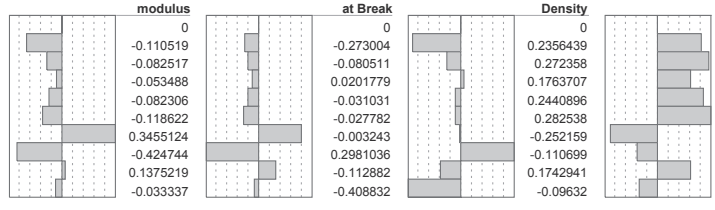

Figure 3. PLS model coefficients for blend property matrix **Y** using four latent factors**.**

Moreover, if two polymer product grades are compatible, i.e. miscible, they can be mixed together to get a polymer with properties somewhere between those of the two polymers mixed. In latent property cluster space, one can rapidly screen out inherently

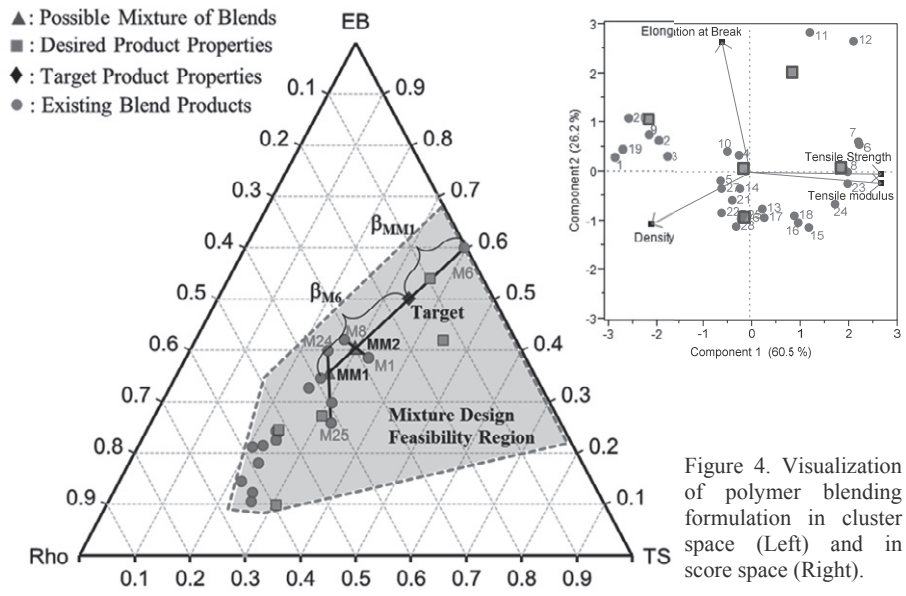

Figure 4. Visualization of polymer blending formulation in cluster space (Left) and in score space (Right).

infeasible combinations of candidate constituents visually. The reduced search space can then be explored for the feasibility of formulating binary, ternary and multi-component mixtures to achieve optimum products based on *lever-arm analysis* without extensive enumeration. For example, the same target product that can be blended from the information in Table 1 can also be formulated by mixing products M6 with MM1 (binary mixture product of M24-M25) in a proportion 0.648 and 0.352 respectively.

4. Conclusions

This research effort has been focused on formulation and solution of product design problems by systematic and insightful use of past data describing the properties of the raw materials, their blend ratios, and the process conditions to predict and enhance the performance of target product. Such a practice in industry results in fewer trials and experiments to run, thereby saving resources, capital and most importantly the product development time.

Abstract

About 20% power output penalties will be incurred for implementing CO2 capture from power plant. This loss can be partially compensated by flexible operation of capture plant. However, daily large variations of liquid and gas flows may cause operation problems to packed columns. Control schemes were proposed to improve the flexibility of power output without causing substantial hydraulic disturbances in capture plant is presented. Simulations were implemented using ASPEN Plus. In varying lean solvent flow strategy, the flow rate of recycling solvent was manipulated to control the CO2 capture rate. The liquid flow of the absorber and gas flow of the stripper will vary substantially. In an alternative strategy, the lean solvent loading will be varied. Variation of gas throughput in the stripper is avoided by recycling part of CO2 vapor to stripper. This strategy provided more stable hydraulics condition in both columns and is recommended for flexible operation.

Keywords: Plantwide control, CO2 scrubbing, ASPEN PLUS, heat integration, flexible operation

1. Introduction

In recent years, global warming and climate change caused by greenhouse gases have received widespread concern. The majority of CO_2 emission comes from flue gas emitted from electricity generation, coal-fired power plant especially. The most mature technology for post combustion CO_2 capture is amine scrubbing. Pilot-scale plants of various sizes have been constructed and operated to investigate the design and operability of such processes. However, Implementing CO_2 capture incurs penalties of electric power output. Coal-fired power plant usually performs as a base load power plant that produces a steady electricity output. However, power demands fluctuate on daily and seasonal basis. Electricity has higher prices in peak load periods. It was suggested that electric power output can be increased to meet higher electricity demand by turning off CO_2 capture plant in peak hours (Cohen et al. 2010). Chalmers et al.(Chalmers, Leach et al. 2009) showed that if CO_2 trading price is included, bypassing CO_2 capture is valuable when \$/MWh electricity selling price are 2~3 times higher than \$/ton CO_2. Thus flexibility added to the power plant was proclaimed as one of the advantages of post-combustion CCS by amine scrubbing. However, a continuous process such as the amine scrubbing and regeneration process commonly used in CCS cannot be shut down and turned on at will. It should be recognized that when flue gas bypasses the CO_2 capture plant, hydraulics conditions of the absorber and the stripper will change substantially. Flooding and poor wetting will occur when the throughput

rate is too high or too low. Normal operation cannot be maintained if the throughput is turned down much beyond this limit because of poor wetting. It was also suggested that rich solvent is stored during peak load period and will be regenerated later in off-peak period (Chalmers, Lucquiaud et al. 2009). This strategy could avoid CO_2 emission penalty because CO_2 is captured all the time. However, this strategy requires huge additional tanks and solvent inventory for buffering between peak and off-peak load period. The additional cost and safety hazards can be staggering (Haines and Davison 2009). Using this strategy, a normal gas and liquid throughput can be maintained in the absorber; but large changes in throughput can still be found in the stripper. In this work, we suggested that flexible operation can be achieved by implementation of proper control strategies. The feasibility of this approach is verified using dynamic simulation of an integrated system with power generation and heat recovery sections of a power plant and the corresponding CO_2 capture plant by Aspen Plus and Aspen Dynamics.

2. 2. Process description

2.1. Power plant

A power plant model is required so that interaction between multi-stage compressor, turbine output and the CCS capture plant can be simulated. In this work, a reference 580MW power plant burning bituminous coal with 36.3% net efficiency (HHV) (NETL R&D Solutions 2007) was selected. Boiler supplies high pressure steam at 170 bar/560oC and reheated steam at 38 bar/560oC for power generation. Flue gas out from boiler then is sent to flue gas desulfurization (FGD) process for removing sulfur dioxide. After that, about 2300 ton/hr flue gas containing 13mol% CO_2 will head to CO_2 capture plant. Power extractions from steam are simulated by series of turbines with different outlet pressures. The outlet steam of each turbine is available for preheating condensate or providing heat for the reboiler in the CO_2 capture plant. To facilitate heat transfer, saturate temperature of heating steam should be at least 10^oC approach above reboiler temperature (Alie 2004).

2.2. CO_2 capture plant

The CO_2 capture plant includes two columns, absorber and stripper, and one lean/rich solvent cross heat exchanger. Flue gas carrying CO_2 generated from power plant is delivered into bottom of packed absorber to contact with lean solvent, an aqueous solution containing 30 wt% MEA. Treated gas is vented to atmosphere from top of absorber. After absorption, the rich solvent is preheated to 100^oC by heat exchanger before being sent to stripper. In the stripper, low pressure steam from power plant is injected into reboiler for CO_2 desorption.

2.3. Multi-stage compressor

CO_2 product accompanying with water vapor is about 100^oC while being stripped out from top of stripper. Before being compressed, CO_2 product is cooled to 40^oC by overhead condenser and part of water will be condensed. Further, the CO_2 is compressed from 2 to 110 bar through multi-stage compressor, which includes intercoolers to cool the exhaust gas back to 50oC before entering next stage. Each stage is simulated by compressor, heat exchanger, and condenser, responsible for compressing, cooling, and knocking water out respectively.

2.4. Heat integration

Romeo et al.(Romeo, Espatolero et al. 2008) showed that heat integration of intercoolers can save about 2% of electricity output. To implement heat integration,

first, heat acquired from cooling CO_2 in overhead condenser and intercoolers of the CCS plant is used to preheat condensate coming out of the condenser of the power plant. Part of condensate is delivered to intercoolers in parallel to cool CO_2 vapor to 50^oC before entering each compressor.

2.5. Flexible operation strategies

The actual optimal operating strategy depends on the pricing, duration of the peak load period and the trading price of CO_2 emission. In this study, we assume that an average capture rate 70% should be attained. If the peak load period is 10 hours per day, electricity output can be increased during peak load period by decreasing CO_2 capture rate to 50%; then, to balance overall capture rate to 70%, CO_2 removal rate has to increase to 90% in the next 14 off-peak load hours. The purpose is to show that we can adjust the CO_2 capture rate without causing large disturbances in the capture plant.

2.5.1. Variation of Lean Solvent Flow (VLSF)

A plantwide control strategy of CO_2 capture plant was proposed by Lin et al (Lin, Pan et al. 2011). As figure 1(a) shows, CO_2 capture rate is controlled by variation of lean solvent flow (VLSF), and reboiler temperature is controlled by manipulating reboiler steam flow rate. In VLSF control structure, flexible operation can be implemented by adjusting setpoint of CO_2 capture rate controller. Lean solvent circulating rate is varied to meet the capture rate target. In the VLSF strategy, reboiler temperature is controlled at a fixed value. Reboiler temperature is an indicator of lean loading. Hence the residual loading of CO_2 in the recirculating solvent is approximately constant during flexible operation.

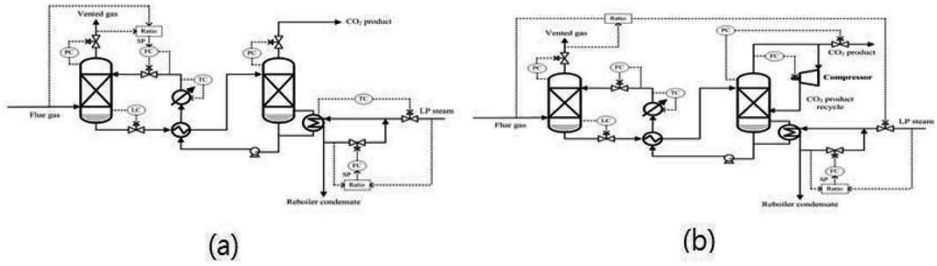

Figure 1(a) Control structure of CO_2 capture plant in variation of lean solvent flow strategy.(b) Control structure of CO_2 capture plant in variation of lean solvent loading strategy.

2.5.2. Variation of Lean Solvent Loading (VLSL)

To avoid the potential fluctuations in liquid flow in the absorber and gas and liquid flow in stripper, we propose an alternative control strategy that stabilizes the hydraulic conditions of both columns during flexible operation.

First, if the circulating lean solvent rate is fixed, lean solvent loading can be used to meet different CO_2 capture rate. The lean solvent loading can be reduced so that more CO_2 can be captured in the absorber with a steady lean solvent flow. Conversely, if we wish to reduce CO_2 capture rate, a higher the lean solvent loading can be allowed, thus reducing the load of the reboiler. Hence the scheme is based on variation of lean solvent loading, VLSL. The control scheme of variation of lean solvent loading is shown in Figure 1b. Lean solvent flow rate is controlled at a given value by a flow controller. CO_2 capture rate is controlled by manipulating reboiler steam flow rate.

2.5.3. Dynamic simulation results and discussions

To understand dynamic behaviors while implementing flexible operation, the integrated system modeled in Aspen Plus is exported to Aspen Dynamics and then simulated dynamically. After being exported to Aspen Dynamics, basic controllers that maintain steady operation are installed. There are several pressure controllers and level controllers in columns and vessels. To implement heat integration between intercoolers when CO_2 vapor flow rate is changing, condensate should be adequately distributed to overhead condenser and intercoolers. So, temperature controllers are installed to manipulate condensate flow rate to each intercooler and rest condensate is sent to overhead condenser.

A base case with 70% capture is used to demonstrate flexible operation decreasing capture rate to 90% and decreasing to 50% in two operating strategies. Fractional capacity is 63% in absorber and 54% stripper in base case.

2.5.4. Results of variation of lean solvent flow

To demonstrate operability, setpoint of capture controller is changed in ramp rate of 1% capture rate/min. Setpoint given is from 70% to 50% or 90% in 20 minutes to increase or decrease power output. Figure 2(a-b) shows dynamic responses of flexible operation implemented by VLSF strategy. CO_2 capture rate starts to change at 5th minute. When CO_2 capture rate is changing, lean solvent rate is manipulated to track correct capture rate. To cope with the changing circulating solvent rate, reboiler steam is manipulated to maintain reboiler temperature. We can see that lean solvent loading is keeping nearly at 0.37 mol CO_2/mol MEA. Using this operation strategy, fractional capacity in absorber varied in a relatively smaller range compared to simple bypass, between 55% in peak hours and 70% in off-peak hours. However, the fluctuation in stripper still exists. Fractional capacity decreases to below 40% when CO_2 capture rate is reduced to 50%.

2.5.5. Results of variation of lean solvent loading

Figure 2 (c-d) shows dynamic responses of flexible operation implemented by VLSL strategy. In this operating strategy, system successfully attains CO_2 capture targets of 50% and 90%. Lean solvent flow rate is fixed at 14000 m^3/hr. The reboiler temperature was increased to 118 ^oC to meet a higher CO_2 capture rate target of 90% and reduced to 110^oC to meet a lower CO_2 capture rate target of 50%. Lean solvent loadings also change from 0.37 to 0.41 and 0.33 mol CO_2/mol MEA at 50% and 90% capture rate respectively. Comparing new steady state value of reboiler duty obtained by two operating strategies, VLSL has slightly lower energy requirement at 90% capture and slightly higher at 50% capture rate.

In VLSL strategy, 30% of CO_2 product is recycled to stripper initially and then fractional capacity increases to 63%. Recycle rate is manipulated to maintain the gas flow rate out from top of stripper constant. By stabilize throughput of absorber and stripper in constant value, we can see that the fractional capacities in both columns are almost unchanged. Fluctuations in both columns due to large variations of liquid and vapor rate during flexible operation are avoided in this control strategy.

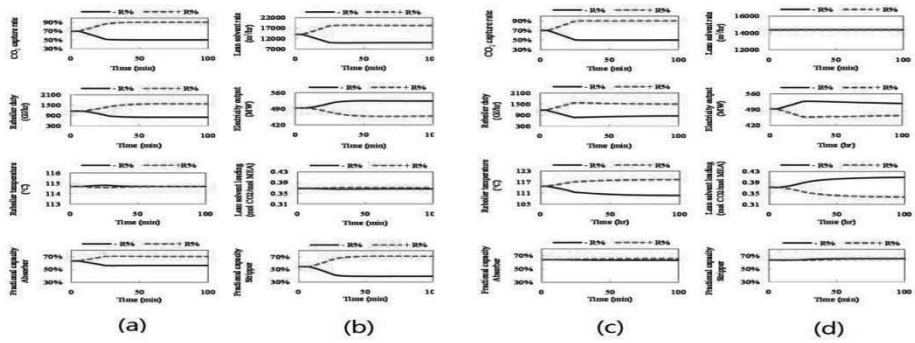

Figure 2. Dynamic responses of flexible operation adjusting capture rate from 70% to 50% and 70% to 90% implemented by variation of lean solvent flow strategy (a-b), and variation of lean solvent loading strategy (c-d).

2.6. Conclusions

Certain degree of flexibility is built in by manipulating the target of CO_2 capture in peak-load and off peak-load periods. However, large changes in hydraulic conditions absorber and stripper will occur if the amount of flue gas entering the capture plant and the amount of circulating solvents change substantially. To implement flexible operation but avoid potential fluctuations in packed columns due to large variation of liquid and gas flow rate, two operating strategy are proposed. In variation of lean solvent flow strategy, instability in absorber is partly reduced by delivering all flue gas to absorber. Capture rate is controlled by manipulating lean solvent rate and reboiler temperature is controlled at constant to maintain a nominal lean loading. In variation of lean solvent loading strategy, lean circulating solvent rate is unchanged to reduce fluctuations in both packed columns. Further, part of CO_2 product is recycled to stabilize stripper's operation. This strategy is able to maintain stable hydraulic conditions in both the absorber and stripper during both peak and off-peak load hours.

Abstract

The transition towards more sustainable biofuels systems might be conveniently driven by purpose-devised quantitative decision-making tools based upon the optimisation of the entire Supply Chain (SC). In this work, a moMILP (multi-objective Mixed Integer Liner Programming) modelling framework is proposed to support strategic investments on bioethanol infrastructures considering both economic and environmental sustainability (e.g., impact on global warming and water resource). Corn grain and stover are accounted for as feedstocks for ethanol production; Northern Italy is taken as a geographical reference. Results show that investments strategies are affected by the trade-off between environmental and financial objectives.

Keywords: MILP optimisation, bioethanol, water footprint.

1. Introduction

In the search for a viable solution to the global energy question, bioethanol has been gaining ever greater attention as alternative energy source. Although starch-based ethanol (first generation) has greater economic profitability and currently dominates the market, second generation (cellulose-based) ethanol seems to represent the technology that may lead to substantial greenhouse gas – GHG – emissions reduction. However, a paradigm shift towards sustainable transport systems needs to account for other urgent issues. In particular, water consumption has become a major concern: its demand is expected to grow significantly, and recent occurrences of local scarcity have showed its supply vulnerability (EU, 2011). Only a few works have addressed water footprint (WF) assessment in the context of biofuels (Hoekstra *et al.*, 2011); some bioethanol production technologies have been recognised as water intensive processes (UNESCO-IHE, 2009). In order to help managing the transition towards sustainable biofuels production, WF assessment needs integrating in a comprehensive financial and environmental framework. Mathematical programming techniques can provide decision makers with the necessary quantitative tools to optimise the overall water requirement guaranteeing an efficient use of the resource. Environmental aspects (carbon and water footprint) should be coupled with economic ones within a Multi-Objective Mathematical Programming (moMP) framework involving the overall SC, to offer an effective approach to explore trade-offs between conflicting objectives. Mixed Integer Linear Programming (MILP) allows addressing alternative configurations simultaneously.

Here, a moMILP modelling framework is proposed to design long-term ethanol SCs, involving both first (from corn) and second (from stover) generation technologies, considering also the possibilities of their mutual integration within hybrid

infrastructures. This work aims at delivering an environmentally conscious decision-making tool for the optimal design of bioethanol production systems where WF assessment along the entire SC is explicitly dealt with. Several technological alternatives are characterised by varying biomass mix between corn grain and stover for bioethanol production. In addition, valuable by-products (i.e. DDGS, Distiller's Dried Grains with Solubles) and stover use to produce energy is investigated.

2. Assumptions and methods

The core task of this work is the development of a design tool to steer investment decisions on general biofuel SCs over the long-term. The objective is to determine the optimal system configuration which maximises the financial profitability while minimising the environmental impacts (i.e., GHG emissions, WF). The key variables to be optimised deal with the best bioethanol SC design in terms of: feedstock mix, plant conversion technology and by-products end-use options. The economics have been assessed by means of SC analysis techniques. Only the upstream SC is considered, involving biomass cultivation and delivery as well as fuel production. The environmental performance is evaluated by adopting LCA (Life Cycle Assessment) techniques for the whole SC according to ISO standards (ISO 14040). The energy unit is taken as a reference for the environmental analysis. In the absence of a universally recognised method to cope with the effect of by-products end-use, three approaches have been assessed: a substitution method as well as a price- and energy-based allocation procedures. The substitution method, in particular, involves that credits derived from the displacement of alternative goods with by-products are subtracted from the primary product (ethanol) overall impact. For instance, in the corn-based bioethanol system, DDGS could be used either as a substitute for cattle feed or as a fuel for CHP generation; in cellulose-based processes, lignin is exploited to produce electricity and a power excess can be sold to the national grid. In case of allocation, the overall SC impact (i.e., GHG emissions, WF) is divided among the products according to their corresponding sharing quota determined either on price or energy content.

Table 1. Ethanol technologies assessed in the study.

Process	Feedstock		Fuel to CHP			Output		
	corn	stover	NG	DDGS	stover	EtOH	CHP	DDGS
DGP	X		X			X		X
DGP-CHP	X			X		X	X	
DGP-stover	X				X	X	X	X
DAP		X				X	X	
Hybrid*	X	X			X	X	X	X
Hybrid-CHP*	X	X		X	X	X	X	

*each hybrid technology comprises three instances at varying biomass mix.

Referring to the conversion phase, ten technologies are taken into account for ethanol production (Table 1), according to the work by Giarola *et al.* (2011): first generation from corn (dry-grind process, DGP), second generation from stover (lignocellulosic process, DAP), and hybrid technologies (Hybrid), where the feedstock mix describes three corn to stover ratios (1:1, 1:2, 1:3). The use of by-products (DDGS) and stover as alternative fuels to natural gas (NG) for the power station (CHP) is then investigated.

3. Mathematical features

The problem is formulated as a moMILP model based on the mathematical approaches commonly adopted in the strategic design of multi-echelon SCs (Tsiakis *et al.*, 2001). It also embodies different features to address the capacity planning and technology selection (Liu *et al.*, 2007) of fuel systems design at the strategic level. The environmental frame is approached as in Giarola *et al.* (2011).

The economic objective function (Obj_{NPV} [€]), is estimated in terms of the Net Present Value (NPV) of the system and needs being maximised in configuring the production network to optimise business profitability. It is calculated by summing up the discounted annual cash flows ($CF_{k,t}$ [€/y]) for each technology k and time period t minus the capital investment (TCI_k [€]) when a production facility of technology k is established. Accordingly:

$$Obj_{NPV} = NPV = \sum_k \left(\sum_t \left(CF_{k,t} \cdot df_t \right) - TCI_k \right) \tag{1}$$

where df_t is the discount factor related to the year t of production considered.

Two environmental objective functions are embedded within the formulation. The former concerns minimisation of the impact on global warming, estimated in terms of the total GHG emissions due to SC operation during time, (Obj_{GHG} [kg CO_2-eq]), $TIOT^{GHG}$. This is estimated by summing up the annual impact related to technology k, $TI_{k,t}^{GHG}$ [kg CO_2-eq/y] over time:

$$Obj_{GHG} = TIOT^{GHG} = \sum_t TI_{k,t}^{GHG} \tag{2}$$

The second environmental objective function (Obj_{WF}, m^3_{H2O}) refers to the minimisation of the overall water footprint due to SC operation over time ($TIOT^{GHG}$) and determined by summing up the annual impact on water resource $TI_{k,t}^{WF}$ [m^3_{H2O}/y] of technology k for ethanol production:

$$Obj_{WF} = TIOT^{WF} = \sum_t TI_{k,t}^{WF} \tag{3}$$

In the environmental model (Eq. (4)), the total impact, $TI_{k,t}^{l}$ ($l \in \{GHG, WF\}$) accounts for both carbon and water footprints per each LCA stage s, $Imp_{k,s,t}^{l}$, [kg CO_2-eq/y or m^3_{H2O}/y]. The impact rate $Imp_{k,s,t}^{l}$ is determined by applying a properly devised impact factor, $f_{i,s}^{l}$, [kg CO_2-eq/unit or m^3_{H2O}/unit], to a reference flow, $F_{i,k,s,t}$ [units/y], specific for biomass i, technology k and LCA stage s. Accordingly:

$$TI_{k,t}^{l} = \sum_s Imp_{k,s,t}^{l} = \sum_s \sum_i f_{i,s}^{l} \cdot F_{i,k,s,t}, \qquad \forall k,t \quad l \in \{\text{GHG,WF}\} \tag{4}$$

4. Case study

The emerging ethanol production system in Northern Italy was chosen as a case study. The problem refers to a single bioethanol production plant of fixed scale (160 kt/y of ethanol) which is supplied with the necessary biomass (corn, stover or both) cultivating a hypothetical land surface of limited extension. The approach proposed by Giarola *et al.* (2011) has been adopted to evaluate the modelling parameters related to the ethanol SC and LCA issues. WF assessment has been defined according to the methodology

proposed by Hoekstra *et al.* (2009) and the modelling parameters reveal the current level of technology development (base case). In addition, three scenarios have been analysed involving improved efficiency of agricultural irrigation (A), process water consumption reduction (B) and both of them (C). Finally, alternative approaches to by-products end-use account affecting total LCA results (e.g., allocation), are evaluated.

5. Results and discussion

The optimisation problem was solved with the CPLEX solver of the GAMS® modelling tool. The resulting set of Pareto optimal solutions (P1, P2, P3) obtained with the substitution method is shown for the base case and scenario C: Figure 1.a presents the trade-off between WF and the NPV; Figure 1.b illustrates the trade-off between the two environmental objectives. In the following, the base case results is first discussed, then the effects of increased efficiency in water consumption outlined. Finally a discussion is provided about the allocation procedure consequences on the optimisation results.

The economic optimum (point P1 in Figure 1.a) involves the establishment of the standard DGP process with DDGS sold as animal fodder. This option allows for more revenues coming from the by-product selling and results in a normalised NPV of 0.54 €/GJ. The environmental outcomes show a high impact on global warming (78.03 kg CO_2/GJ, Figure 1.b) as well as on WF (about 6.16 m^3/GJ). This configuration results in a medium stress of water withdrawals over resource availability (UNESCO-IHE, 2009).

Moving down towards a better environmental performance, (point P2 in Figure 1) the strategic investment involves the establishment of a hybrid technology with a corn/stover ratio of 1/3, where DDGS is sold as animal fodder. This solution has a lower profitability (NPV equal to 0.03 €/GJ, Figure 1.a), but leads to great improvements in the environmental performance (e.g., WF is about 1.71 m^3/GJ and GHG emissions drop down to 13.59 kg CO_2-eq/GJ).

The environmental optimum (point P3 in Figure 1) involves the establishment of a standard DAP process. The negative value for the WF (-0.046 m^3/GJ) is due to the amount of credits from electricity displacement which exceeds the water consumed along the entire SC. The carbon footprint is reduced down to 1.8 kg CO_2-eq/GJ (Figure 1.b). This is mainly due to the lower emissions resulting from stover production and conversion to ethanol when compared to conventional first generation biomass. However, this solution is not economically sustainable: the normalised NPV drops down to -4.31 €/GJ (Figure 1.a), which clearly shows the scarce competitiveness of the business due to the consistent capital costs.

The improvement of water efficiency in scenarios A, B and C does not change the optimal solutions, in terms of technology selection for the business to be established. WF changes considerably, however, dropping down to 4.1 and 0.72 m^3/GJ for solutions P1 and P2 of scenario C (with about 33% and 58% of reduction with respect to the base case). A complete cellulose-based facility (P3) will lead to a negative WF (-0.19 m^3/GJ, Figure 1), thus providing water use savings up to four times greater than the base case. The water use decrease characterising scenario C, is mainly due to improvements of irrigation efficiency for solutions P1 and P2, accounting for about 31% and 49% of WF reduction (scenario A). Being corn stover a residual feedstock, according to the substitution method, which attributes the overall water consumption to the main crop, a complete stover-based WF, solution P3 (Figure 1), is not affected by increasing efficiency of irrigation, but from process water usage optimisation, only (scenario B).

Two allocation methods have also been considered to estimate the impacts in terms of WF and GHG emissions. Price allocation gives the same trade-off between

environmental and economic purposes as those obtained with the expansion method in terms of technological selection. According to an energy allocation method, the DAP process, while minimising the GHG emissions, produces a greater WF than first generation, which becomes the most suitable solution not only on economic terms but also when considering water use impact.

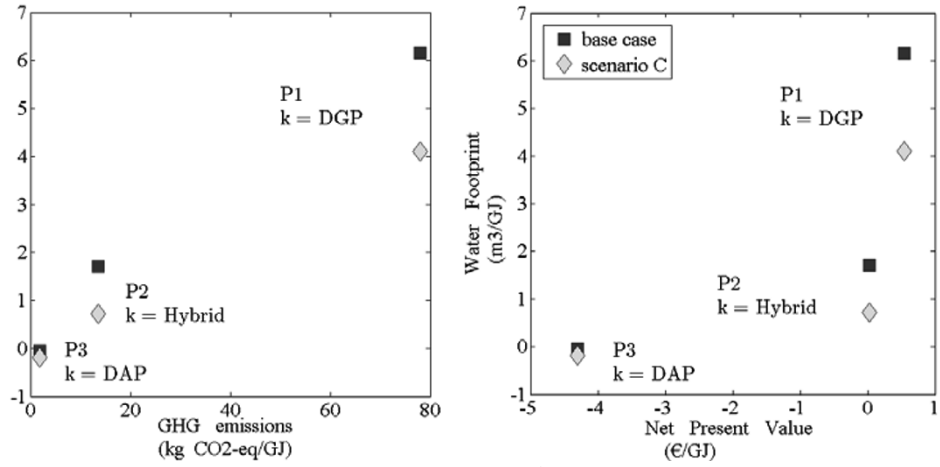

Figure 1: Pareto frontier: impact on water footprint against a) NPV, and b) GHG emissions.

6. Final remarks

A moMILP modelling framework to support strategic design and planning of biofuel systems has been developed in steering the transition towards more sustainable generation productions under both economic and environmental criteria. Results show that business strategies are influenced by the trade-off between profitability and sustainability. Some ethanol production processes (first generation) involve intensive use of water resource, but results are significantly affected by the procedure used to account for by-products end-use effect on the overall environmental SC performance.

Abstract

In the present contribution a biogas production system is systematically analysed based on the Anaerobic Digestion Model No.1 (ADM1). Steady-state solutions as well as dynamic responses after disturbances are taken into account. The stationary solutions give insights in the qualitative difference of operation conditions. Conclusions are drawn from the analysis of the transient behaviour regarding intervention strategies after disturbances.

Keywords: biogas production system, anaerobic digestion, steady-state multiplicity, ADM1

1. Introduction

Currently, the complex problems of energy supply become increasingly important. The world is faced with two main difficulties: the limitations of fossil resources, while the energy demand is rising, as well as the problems caused by increasing CO_2 emissions. In this context, the utilization of biomass is a promising option for a sustainable energy supply, because it is a renewable and easily available resource.

One technology following this direction is anaerobic digestion for biogas production. Fig. 1 shows a scheme of such a biogas plant. The essential component is the biogas fermenter, where organic matter, such as wastes or energy crops as well as cattle manure, is biochemically degraded to biogas. The biogas contains carbon dioxide and methane and can be used in power plants or fuel cells to produce electricity and heat. The remaining digestate can be used as a natural fertiliser and closes the nutrient cycle.

The anaerobic digestion process, like every biological system, is characterized by large complexity. It arises from different aspects such as a large number of metabolites and its heterogeneity with selective interactions (Kitano, 2000). Furthermore macroscopic phenomena like different phases and physical effects play an important role. In particular anaerobic digestion is a complex multi-step degradation process (see illustration Fig. 1 right hand side). Due to its structure the system shows strongly nonlinear behaviour such as steady-state multiplicity (Shen et al., 2007). Therefore a detailed stationary and transient analysis of the anaerobic digestion process is performed in the present study. The findings are applied for operation issues of biogas plants.

2. Model based approach

In the present contribution the Anaerobic Digestion Model No. 1 (ADM1) is analysed to study the complex system of anaerobic digestion. ADM1 was introduced in 2002 by

*hanke-rauschenbach@mpi-magdeburg.mpg.de

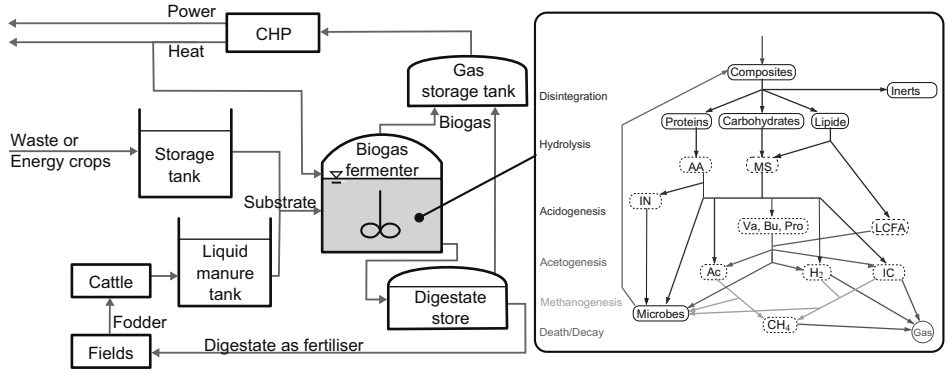

Figure 1. Scheme of components of a biogas plant (left) and reaction steps within the anaerobic digestion (right).

Batstone et al. (2002) and since then successfully used in several analyses (see e.g. review of Batstone et al. (2006)). The application not only to waste water but also to agricultural waste and energy crops has been demonstrated e.g. by Koch et al. (2010) and (Zhou et al., 2011).

ADM1 is a kinetic model and considers two compartments, namely a liquid and a gas phase. For each of them spatially lumped material balances are formulated. The biochemical reactions and the liquid-gas transfer are included through sink and source terms in the material balances. For the different processes first order kinetics and Monod kinetics are assumed. The microbial degradation processes can be inhibited by different mechanisms (e.g. pH and ammonium), which are modelled by nonlinear inhibition factors. Furthermore acid base reactions are included and assumed to be in equilibrium to determine the pH value. The liquid-gas transfer is modelled as first order kinetics with respect to Henry's law.

The complete model consists of 15 algebraic and 29 ordinary differential equations. This differential algebraic equation system was implemented in MATLAB and analysed using bifurcation theory. The results of the stationary analysis and the study of the dynamic effects are described in the next section.

3. Results

The biogas reactor has typically two input parameters which can be influenced by the operator. The first one is the dilution rate D, which can be easily changed by the flow rate of the substrate. The second one is the inlet substrate concentration $X_{\mathrm{C,in}}$. The output variables of interest are for example the methane flow rate G_{CH4}, the biogas flow rate q_{gas} or the pH value.

3.1. Steady-state operating boundary

In a first step of the analysis only the dilution rate is changed whereas the inlet substrate concentration is kept constant. It was found that depending on the operation condition

the system can reach up to ten different steady-states (not shown here). One relevant output value is the methane flow rate at the different steady-state solutions. It is shown in Fig. 2 (a). There it can be seen, that at branches III–X no methane is produced, consequently they are not desirable for the operation. Since branch II is unstable, indicated by the dashed line in Fig. 2 (a), it is also not a feasible working point. The only meaningful solution of the system is branch I, as it is stable and methane is produced.

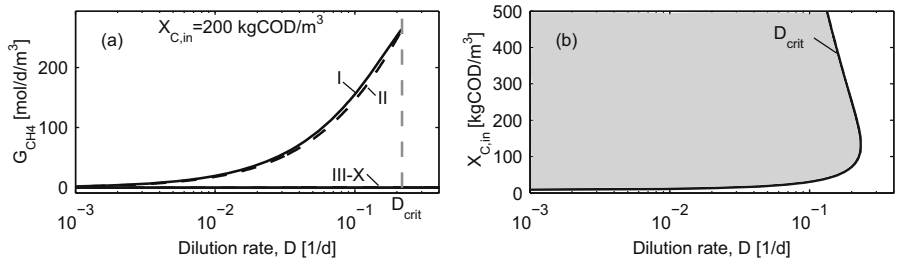

Figure 2. (a) Molar methane flow rate at steady-state solutions depending on dilution rate D and for a given inlet substrate concentration $X_{\mathrm{C,in}} = 200\,kgCOD/m^3$. *(b) Dependency of critical dilution rate* D_{crit} *on inlet substrate concentration* $X_{\mathrm{C,in}}$. *The grey area shows the feasible operating range.*

Furthermore it can be seen, that branch I ends at a critical dilution rate D_{crit}. For larger dilution rates no methane can be produced, this state is commonly known as the washout state and is obviously undesired for the system operation.

In the second step of the analysis the influence of the inlet substrate concentration on the critical dilution rate is analysed, the results are shown in Fig. 2 (b). The resulting curve is very important for the operation, since only on the left hand side (grey area) a methane producing working point is feasible. To determine a favourable operating point within that area, Fig. 3 shows the methane flow rate (3a) and the methane yield (3b).

It becomes obvious that for the operation of a biogas plant, there is a trade-off between high yield and high methane production rates. That corresponds to the considerations of higher investment costs for larger reactors against higher operation costs for a larger amount of feedstock. Typically the investment costs for the reactor are much higher than the costs for the substrate. Consequently, the biogas plants are intended to operate as close as possible to the washout line (Liu et al., 2004).

3.2. Critical disturbances: Analysis and intervention

As discussed before, the operation near the boundary curve is favourable. However, this kind of operation is risky, because the exact location is a priori unknown and due to disturbances the boundary can be crossed eventually. One can divide possible disturbances into two classes: On the one hand disturbances within the operation area, which lead to a desirable new operating point, and on the other hand the boundary crossing disturbances, that lead to washout states.

Both kinds of disturbances are systematically analysed. It was found, that they differ qualitatively in the dynamic response. Here only one example is shown (Fig. 4), namely

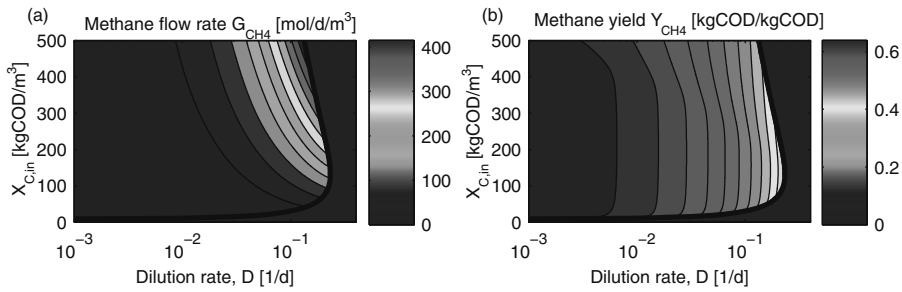

Figure 3. Steady-state solutions with respect to dilution rate D and inlet substrate concentration $X_{C,in}$: (a) Molar methane flow rate, (b) Methane yield.

an increase of the dilution rate to a higher value than the critical dilution rate at t=0 days (see Fig. 4 (b)). Fig. 4 (c) shows the transient of the volumetric flow rate of the biogas (in black). It initially increases and then rapidly decreases to a new lower value. The pH value in Fig. 4 (d) shows a continuous decrease.

The analysis of different disturbances indicates that the overshoot of the biogas flow rate in conjunction with the decrease of the pH value is typical for critical disturbances. The

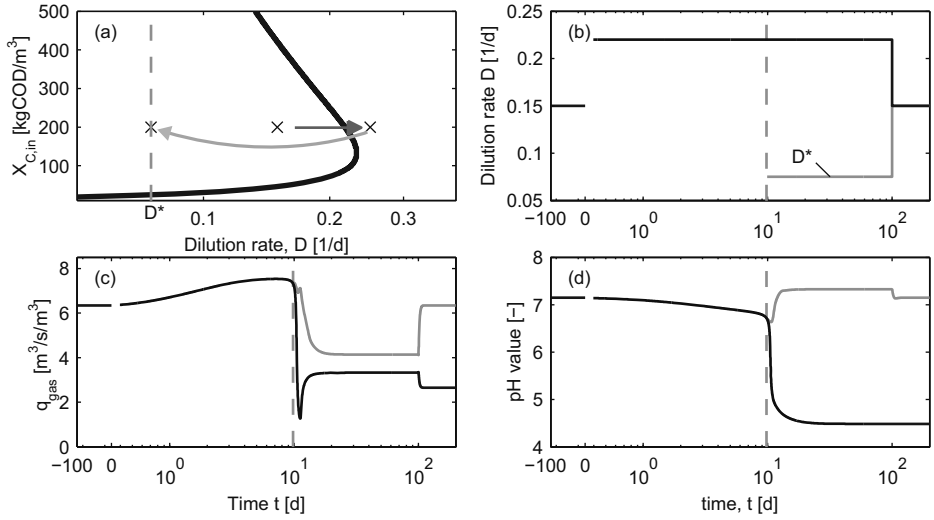

Figure 4. Dynamic system response: (a) Red arrow disturbance; grey arrow intervention, (b) Dilution rate over time, (c) Volumetric flow rate of biogas over time, (d) pH value over time.

following deduced diagnosis rule can be used as a tool to detect critical disturbances before the undesired washout state is reached.

$$\frac{\mathrm{d}q_{\mathrm{gas}}(t)}{\mathrm{d}t} = 0; \qquad \frac{\mathrm{d}q^2_{\mathrm{gas}}(t)}{\mathrm{d}^2t} < 0; \qquad \frac{\mathrm{dpH}(t)}{\mathrm{d}t} < 0 \tag{1}$$

Once the critical disturbance is detected, the operator can intervene to avoid the washout state. An example for an intervention is a reduction of the dilution rate. It is illustrated in Fig. 4 (grey lines). It can be seen, that after the intervention the old operating point can be reached again. In contrast to that without an intervention the system remains in the washout state and is not producing any methane (black line in Fig. 4).

4. Conclusions

In the present contribution ADM1 is analysed with respect to steady-state multiplicity and up to 10 coexisting stationary solutions were found depending on the input parameter. Furthermore different disturbances and intervention strategies were systematically analysed and qualitative operating diagrams were generated. They give information in what way the suggested strategy acts and whether and in which region it is successful. In a next step this theoretical considerations will be validated experimentally.

Abstract

Presented in this paper, a unified framework to optimize both water and energy usage simultaneously, together with the scheduling problem, is developed. In this manner, the timing of tasks remains a variable throughout optimization. Due to the fact that a flexible process schedule is employed, an improved result in the form of a better overall production schedule compared to the schedules obtained from optimizing water and energy separately is achievable. Opportunities for direct water reuse and indirect water reuse, using wastewater storage, were explored. Both direct and indirect heat integration were explored for reducing external utilities. The objective was to improve the profitability of the plant by minimizing wastewater generation and utility usage. The results from a case study show that the profit using only external utilities and freshwater was 18 537 cu with requirements of 390 kWh for cooling water, 240 kWh for steam and 816 kg for freshwater. The profit improved to 22 235 cu when opportunities for both direct and indirect water reuse as well as direct and indirect heat integration were explored. In this case, the requirements for cooling water, steam and freshwater were 190 kWh, 10 kWh and 896 kg, respectively.

Keywords: Wastewater minimization, heat integration, heat storage, multipurpose

1. Introduction

Utility and water requirements in many batch plants, such as in the food industry, breweries, dairies, biochemical plants and agrochemical facilities, contribute largely to their overall running costs. Heating and cooling are unavoidable aspects of many plant facilities, with operations where heat is generated and others where heat is required. It is because of this occurrence that heat integration becomes a possibility. Process equipment cleaning is usually associated with large amounts of water, due to the inherent sharing of equipment by different tasks. Hence, efficient use of water for process equipment cleaning is pursued to ensure that the amount of freshwater consumed as well as the amount of wastewater generated is minimized.

Published literature exists for the independent consideration of wastewater minimization (Gouws *et al.,* 2010; Liu *et al.,* 2009; Adekola & Majozi, 2011) and heat integration (Halim & Srinivasan, 2009; Stamp & Majozi 2011) in batch plants. The simultaneous consideration of both wastewater minimization and heat integration has been largely ignored, due to the potential complexities of such a model.

Halim and Srinivasan (2011) developed a framework that integrated scheduling, direct heat integration and direct water reuse optimization based on sequential steps. Firstly, the process schedule was optimized to meet an economic objective. This was followed by the generation of alternate schedules through a stochastic search-based integer cut procedure. These alternate schedules were used to optimize energy and water consumption with the aim of retaining the optimality of the scheduling solution. Next, heat integration analysis and water reuse synthesis were each performed to optimize water and energy requirements on each schedule.

2. Problem Statement

The problem considered in this paper can be stated as follows.
Given:

(i) Scheduling data (production recipe for each product, available units and their capacities, time horizon of interest, costs of raw materials and products)
(ii) Heat integration data (hot and cold duties of tasks, operating temperatures of tasks, minimum allowable temperature differences, design limits on heat storage, cost of utilities)
(iii) Wastewater minimization data (mass load of contaminant, maximum inlet and outlet concentration of contaminants, washing time for each unit, storage capacity for water, cost of freshwater and effluent treatment)

Determine the production schedule that achieves the maximum profit with the minimum amount of external utility and freshwater use.

3. Mathematical Formulation

The mathematical formulation consists of three modules: production scheduling, heat integration and wastewater minimization. For production scheduling, the objective is profit maximization. During production, certain tasks require cooling or heating, for instance, exothermic reactions that require cooling or endothermic reactions that require heating. The requirements for heating or cooling afford opportunities for heat integration. In multipurpose batch plants, particularly at the completion of a processing task in a unit, the equipment unit is washed before performing subsequent tasks. This is to ensure product quality and prevent contamination. The washing operations present an opportunity for wastewater minimization. For the sake of brevity, only the objective function, maximization of profit, is presented in Equation (1). The first term is product revenue, the second term is the cost of freshwater, the third term is the cost of effluent treatment, the fourth is the cost of cooling water and the last term is the cost of steam. The complete description of the heat integration constraints used in this model can be found in literature (Stamp & Majozi, 2011) and also the complete description of the wastewater minimization constraints (Adekola & Majozi, 2011). These two formulations were embedded in a production scheduling framework based on the state sequence network representation of Majozi and Zhu (2001). The overall formulation resulted in a mixed integer nonlinear problem, MINLP.

$$Max\ profit = \sum_{s}\sum_{p} CP(s)d(s,p) - CF\sum_{s_{in,j}}\sum_{p} mw_f\left(s_{in,j},p\right) - CE\sum_{s_{in,j}}\sum_{p} mw_e\left(s_{in,j},p\right) - Cost\_cw\sum_{s_{in,jh}}\sum_{p} cw\left(s_{in,jh},p\right) - Cost\_st\sum_{s_{in,jc}}\sum_{p} st\left(s_{in,jc},p\right) \quad (1)$$

4. Case Study

Consider the multipurpose batch facility in Figure 1 popularly referred to as Batch1 in literature (Kondili *et al.,* 1993), which has been adapted to suit the problem at hand. The heat integration data are given in Table 1. The production data and wastewater minimization data can be obtained from literature (Adekola & Majozi, 2011). The time horizon of interest is 12 h. The costs of steam, cooling water, freshwater and effluent treatment are 10 cu, 2 cu, 2 cu and 3 cu (cost units) respectively.

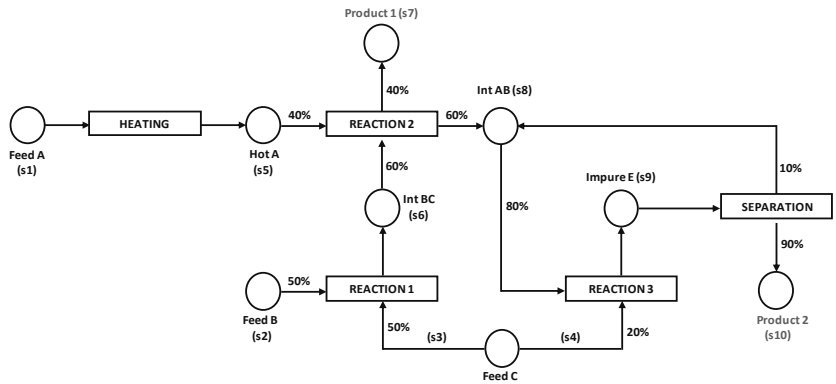

Figure 1.Multipurpose batch facility, Batch1.

Table 1.Heat integration data.

Reaction	Type	Heating/cooling requirement (kWh)	Operating Temperature (°C)
RX1	exothermic	60 (cooling)	100
RX2	endothermic	80 (heating)	60
RX3	exothermic	70 (cooling)	140

The case study was solved with GAMS 22.0 using the DICOPT2 algorithm, with CPLEX 9.1.2 as the MIP and CONOPT3 as the NLP solvers. Different variations of the case study were solved to demonstrate the capabilities of the developed model, the results of which are provided in Table 2. These variations are as follows:

- Production scheduling + freshwater + hot and cold utilities
- Production scheduling + freshwater + direct water reuse + hot and cold utilities + direct heat integration
- Production scheduling + freshwater + direct/indirect water reuse + hot and cold utilities + direct/indirect heat integration

Direct water reuse refers to the use of an outlet wastewater stream from a processing unit in another processing unit. Indirect water reuse refers to the use of previously stored wastewater in a procesing unit. Similarly, direct heat integration refers to the use of heat generated from a processing unit, in a processing unit requiring heat. Indirect

heat integration refers to the use of heat previously stored in a heat storage vessel by a processing unit requiring heat. The storage capacity for indirect water reuse was given to be 200 kg. In the case of indirect heat integration, heat is stored through a fluid medium. The storage capacity and the initial storage temperature of the storage vessel are variables to be optimized (Stamp & Majozi 2011). Heat losses were not considered.

Table 2.Results of the case study.

	Freshwater and utilities	Direct water reuse and direct heat integration	Direct/indirect water reuse and direct/indirect heat integration
Profit (cu)	18 537	19 836	22 235
Cooling water (kWh)	390	250	190
Steam (kWh)	240	180	10
Freshwater (kg)	816	1 020	896
Time points	11	11	13
CPU time (s)	9.9	110.7	176 705
Binary variables	128	508	954
Initial storage temperature (ºC)			82.9
Heat storage capacity (ton)			2.024

From Table 2 it can be observed that the inclusion of both indirect water reuse and indirect heat integration lead to a substantial decrease in both the utility and freshwater requirements. The resulting process schedule for the results in column 4 is illustrated in Figure 2.

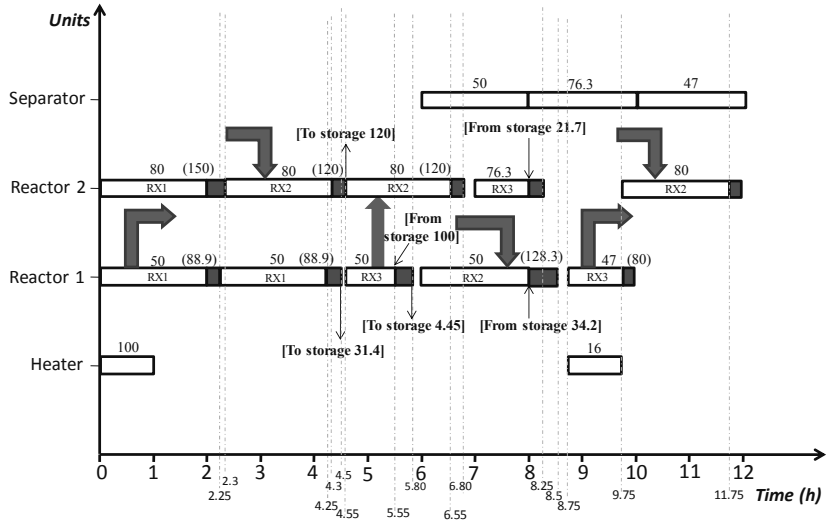

Figure 2. Resulting process schedule when both direct/indirect heat integration and wastewater minimization are possible.

The clear blocks represent the production operation in the unit while the dark blocks represent the washing operations which take place after tasks are completed. The numbers above the clear blocks represent the amount of raw material used in the unit for

production and the numbers in brackets represent freshwater. Water transfer to and from storage has been clearly labelled. The straight arrows represent direct heat integration, while the bent arrows represent indirect heat integration to or from the heat storage unit.

A comparison was made between the simple sequential profit maximization problem from Halim and Srinivasan (2011). The results can be seen in Table 3. The overall profit improved in the simultaneous case when compared to the sequential method.

Table 3.Statistics of profit maximization comparison.

	Halim & Srinivasan (2011)	Proposed formulation
Profit ($)	4 764	4 773
Cooling water duty (MJ)	313.9	319
Steam duty (MJ)	43.9	11.5
Freshwater (kg)	1238.4	1086
Time points	7 (slots)	9
CPU time (s)		500

5. Conclusions

In the presented method, wastewater minimization and heat integration are both embedded within the scheduling framework, thus leading to a truly flexible process schedule. Results from a case study show that profit maximization together with heat integration and wastewater minimization were achieved. The profit using only external utilities and freshwater was 18 537 cu with requirements of 390 kWh for cooling water, 240 kWh for steam and 816 kg for freshwater. The profit improved to 22 235 cu when opportunities for both direct and indirect water reuse as well as direct and indirect heat integration were explored. In this case, the requirements for cooling water, steam and freshwater were 190 kWh, 10 kWh and 896 kg, respectively. The optimality of the case study solution was determined using the procedure used by Adekola and Majozi (2011) and Stamp and Majozi (2011).

Evaluation of coal-based dimethyl ether production system using life cycle assessment in South Korea

Seunghyok Kim[a], Jaeha Kim[a], En Sup Yoon[a,b] *

[a] *School of Chemical and Biological Engineering, Institute of Chemical Processes, Seoul National University, Seoul, Republic of Korea*

[b] *Automation System Research Institute, Seoul National University, Seoul, Republic of Korea*

Abstract

Dimethyl ether is one of the sustainable energy sources because it is clean and easy to handle. DME can be produced from various materials such as coal, natural gas (NG), and biomass. Actually, NG-based DME plant is in operation in Korea. Many studies have also investigated NG-based processes and reactor design needed for use of dimethyl ether. Unlike the previous studies, this study focuses on DME production system using coal as a raw material. Coal is drawing attention as the upcoming energy source due to the depletion of oil in Korea. Whereas Korea depends entirely on imports for crude oil, coal can be supplied by domestic production. To decide coal as a raw material, we need to assess the competitiveness of coal. A life cycle assessment of coal-based DME production system was performed to evaluate environmental impact and energy consumption. The assessment of coal-based DME production system with respect to the environment and energy use is essential for sustainable DME production in Korea. The aim of this study was to analyze the amount of CO_2 emission and energy consumption of coal-based DME production. The life cycle of DME production includes the mining of coal, pretreatment of the mined coal, transportation to the DME production plant, and DME conversion. Related data and the assumptions pertinent to South Korea are introduced and adopted as a case study.

Keywords: life cycle assessment, dimethyl ether, coal-based DME production

1. Introduction

Ensuring of energy security may be major challenges to secure national competitiveness. The current crisis regarding the depletion of oil resources around the world demands the development of a next generation energy system in many countries. Korea is no exception; actually Korean government has invested many efforts to control its energy situation for sustainable development. Among the candidates for upcoming energy resources, dimethyl ether (DME) is one of the most favorable because it can easily replace conventional fuels and is more eco-friendly than traditional fuels.

DME can be synthesized in at least two steps. The first is the synthetic gas (syngas) generation step; hydrocarbons obtained from natural gas, coal, or biomass are converted to synthetic gas (syngas), which is a combination of carbon monoxide (CO) and hydrogen gas. The second is the DME conversion step; the obtained syngas is converted to

*esyoon@pslab.snu.ac.kr

DME by several processes. DME conversion process has two different methods. These methods are indirect synthesis and direct synthesis. Indirect synthesis requires two reactors for methanol synthesis and dehydration whereas direct synthesis produces DME directly from syngas and does not include the intermediate steps of methanol production and purification.

The commercial DME plant using direct synthesis method have been in operation in Korea. The natural gas (NG) is now used as a raw material for DME production. Meanwhile, a coal is in the limelight for DME production because the domestic consumption of NG is growing rapidly. Korean government needs to seek alternatives to replace the NG as the price of NG grows. In this study, a DME production system from coal is analyzed for an entire life cycle. For sustainability, the analysis considers the factors of energy and carbon dioxide emission, and the life cycle of DME production includes the mining of coal, pretreatment of the mined coal, transportation to the DME production plant, and DME conversion. All processes for DME synthesis are simulated using an ASPEN Plus simulator. Recent technologies pertinent to practical plant in Korea and Korean energy situation data are introduced in the case study.

2. LCA of DME production processes

2.1. Life cycle assessment (LCA)

Life cycle assessment (LCA) is a technique used to identify the environmental load and lessen environmental impact, and a critical factor determining policy decisions. The main aim of LCA is to quantify and compare the full range of environmental impacts of materials and/or processes. In this study, LCA is used to evaluate coal as a raw material for DME production. Obtaining raw materials, pretreatment, manufacture, transportation, use and disposal are all involved in the life cycle. As a rule, LCA is comprised of four phases with include goal and scope definition, inventory analysis, impact assessment, and interpretation.

2.2. Goal and scope definition

The goal of this study is to assess the environmental impact (e.g. CO_2 emission) and energy impact of the entire DME production process. The prospective raw material in this study is coal. The scope of the DME production process includes the pretreatment of coal, transportation, and conversion. The main structure of the system is shown in Figure 1, and a detailed description will be presented in subsequent sections.

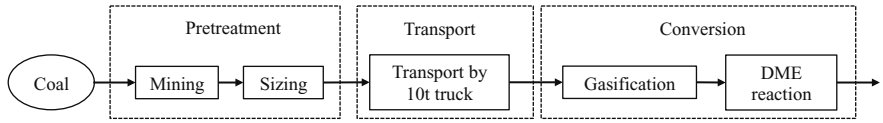

Figure 1. Block diagram of DME production

2.3. Inventory analysis

As previously mentioned, a coal is treated in accordance with the defined scope. The pretreatment process represents improvement of the quality of raw coal for DME conver-

sion. The transportation process includes movement of coal to the DME production plant, and the conversion process includes syngas production and the DME reaction. These inventories are simulated using an Aspen Plus simulator based on some assumptions. The capacity of a DME plant is assigned as 1,000 t/day, which is the practical target in a Korea Gas Corporation (KOGAS) DME plant (Baek et al., 2010). The amount of CO_2 emission and energy consumption is adopted for inventory analysis, the intensity term is introduced. The intensity parameters can be calculated by Equations (1) and (2).

$$\text{CO}_2 \text{ emission intensity}_{inv} = \frac{w_{CO_2,inv}}{PE_{DME}} \tag{1}$$

$$\text{Energy intensity}_{inv} = \frac{\sum_{inv}(FE+RE)}{PE_{DME}} \tag{2}$$

where *inv* represents each inventory. In the numerator terms of two impact parameters, w indicates weight of materials while FE and RE are consumed fuel energy and required energy in process, respectively. In the denominator, PE_{DME} stands for total produced DME energy.

Coal is assumed to be obtained by mining at Taebaek in Korea. The methods of mining are open-cut mining and underground mining. In Korea, most mines are in mountainous districts, and underground mining is favored. Table 1 shows the energy consumed and the amount of CO_2 produced by coal mining.

Table 1. Energy consumption and CO_2 emission for mining coal

	Coal mining	Unit
Electricity	19.4	[kWh/t coal]
Diesel	0.66	[L/t coal]
CO_2 emission	0.228	[gCO_2/MJ coal]

Coal is mined in an irregular size, and should be sized uniformly. Sizing process can be simulated by Aspen Plus. The coal is mixed with water and sent to a crusher that pulverizes the coal to a maximum particle diameter of 0.0002m. Then, coal is moved to the Incheon base by 10 t-trucks. For truck transportation, CO_2 emissions and the required energy are related to the fuel consumption of the truck, which can be expressed as a function of the loading rate of weight (Dowaki and Genchi, 2009) (Equations (3)-(5)).

$$f_{FC}(\lambda) = a\lambda + b \tag{3}$$

$$\lambda_{avg} = \frac{w_{material}}{10N_{material}} \tag{4}$$

$$N_{material} = \left(\frac{w_{material}}{24.7\rho}\right) + 1 \tag{5}$$

where a(=714 gCO_2/km) and b(=508 gCO_2/km) are constants on the fuel consumption, ρ indicates bulk density of materials and N is total number of transportation (Dowaki and Genchi, 2009). The data for coal transportation in Korea is listed in Table 2.

Table 2. Data of coal transportation

	Transportation	Unit
Bulk density (coal)	1,056	[kg/m^3]
Distance (round trip)	540	[km]
CO_2 emission	3.015	[gCO_2/g diesel]
Fuel efficiency	2.4	[km/L diesel]

In conversion process, the gasification for generating syngas is required. The gas cleaning process should be included to remove sulfur and CO_2 in the feed stream. The CO_2 removal process removes CO_2 in the generated syngas stream using methanol as a solvent. After the gas cleaning process, DME synthesis and DME purification process are required. The block diagram of proposed process is shown in Figure 2.

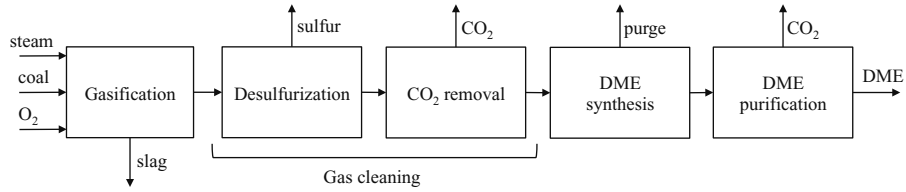

Figure 2. Block diagram of conversion processes of DME production from coal in Aspen Plus environment

In the DME synthesis block, which is for DME reaction, the direct method (one-step) is used. The products of the DME reaction, which are DME, syngas, methanol, water, and CO_2, pass through the DME purification section to separate DME. The property methods for simulation are SRK when substances have a vapor phase behavior and RKSMHV2 when substances have a vapor-liquid phase behavior (Kim et al., 2010).

3. Results of impact assessment and its interpretation

Table 3 shows simulation results. As previously mentioned, the Incheon plant produces DME of 1,000 t/day. Energy efficiency means produced DME energy per each feed potential energy.

Figure 3 shows the resulting CO_2 emission intensity and energy intensity of the inventories for coal. The conversion process plays an important role in both intensities. This implies that a CO_2 capture system used for DME production from coal should be developed and added in conversion process.

4. Conclusion

DME is widely used as a commercial fuel, and therefore, Korea does need to develop DME production technologies and cultivate the market for sustainable development. In

Table 3. Results of energy consumption and CO_2 emission in DME production

	DME [ton]	Feed [ton]	Total CO_2 [ton]	Energy efficiency	CO_2/DME [gCO_2/MJ]	Required energy [MJ]
Coal	1,000	1,956	1459.15	0.475	48.23	1,977,528

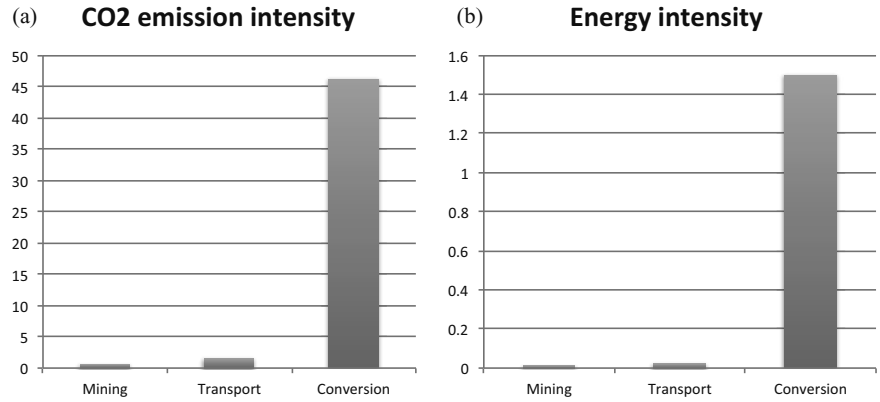

Figure 3. Results of (a) CO_2 emission intensity and (b) energy intensity in life cycle

this study, life cycle assessment of DME production using coal was conducted in terms of CO_2 emission and energy consumption. The goal, scopes, and inventories were defined to implement life cycle assessment. Practical data from Korea and several assumptions were adopted for this case study, the pretreatment process and DME conversion process were simulated using an Aspen Plus simulator to evaluate the amount of feed, CO_2 emission, and energy consumption. Results showed that the conversion process should be improved in terms of CO_2 emission.

Abstract

We present a systematic approach of information modeling towards more systematic consideration of environmental, health and safety aspects during process design. Unified modeling language (UML) and type zero method of integrated definition (IDEF0) are applied for analyzing and defining required information in the comprehensive process evaluation. The proposed model visualizes the procedures of multiple assessments on various aspects of process system with data acquisition in process design and operation. Collaborated information modeling by UML and IDEF0 enables the discussion of integrated software system supporting process assessment within process development.

Keywords: activity modeling, information modeling, life cycle assessment, risk assessment, process development.

1. Introduction

In the development of chemical processes, it has become a common practice to consider various consequences of decisions, i.e. not only direct profit, but also non-monetary aspects. Among others, environment, health, and safety (EHS) issues have been gaining increasing attentions, for preventing short term as well as long term damages to companies. Various methods have been developed, which can be used for identifying weak points needing technical countermeasures, or comparing different process options for prioritized investment of resources. The scope differs between methods, e.g., hazard assessment focuses more on the accidental issues around the place where chemicals are used, while life cycle assessment (LCA) highlights longer term and steady-state impacts via the environment. Ideally, multiple assessment methods should be applied in order to reflect impacts on various areas into decisions. However in practice, companies are facing challenges in (1) collecting required data for executing non-conventional assessment such as LCA (2) combining various assessment results in making a decision (3) systematizing tools, data and activities across different units/departments.

The key steps to close these gaps are to precisely (re)define required data, information, simulation tools and mechanisms at different stages of assessment and to present the entire as a business model. Several contributions can be found in the field of PSE/CAPE, such as extensive application of information technology (Schneider and Marquardt

2002), or effective connection of various computer-aided design tools by developing design ontology for sharing data over different design tools (Marquardt et al. 2010; Wiesner et al. 2011).

In this study, we present a business-model based approach for analyzing information required for multiple assessment methods, with a specific focus on environmental LCA and EHS hazard assessment. In the business process analysis, we have applied type zero method of integrated definition (IDEF0) (Ross 1985) and unified modeling language (UML) (OMG 2011) in a combined manner to exploit strength of both methods. For EHS hazard assessment, where various contributions can be found, a method by Koller et al. (2000) was selected as an example.. Having understood characteristics of required data, difficulty will still remain in operationalizing multiple assessment methods, especially in data collection and information/tool integration. To guide a gradual development for industry, four levels of maturity have been defined according to the degree of tool and information integration, which could be distinguished in the collaborative use of IDEF and UML.

2. Method

2.1. Information required for process assessment

Figure 1 presents the syntax of IDEF0 and UML. In industry, IDEF0 is widely used especially in the field of business process reengineering (BPR). The feature of IDEF0 is the hierarchical break down of "activities" into "sub activities" with keeping consistency of input and output on all different levels. Here, three types of "input" are differentiated: (1) input – can be transformed to "output" (2) constraint – unchangeable input and (3) mechanism – required in executing an activity. Several authors applied IDEF0 in integrating new or existing engineering methods and tools for environmental protection and EHS risks in chemical process design (Sugiyama et al. 2008) and other industrial process design (Kikuchi and Hirao 2009). UML for systems modeling has a large potential to visualize data requirements clearly for software tools from design stages to maintenance and sustainment stages in companies' activities. In UML class diagram, information categories are structured and characterized by specifying their properties and relationships. In addition to the static modeling by UML class diagram, dynamic information flows among information providers involved in process assessment such as assessment engineers, operators, and process designers can be discussed on UML activity diagram.

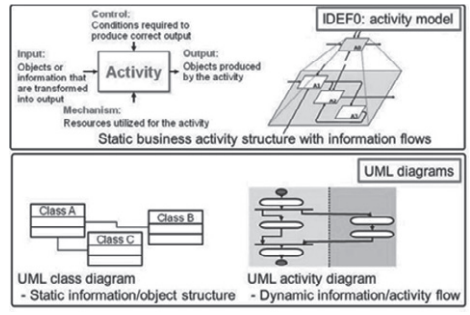

Figure 1 Syntax and basic features of IDEF0 and UML

Activity model by IDEF0 can be a highly re-usable concept of implementing multiple assessments into practice. It can be a strong rationale of business model. UML is

capable of showing more usable models, which are static structure of elements included in information system and dynamic work flow. We attempt to apply both methods in order to analyze truly required activity and information conceptually and practically.

2.2. Analyzed process assessment method

LCA quantifies various environmental impacts throughout the "life cycle" of a product or a service, e.g. from raw material production to the final disposal. Although there are ongoing researches mainly in individual impact assessment methods, e.g. global warming, or acidification, it is commonly agreed that an LCA of a chemical process requires mass and energy balances. On contrary, input information for EHS hazard differs from method to method (Adu et al. 2008). The EHS method is data-intensive, in order to cover wide range of hazard elements, and thus was selected for analyzing the complexity of information transfer as well as creating a robust business process model.

3. Results and discussion

3.1. Information required for process assessment

Figure 2 shows a general activity model of process assessment utilizing multi assessment methods on the basis of an activity modeling template (Sugiyama et al. 2008) and existing process improvement framework (Kikuchi and Hirao 2009). Figure 3 shows the example of developed information models of assessment method, where EHS method is analyzed. Based on the developed IDEF0 and UML models, the process assessment using LCA and EHS method was analyzed. While LCA considers only material and energy input/output per functional unit (e.g., kg-product), hazard assessment methods can also require additional properties such as temperature of stream, as expressed in conditions of steam in Figure 3. This can lead to disagreement of results in LCA and hazard assessment.

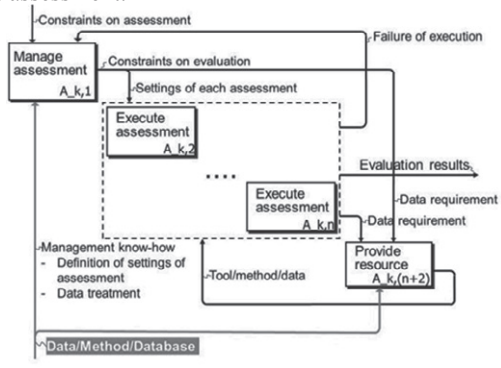

Figure 2 A part of developed general-activity model of process assessment utilizing multiple assessment methods

In our proposed model, information required in process assessment is differentiated into three categories; general, assessment-specific and technical data. Technical data is a set of information specific to the process, which can be represented by "condition of streams" such as flow rates and "condition of units" such as reaction conversions or structure of unit operations such as reactor, distillation column, and tank in chemical process. Typically, these data are primarily available to process engineers and thus technical data must be collected by process engineers for hazard assessment and LCA.

Assessment-specific data e.g., normalization methods of quantifying process hazards or life cycle impact factors, is independent of the process to be evaluated, i.e. can be

separately stored. Some existing databases on assessment methods (Swiss Centre for Life Cycle Inventories 2011) are applicable. All other related data for assessment is categorized into general data. It includes not only physicochemical data such as properties of chemical substances, but also plant-specific conditions and project-specific settings such as local regulation, ambient surroundings, budget and timeline.

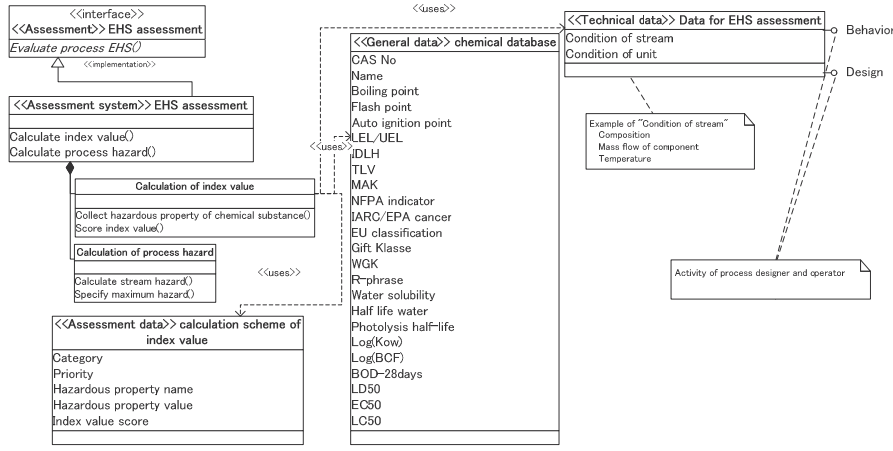

Figure 3 UML class diagram of assessment method: an example of EHS assessment methods

3.2. Maturity level of systematic process assessment

Figure 4 presents different levels of organization from poor to matured status, considering the degree of integrating and sharing process information, simulation software and assessment data. At an initial level or Level 0, no systematic information sharing exists on process assessment; therefore engineers, being responsible for process assessment, must collect all required data for each assessment method, i.e. general, assessment-specific and technical data. In some cases, engineers have to study and understand the assessment method to extract required process data and to create a calculation model. At Level 1, all methods are understood and data requirements are listed up. This unifies the data collection procedure for each design cases. However, the collection itself is repeated at each design project. Process manager can facilitate process assessment with process design and behavior in Level 2 by sharing knowledge on assessment methods. At Level 2, knowledge from past design cases or other sites are well shared within process engineering group. However, the group manager has to trigger the assessment activity, i.e. actively collect data and information. Finally at Level 3, tools and assessment methods are systematically connected during all activities of the design. This means, for example, a full and online integration of process simulator with LCA or hazard assessment. As shown in Figure 4, the combination of static and dynamic models by IDEF0 and UML enabled distinction of different maturity levels, which serves as a guidance to companies for organizational development. This application is not limited to incorporation of LCA and EHS but to any other assessment methods.

4. Conclusion

We developed information models described by a unique combination of UML and IDEF0 for systematizing process assessment methods. These models visualize the procedures of multiple assessments on various aspects of process system with data

acquisition in process design and operation. Through this study, we concluded that visualization of information and activities enables detail indication of process information required for assessment methods. Collaborated information modeling by UML with business activity modeling by IDEF0 enables the discussion of integrated software system used in process assessments within plant life cycle.

Correlations among Footprints within Biomass Energy Supply-Chains

Lidija Čuček,[a] Jiří J. Klemeš,[b] Petar S. Varbanov,[b] Zdravko Kravanja[a]

[a]*Faculty of Chemistry and Chemical Engineering, University of Maribor, Smetanova ulica 17, 2000 Maribor, Slovenia, e-mail: zdravko.kravanja@uni-mb.si*
[b]*Centre for Process Integration and Intensification – CPI², Research Institute of Chemical and Process Engineering, Faculty of Information Technology, University of Pannonia, Egyetem utca 10, 8200 Veszprém, Hungary*

Abstract

In this contribution correlations among different direct footprints are studied within a multi-objective optimisation (MOO) where profit is maximised vs. footprints in the synthesis of biomass energy supply-chains. We investigate correlations among two-dimensional (2D) Pareto projections of carbon footprint (CF), energy footprint (ENF), water footprint (WF), water pollution footprint (WPF), land footprint (LF) and food-to-energy footprint (FEF). 'Dependent' footprints are i) linearly and ii) nonlinearly correlated with respect to a chosen 'independent' one (CF). The MOO is performed only for one footprint, the 'independent' one, rather than for all of them whilst the rest of the 'dependent' footprints are evaluated after the optimisation from the independent one. In this way, the number of optimisation runs in the MOO can be substantially reduced.

Keywords: footprint, multi-objective optimisation, bioenergy supply-chain, correlations among footprints.

1. Introduction

Environmental and social concerns are becoming increasingly important in many areas (Guillén-Gosálbez, 2011). Plenty of indicators measuring environmental and social issues have been developed, amongst them also footprints. They are usually measured in units of area, and one of the most well-known is the ecological footprint. However, the data expressed in units of area show high variability and the high inherited inaccuracy since they could be based on a variety of different assumptions (Wiedmann and Minx, 2008). Converting some of the footprints to area units can prove to be even problematic, especially for processes that are not primarily area-based (De Benedetto and Klemeš, 2009). In many studies only one footprint is considered and evaluated, which most likely leads to inaccurate conclusions. It is much more realistic when more impacts are considered. However, the reduction and aggregation of different objectives have mostly relied on the decision-makers' preferences rather than on a systematic mathematical approach (Guillén-Gosálbez, 2011).

This contribution presents the MOO method of reduced dimensionality (2D) with emphasis on environmental footprints. The correlations among 2D projections of footprints are investigated. 'Dependent' footprints are aggregated and expressed through one, selected as independent, footprint only. This approach with correlated footprints is applied to the aggregated regional biomass supply chain (Čuček et al., 2010, 2012).

2. Description of the Proposed Methodology

2.1. The Multi-Criteria Approach

The conventional way of obtaining 2D projections for footprints is to perform the MOOs by the use of ε-constraint method. A sequence of constrained single-objective mixed-integer non-linear programming $(\mathrm{MINLP}_j)_f$ problems is thus solved for each footprint $f \in F = \{\mathrm{CF}, \mathrm{ENF}, \mathrm{WF}, \mathrm{WPF}, \mathrm{LF}, \mathrm{FEF}\}$ as the maximisation of the profit (P) subjected to a relative footprint, $f^r_{j,f}$, where $f^r_{j,f}$ is defined as the footprint obtained by MOO, divided by its reference value obtained at the maximal profit. During the sequence of $(\mathrm{MINLP}_j)_f$ the footprint is forced to decrease sequentially from its maximal value $(f^r_{j,f} = 1)$ by a suitable step size $\Delta\varepsilon$ until there is no feasible solution. Different sets of non-inferior Pareto optimal solutions are generated, one for each footprint:

$$\max_{x,y} \; P = \boldsymbol{c}^{\mathrm{T}}\boldsymbol{y} + f(\boldsymbol{x}) - \sum_f 10^{-6} \cdot ENVB_f - \sum_f 10^{-6} \cdot SOCB_f$$

$$\text{s.t.} \quad \boldsymbol{A}\boldsymbol{y} + \boldsymbol{h}(\boldsymbol{x}, \boldsymbol{y}) = 0$$

$$\boldsymbol{B}\boldsymbol{y} + \boldsymbol{g}(\boldsymbol{x}, \boldsymbol{y}) \le 0 \qquad (\mathrm{MINLP}_j)_f$$

$$f^r_{j,f}(\boldsymbol{x}, \boldsymbol{y}) \le \varepsilon_{j,f}$$

$$(\boldsymbol{x}^{\mathrm{LO}} \le \boldsymbol{x} \le \boldsymbol{x}^{\mathrm{UP}}) \in \boldsymbol{X} \subset \boldsymbol{R}^n, \quad \boldsymbol{y} \in \boldsymbol{Y} = \{0,1\}^m$$

$$\varepsilon_{j-1,f} = \varepsilon_{j,f} - \Delta\varepsilon, \quad \Delta\varepsilon = \frac{1}{N}, \quad \varepsilon_{j,f} = \frac{1}{N} \cdot (j-1), \quad j = \{1,\ldots,N+1\}$$

With the above described approach two-criterion optimisation is performed for each footprint in all the points defining the Pareto curves, which is a time-consuming task especially if complex MINLPs have to be solved. The intention of this work is to replace the reiterated generation of two-dimensional (2D) projections by linear or more accurate quadratically-based correlations. If we select CF as an 'independent' footprint $(i \in I \subset F$, I = {CF}), and perform ε-constrained $(\mathrm{MINLP}_j)_{\mathrm{CF}}$, then all other 'dependent' footprints' 2D projections ($d \in D \subset F$, D = {ENF, WF, WPF, LF, and FEF}) can be evaluated from the CF' projection.

2.2. Methodology for Obtaining Linear Correlations among Footprints' 2D Projections

For 'independent' footprint the MOO is performed in order to obtain sets of Pareto optimal solutions defined at points $\left(f^r_{j,f}, P_{j,f}\right)$, $j = \{1,\ldots,N+1\}$. For the rest of 'dependent' footprints only two MINLPs are performed, one at zero and one at unit value of relative footprints. In this way, two data points can be defined: $\left(f^r_{1,f}, P_{1,f}\right)$ and $\left(f^r_{N+1,f}, P_{N+1,f}\right)$. From the first and last points the following linear function for each footprint can be derived:

$$P_{j,f} = k_d \cdot f^r_{j,f} + P_{1,f}, \quad f \in F, \quad f^r_{j,i} = (1/N) \cdot (j-1), \quad j = \{1,\ldots,N+1\} \tag{1}$$

where k_d is the slope of the line, and N is e.g. 20.

The profit of the linearly-correlated 'dependent' footprint, $P_{j,d}$, should be equal to the one of the 'independent' footprint, $P_{j,i}$:

$$k_d \cdot f^r_{j,d} + P_{1,d} = k_i \cdot f^r_{j,i} + P_{1,i}, \quad \forall d \in D \wedge \forall i \in I \wedge d \ne i, \quad f^r_{j,i} = (1/N) \cdot (j-1), \quad j = \{1,\ldots,N+1\} \tag{2}$$

The line equations Eq. (3, 4) for each 'dependent' footprint can be expressed through 'independent' footprint from Eq. (2):

$$f_{j,d}^r = \frac{k_i}{k_d} \cdot f_{j,i}^r + \frac{P_{1,i} - P_{1,d}}{k_d} = \frac{P_{j,i} - P_{1,d}}{k_d}, \forall\, d \in D \wedge \forall\, i \in I \wedge d \neq i, f_{j,i}^r = (1/N) \cdot (j-1), j = \{1,\ldots,N+1\} \quad (3)$$

$$f_{j,d}^r = \max\left\{0, \frac{P_{j,i} - P_{1,d}}{k_d}\right\}, \quad \forall\, d \in D \wedge \forall\, i \in I \wedge d \neq i, \quad j \leq \{1,\ldots,N+1\} \quad (4)$$

Note that max operator is introduced in order to prevent negative values.

2.3. Methodology for Obtaining Quadratically-Based Correlations among Footprints

In order to obtain quadratically-based correlations among footprints, now three data points were selected, at zero, half and unit values of footprints: $\left(f_{1,f}^r,\, P_{1,f}\right)$, $\left(f_{(N+1)/2,f}^r,\, P_{(N+1)/2,f}\right)$ and $\left(f_{N+1,f}^r,\, P_{N+1,f}\right)$. The profits for quadratically-based correlated footprints are defined as:

$$P_{j,f} = b_f \cdot (f_{j,f}^r)^2 + c_f \cdot f_{j,f}^r + e_f, \ \forall f \in F, f_{j,f}^r = (1/N) \cdot (j-1), \ j = \{1,\ldots,N+1\} \quad (5)$$

Parameters b_f, c_f and e_f are obtained through the following relations: $b_f = a_{f,2}$, $c_f = a_{f,1} - a_{f,2} \cdot (f_{1,f}^r + f_{(N+1)/2,f}^r)$ and $e_f = a_{f,0} - a_{f,1} \cdot f_{1,f}^r + a_{f,2} \cdot f_{1,f}^r \cdot f_{(N+1)/2,f}^r$, where:

$a_{f,0} = P_{1,f}$, $a_{f,1} = \dfrac{P_{(N+1)/2,f} - P_{1,f}}{f_{(N+1)/2,f}^r - f_{1,f}^r}$, and $a_{f,2} = \dfrac{1}{(f_{N+1,f}^r - f_{(N+1)/2,f}^r)} \cdot \left(\dfrac{P_{N+1,f} - P_{1,f}}{f_{N+1,f}^r - f_{1,f}^r} - \dfrac{P_{(N+1)/2,f} - P_{1,f}}{f_{(N+1)/2,f}^r - f_{1,f}^r}\right)$.

Since the profit of the correlated 'dependent' footprint must be equal to the one of the 'independent' footprint, it follows:

$$b_d \cdot (f_{j,d}^r)^2 + c_d \cdot f_{j,d}^r + e_d = b_i \cdot (f_{j,i}^r)^2 + c_i \cdot f_{j,i}^r + e_i, \quad \forall\, d \in D \wedge \forall\, i \in I \wedge d \neq i, f_{j,i}^r = (1/N) \cdot (j-1), \ j = \{1,\ldots,N+1\} \quad (6)$$

Each 'dependent' footprint is then expressed from Eq. (6) through the 'independent' one as:

$$(f_{j,d}^r)_{1,2} = \frac{-c_d \pm \sqrt{(c_d)^2 - 4 \cdot b_d \cdot (e_d - (b_i \cdot (f_{j,i}^r)^2 + c_i \cdot f_{j,i}^r + e_i))}}{2 \cdot b_d}, \ f_{j,d}^r = \max\left\{0, f_{j,d_{1,2}}^r\right\} \quad (7)$$

It should be noted that besides MINLPs needed to define the Pareto curve of the chosen 'independent' footprint we have to perform now three additional MINLPs for each 'dependent footprint in order to generate 2D projections of 'dependent' footprints.

3. Case Study of Biomass Energy Supply-Chains

The simple methodology described above was applied on a case study of biomass energy supply-chains (Čuček et al., 2010, 2012) to derive 2D Pareto projections for a multi-criteria problem.

Biomass and bioenergy supply chains involve harvesting (agricultural layer), storage and pre-treatment (pre-processing layer), conversion steps (processing layer), distribution and usage of products (use layer), and transport amongst their activities. The total area of the region was assumed as 1,000 km^2. Several biomass types, technology options, and bio-products have been considered in the synthesis. The biomass types utilised were corn, corn stover, wood chips, municipal solid waste (MSW), manure, and timber. The technologies for converting biomass were the dry-grind process, anaerobic digestion, MSW incineration, timber sawing and incineration, and the produced bio-products were bioelectricity, bioheat, bioethanol, boards, organic

fertiliser, and distiller dried grains with solubles. The required data for obtaining correlations among footprints are presented in Table 1.

Table 1. Required data for obtaining linear and quadratically-based correlations among footprints

Footprint	$P_{1,f}$ (M€/y)	$P_{(N+1)/2,f}$ (M€/y)	$P_{N+1,f}$ (M€/y)
CF	$0.162 \cdot 10^{-6}$	19.743	34
ENF	0	20.937	34
WF	$-7.259 \cdot 10^{-2}$	20.536	34
WPF	0.748	19.388	34
LF	2.360	19.429	34
FEF	26.104	30.050	34

From the above data, the obtained linear and nonlinear (based on quadratic function) correlations among footprints are shown in Table 2.

Table 2. Obtained linear and nonlinear correlations among footprints

Footprint	Linear correlation	Nonlinear correlation based on quadratic function
ENF	$f^r_{j,\mathrm{ENF}} = f^r_{j,\mathrm{CF}} + 4.77 \cdot 10^{-9}$	$f^r_{j,\mathrm{ENF}} = 1.58 \pm \sqrt{0.70 \cdot (f^r_{j,\mathrm{CF}})^2 - 2.86 \cdot f^r_{j,\mathrm{CF}} + 2.50}$
WF	$f^r_{j,\mathrm{WF}} = 0.10 \cdot f^r_{j,\mathrm{CF}} + 2.13 \cdot 10^{-3}$	$f^r_{j,\mathrm{WF}} = 1.69 \pm \sqrt{0.77 \cdot (f^r_{j,\mathrm{CF}})^2 - 3.15 \cdot f^r_{j,\mathrm{CF}} + 2.86}$
WPF	$f^r_{j,\mathrm{WPF}} = 1.02 \cdot f^r_{j,\mathrm{CF}} - 2.25 \cdot 10^{-2}$	$f^r_{j,\mathrm{WPF}} = 2.56 \pm \sqrt{1.36 \cdot (f^r_{j,\mathrm{CF}})^2 - 5.58 \cdot f^r_{j,\mathrm{CF}} + 6.67}$
LF	$f^r_{j,\mathrm{LF}} = 1.08 \cdot f^r_{j,\mathrm{CF}} - 7.46 \cdot 10^{-2}$	$f^r_{j,\mathrm{LF}} = 3.67 \pm \sqrt{2.20 \cdot (f^r_{j,\mathrm{CF}})^2 - 9.00 \cdot f^r_{j,\mathrm{CF}} + 13.92}$
FEF	$f^r_{j,\mathrm{FEF}} = 4.31 \cdot f^r_{j,\mathrm{CF}} - 3.31$	$f^r_{j,\mathrm{FEF}} = -680.23 \pm \sqrt{-1{,}891.38 \cdot (f^r_{j,\mathrm{CF}})^2 - 7{,}753.45 \cdot f^r_{j,\mathrm{CF}} + 458{,}216.00}$

Then MOO for CF was performed and its Pareto 2D 'independent' projection was obtained, from which all the rest 'dependent' projections were derived by the above defined linear (Figure 1) and nonlinear (Figure 2) correlations. Note that nonlinearities in Figure 2 are better preserved than in Figure 1. At N=20, only about 30 MINLPs with linear and 35 MINLPs with nonlinear correlations have to be performed instead of 120.

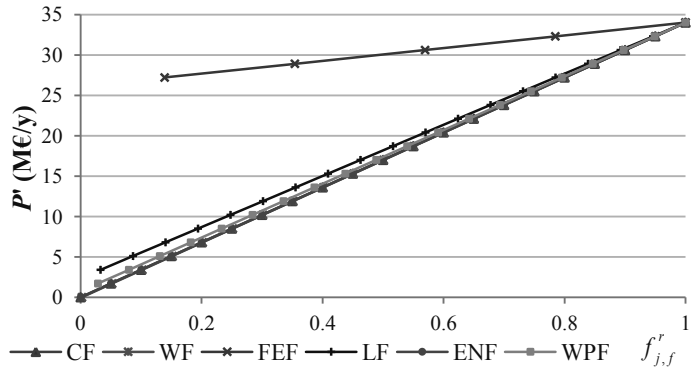

Figure 1. Linearly-correlated curves

For the estimation of the error we used the mean difference measure (Δf' for linear and Δf'' for nonlinear correlation) and standard deviation measure (σ' for linear and σ'' for nonlinear correlation). The mean differences and standard deviations between footprints obtained by MOO and those correlated ones are presented in Table 3.

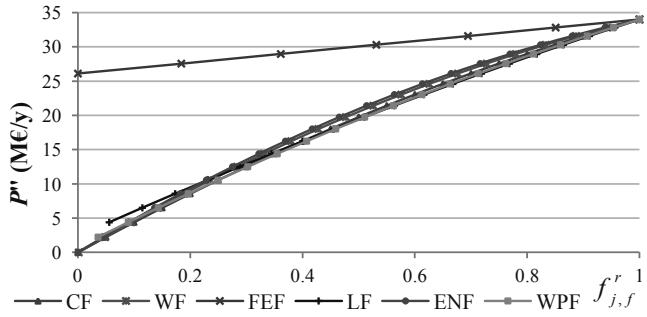

Figure 2. Nonlinearly-correlated curves

From Table 3 it can be seen that errors are especially small for quadratically-based correlated footprints (usually around 1 % or less). Similar results as by the MOO can be obtained by nonlinearly-correlated footprints.

Table 3. Mean differences and standard deviations between obtained and correlated footprints

Footprint	$\Delta f'$	σ'	$\Delta f''$	σ''
CF	6.59 %	2.81 %	1.20 %	1.18 %
ENF	9.20 %	4.37 %	1.02 %	2.23 %
WF	8.92 %	3.30 %	2.11 %	2.02 %
WPF	4.85 %	2.75 %	0.61 %	1.91 %
LF	2.83 %	1.76 %	0.14 %	0.98 %
FEF	0.12 %	0.86 %	0.10 %	0.87 %

4. Conclusions

The current contribution presents the development of the correlations among different footprints within an MOO approach. Different footprints have been investigated on the case study of the biomass energy supply-chain. The nonlinearly-correlated curves fit well to the 2D Pareto projections obtained by maximising the profit against each footprint. The number of MINLPs to be solved has been significantly reduced by applying those correlations yet yielding solutions of acceptable accuracy, thus enabling a large number of footprints to be considered in the LCA-based MINLP synthesis approach.

Abstract

Waste to Energy (WTE) carries a trade-off between energy generation and the energy spent on collection, transport and treatment. Major performance indicators are cost, Primary Energy Savings (PES), Carbon Footprint (CFP). This presentation analyses the trade-off introducing a new indicator – the Waste Energy Potential Utilisation (WPU). The results indicate that the impact of logistics and energy distribution can be significant, and distributed WTE architectures may be good candidates for optimal solution, subject to further economical and environmental assessment.

Keywords: Waste-to-Energy, Waste Energy Potential Utilisation, optimisation processing distribution

1. Introduction

Waste management has become a significant problem due to its environmental impact (Eurostat, 2011). It mainly relates to atmospheric emissions and aqueous effluents from landfills, waste collection, transport, and processing. The growing demands for securing cleaner energy supplies (EIA, 2011) make necessary to achieve maximum savings of fossil fuels at minimum Carbon Footprint (CFP) in an economically viable way.

Studies of Waste-to-Energy (WTE) at the level of equipment and process design (Stehlík, 2011; Fodor and Klemeš 2012; Tabasová et al., 2012) and integrated waste utilisation (Singhabhandhu and Tezuka, 2010) have been published. There have been also studies on Carbon-Constrained economy targeting from New Zealand (Atkins et al., 2010) and Malaysia (Wong et al., 2011). Bastin and Longden (2009) compared fuel costs and CO_2 emissions of waste logistics networks with centralised vs. distributed location of UK waste processing, indicating 30 % higher fuel consumption for the centralised arrangement. A systematic evaluation of the CFP, energy saving and utilisation trends of WTE networks is important as well. One step in this direction for the synthesis of regional bioenergy networks has been the work by Čuček et al. (2010).

This contribution extends the analysis of WTE processing by defining a new performance indicator of the significance of the centralised versus distributed networks. The former allow larger and more efficient WTE plants but involve longer distances for waste transportation and energy distribution, while the latter feature the opposite trends.

2. Problem Description

The problem is to select a waste management network utilising the waste energy value optimally. The objective functions are typically minimum total cost, maximum waste energy utilisation or minimum environmental impact. Other criteria are also possible

(Zhang et al., 2011). The system includes households and intermediate WTE nodes, all connected with links for waste transportation and energy distribution (Figure 1).

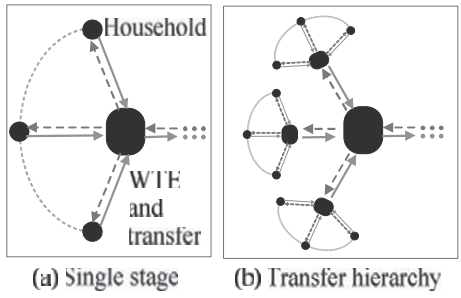

Figure 1. Nodes connectivity

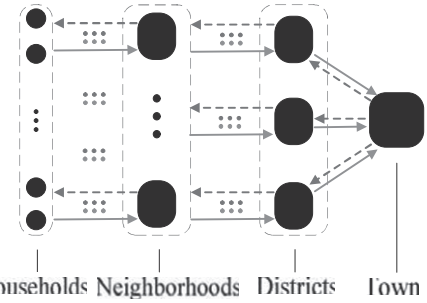

Figure 2. Network topology

WTE networks can be classified as reverse-logistics supply chain problems (Zhang et al., 2011). This work assumes that the household waste is separated to obtain a biomass fraction for anaerobic digestion to biogas. This is only one possible technology selected for the illustration the spatial development aspect. Other WTE technologies could be used too (Fodor and Klemeš, 2012).

2.1. Major Factors and Degrees of Freedom

The main activities in WTE processing include waste generation, collection, separation, transportation, conversion, energy distribution. The separation and WTE conversion may be performed at any network layer (Figure 2). The most significant factor in selecting the distribution of the processing activities within the WTE network is the CFP reduction. It is represented by the Primary Energy Savings (PES) concept. Other indicators are the waste volume sent to landfills, the type of WTE technologies and their environmental and health impacts, and the operating and investment cost of the system.

The main degrees of freedom are the choices of the technologies and locations for WTE and separation plants. It is important which WTE technologies will be selected. It is a common misconception to identify WTE as only waste incineration with heat recovery, which is the most common application to date (Stehlík, 2011). Other options as anaerobic digestion to biogas with further use as a fuel can also be applied.

Other implications concern capital cost (equipment and vehicles) and land cost. Situating WTE plants closer to the waste sources (households) may impose higher land cost and emission problems, but could reduce transport cost. Building the WTE plants at a distance, outside cities, would tend to reduce the land cost and increase transport cost.

2.2. Constraints and Trade-offs

WTE location and technology have significant public acceptance implications affecting the project feasibility– e.g. incineration is frequently resisted in populated areas. A comprehensive solution must account for this. The current study focuses on the energy trade-off aspect. An interesting constraint of WTE lies in the duality of its goals. Firstly it is needed to safely treat the waste and minimise landfilling. But with increasing concerns for energy security and CFP minimisation (Dovì et al., 2009), energy recovery can be considered equally important. There is a maximum distance, at which the energy for transporting the waste becomes equal to its energy value. It depends on the ratio of the waste specific heating value and the energy consumption for transport.

2.3. General Solution Algorithm

The general solution to the problem can be carried out using various algorithms. Examples are the inexact reverse logistics (Zhang et al., 2011), an adaptation of the

synthesis of biomass-based energy supply chains (Čuček et al., 2010; Iakovou et al., 2010), which involve rigorous mathematical models. The algorithm should be able to adapt to the size and circumstances accounting for the trade-off of centralised vs. distributed processing. It has to define the following stages: (i) System identification – boundaries, sizes, zones, waste generation rates and energy value, transportation distances, main constraints; (ii) Scoping, identification of the system interactions, trends limitations; (iii) Formulation of the network architecture using clustering (Lam et al., 2010); (iv) Detailed supply chain modelling and optimal synthesis inside each cluster.

3. Utilisation of the waste energy potential

Municipal Solid Waste (MSW) potential (Step ii above) can be utilised at several stages (Figure 2) – households, neighbourhoods, districts, city, regional level. Transport decreases its energy value. Heat and power distribution are associated with losses proportional to the distance. The appropriate indicator for evaluating these options is the Primary Energy Savings – PES (Pavlas et al., 2010), and the Waste Potential Utilisation (WPU) – defined in this work:

$$\mathrm{PES} = \mathrm{FDD} - \mathrm{FTr} \tag{1}$$

$$\mathrm{FDD} = \frac{\mathrm{Q_{rep}}}{\mathrm{FQ} \cdot \mathrm{DQ}} + \frac{\mathrm{W_{rep}}}{\mathrm{FW} \cdot \mathrm{DW}} \tag{2}$$

$$\mathrm{WPU} = \frac{\mathrm{PES}}{\mathrm{WEV}} \left[\frac{\mathrm{GJ}}{\mathrm{GJ}} \right] ; \mathrm{WPU}^{*} = \mathrm{WPU} \cdot 100 \, [\%] \tag{3}$$

FDD is the fuel saving from displaced demand; FTr is the transport fuel, Q_{rep} and W_{rep} – the replaced heat and power user demands, FQ and FW – efficiency factors for conversion to heat and power, DQ and DW – distribution efficiency factors. WPU is the ratio of PES to the waste energy value (WEV) before conversion or transportation. Using these indicators, a task is to evaluate at which stage the WTE facilities would yield the best effect – maximum WPU.

4. Illustrative Example

The defined framework is illustrated on an example of a town of 100,000 inhabitants, with an average of 4 persons per household (HH). The town has 3 districts with 4 neighbourhoods (NH) in District 1 (D1), 3 NH in D2 and 4 NH in D3. The average waste generation is 450 kg/y per inhabitant (Eurostat, 2011). From that 30 % is suitable for energy generation, LHV = 0.01 GJ/kg, translating to waste heating value WHV = 135,000 GJ/y for the town. Each HH has an average demand of 4,500 kWh/y for power and 12,000 kWh/y for heat. Fuel consumption for waste transport is 0.02 GJ/(t·km). The performance of the energy conversion plants is specified in Table 1. It is assumed that WTE processing takes place at only one of the four potential levels – HH, NH, D, town. In this case the WEV is completely offset after transportation to 500 km, so this is not constraining for the scale of the system (smaller than 100 km). The energy trends for the network are summarised in Figure 3.

It can be seen from Figure 3 that the WPU features a trend with a maximum, explained on by the trade-off between two factors as follows. The increasing distance from the waste source tends to decrease the PES via FTr. Also the WTE conversion efficiency increases with the plant scale to a saturation point. The WPU can be above 100 %, which means that more fossil fuel energy can be saved than the energy value of the

utilised waste. This is caused by the distribution losses for heat and power, associated with the fossil based reference system for central utility supply and of the WTE options.

Table 1. Performance factors for the WTE plants

	BGD	**FQ**	**FW**	**DQ**	**DW**
	GJ/GJ	GJ/GJ	GJ/GJ	GJ/GJ	GJ/GJ
Reference system (fossil based CHP)	-	0.55	0.30	0.88	0.95
Biogas based heating at HH level	0.58	0.8	0	1	1
Biogas based CHP – NH level	0.58	0.55	0.24	0.92	0.98
Biogas based CHP – districts	0.58	0.55	0.24	0.90	0.96
Biogas based CHP – town	0.58	0.55	0.24	0.88	0.95

CHP: Combined Heat and Power generation; BGD: BioGas Digester efficiency

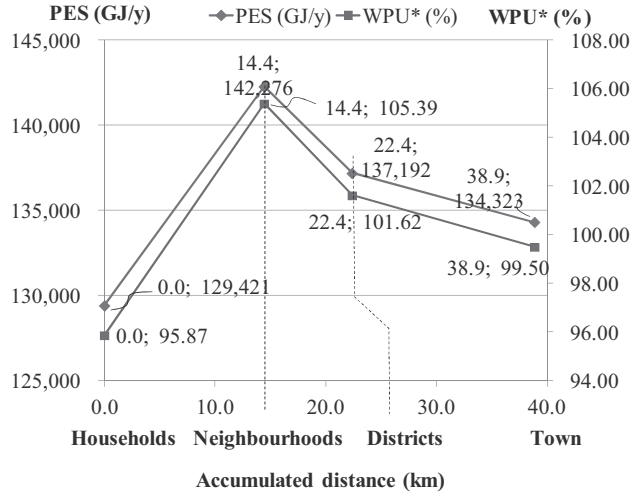

Figure 3. Energy trends for the illustrative example

5. Conclusions and Further Work

This work analyses the trend of utilising the waste energy value between distributed and centralised WTE processing. A new indicator – the WPU, has been formulated. The impact of the waste transport and energy distribution distances can be significant, reaching up to 10 % WPU variations even for smaller urban systems. The results also indicate that the WTE processing location between completely centralised or completely distributed arrangements has to be explored systematically with further indicators, as even an intermediate level such as neighbourhood-scale WTE facilities may be optimal. It should be also considered that the problem is not static, but developing with changing conditions as population growth, fuels prices increase, more efficient transport means.

Future work should involve a more detailed formulation of a systematic procedure for optimal WTE networks synthesis within the context of the waste management priorities and more accurate specification of the efficiency for energy conversion. It should include additional indicators – such as CFP and the other footprints as well as economic performance – especially the economy of scale (Čuček et al, 2012). A number of constraints should be satisfied – social acceptance, health regulations, availability of land for the WTE plants as well as for landfills. To solve this extended problem a multi-objective optimisation would be an obvious approach.

Abstract

Carbon Capture and Utilization (CCU) has the potential to reduce both greenhouse gas emissions and fossil fuel use. However, the conversion of CO_2 is intrinsically difficult due to its low energetic state. Thus, a positive environmental effect of a CO_2-consuming reaction cannot be taken for granted. In this work, we therefore present a graphical method to identify promising reaction schemes using CO_2 as a feedstock. Reactant mixtures leading to minimal life-cycle greenhouse gas (GHG) emissions are determined. The optimal reaction schemes strongly depend on the reactants' global warming potential (GWP); in the case of CCU, the future GWP values of CO_2 and H_2 are particularly critical and subject to major uncertainty today. The graphical method therefore provides GWP targets for CO_2 capture and H_2 production technologies. The method is demonstrated for the production of methanol. Five optimal reaction schemes are identified depending on the GWP values of CO_2 and H_2. Thus, four threshold relations for the GWP of CO_2 and H_2 are derived showing directly under which conditions the utilization of CO_2 as a feedstock is environmentally preferential.

Keywords: Carbon Capture and Utilization, LCA, Methanol, CO_2 Conversion

1. Introduction

The utilization of captured CO_2 is drawing increasing attention [1]. With progress in capture technologies, high purity CO_2 can become abundantly available, e.g. from fossil fueled power plants. Using CO_2 as a feedstock for the production of chemicals and fuels might allow for a reduction of both greenhouse gas emissions and fossil fuel depletion. However, major challenges have to be overcome to implement CCU on a large scale: new products and pathways have to be identified and the reaction must be exergonic [2]. Systematic methods to identify promising candidate reactions are therefore desirable. Patel et al. [3] recently introduced a thermodynamic process design framework. The framework can directly be employed to identify promising CO_2-based reactions from a thermodynamic perspective. But the utilization of CCU is most often motivated environmentally. Therefore, we extend the framework from Patel et al. [3] by an optimization step based on ecological criteria such as the GWP. This extension enables the identification of the ecologically optimal composition of reactants and products. In a further step, the method can be used to determine GWP targets for CO_2 capture and H_2 production technologies.

In Section 2, the graphical method is introduced for the example of methanol production. In Section 3, results are presented before conclusions are given in Section 4.

2. Graphical Targeting Approach

After a short description of methanol production, the graphical design framework by Patel et al. [3] is briefly summarized and then extended for environmental analysis.

2.1. Methanol production from CO_2

Methanol production from CO_2 has been evaluated both from a thermodynamic [4] and a simplified environmental [2] perspective, mostly for one particular reaction, namely:

$$CO_2 + 3\ H_2 \rightarrow CH_3OH + H_2O \tag{1}$$

Although reaction (1) is thermodynamically feasible, it might not be environmentally optimal. The following section will provide a graphical method to obtain an ecologically optimal scheme for the production of methanol. The approach is directly applicable to any other compound of the form $C_xH_yO_z$.

2.2. Obtaining an ecologically optimal reaction scheme

From a thermodynamic perspective, a reaction must fulfill the mass, energy and entropy (in terms of Gibbs energy) balances. Patel et al. [3] use these balance equations as constraints for a linear program (LP). We adopt the approach for the production of any compound of the form $C_xH_yO_z$ at standard conditions (298K, 1 bar). The considered components (reactants or by-products) are limited to methane (CH_4), water (H_2O), oxygen (O_2), carbon dioxide (CO_2) and hydrogen (H_2):

$$\nu_{CH_4}\,CH_4 + \nu_{H_2O}\,H_2O + \nu_{O_2}\,O_2 + \nu_{CO_2}\,CO_2 + \nu_{H_2}\,H_2 \rightarrow C_xH_yO_z \tag{2}$$

The stochiometric coefficient of the product $C_xH_yO_z$ is always fixed to 1. The other components are reactants for negative and by-products for positive stochiometric coefficients ν_i. The mass, energy and entropy balances can be written as follows [3]:

$$0 = \nu_{CH_4} + \nu_{CO_2} + x \tag{3}$$

$$0 = 4\,\nu_{CH_4} + 2\,\nu_{H_2O} + 2\,\nu_{H_2} + y \tag{4}$$

$$0 = \nu_{H_2O} + 2\,\nu_{O_2} + 2\,\nu_{CO_2} + z \tag{5}$$

$$\Delta h^{R,0} = \Delta h^{f,0}{}_{CxHyOz} + \sum_i \nu_i\,\Delta h^{f,0}{}_i \leq 0 \tag{6}$$

$$\Delta g^{R,0} = \Delta g^{f,0}{}_{CxHyOz} + \sum_i \nu_i\,\Delta g^{f,0}{}_i \leq 0 \tag{7}$$

In this work, a reaction with a minimal environmental impact is sought after. Since the focus of CCU is on greenhouse gas emissions, the method is exemplified using the GWP as an environmental impact category. Only the supply of the reactants is considered to contribute to the GWP of the reaction whereas no benefit, i.e. no avoided burden, is given to any of the by-products.

For the methanol example, the GWP values for CH_4, H_2O and O_2 are taken from the ecoinvent database [5] whereas those of CO_2 and H_2 are treated as variable. The resulting optimization problem can be formulated as follows:

$$\min \quad OF = -\sum_i \nu^R{}_i\,GWP_i \tag{8}$$

$$\text{s.t.} \quad (3)-(7) \ \text{ where } \ \nu_i^R = \begin{cases} \nu_i, \text{ if } \nu_i < 0 \\ 0, \text{ if } \nu_i \geq 0 \end{cases} \tag{9}$$

Due to the discontinuity (9) of the objective function (OF), the problem is not an LP. A formulation as a mixed-integer linear program (MILP) is possible. However, it is insightful to decompose the solution space into regions with different, but continuous

OFs leading to several LPs. These regions are particularly conveniently determined by the graphical approach by Patel et al. [3] using so-called zero lines.

The procedure is demonstrated for the example of methanol synthesis where CO_2 and/or CH_4 act as potential carbon sources ($v_{CH_4} \leq 0$, $v_{CO_2} \leq 0$). Figure 1 shows the amount of H_2 produced or required as a function of the CO_2 amount used as feedstock. The zero lines represent stochiometries with zero amounts of a certain compound ($v_i=0$), zero reaction enthalpy ($\Delta h^{R,0}=0$) or zero Gibbs energy ($\Delta g^{R,0}=0$). Here, the $\Delta h^{R,0}=0$ constraint (6) is dominated by the $\Delta g^{R,0} \leq 0$ constraint (7) due to a negative reaction entropy and is neglected for clarity in Figure 1.

The objective function OF_k is continuous within each region k bounded by the zero mass balance lines. In Figure 1, four reasible regions ($k=1,...4$) exist, hence four LPs are solved. For example in region $k=3$, the following objective function is used:

$$OF_3 = - (v_{CH_4} GWP_{CH_4} + v_{O_2} GWP_{O_2} + v_{CO_2} GWP_{CO_2} + v_{H_2} GWP_{H_2}) \quad (11)$$

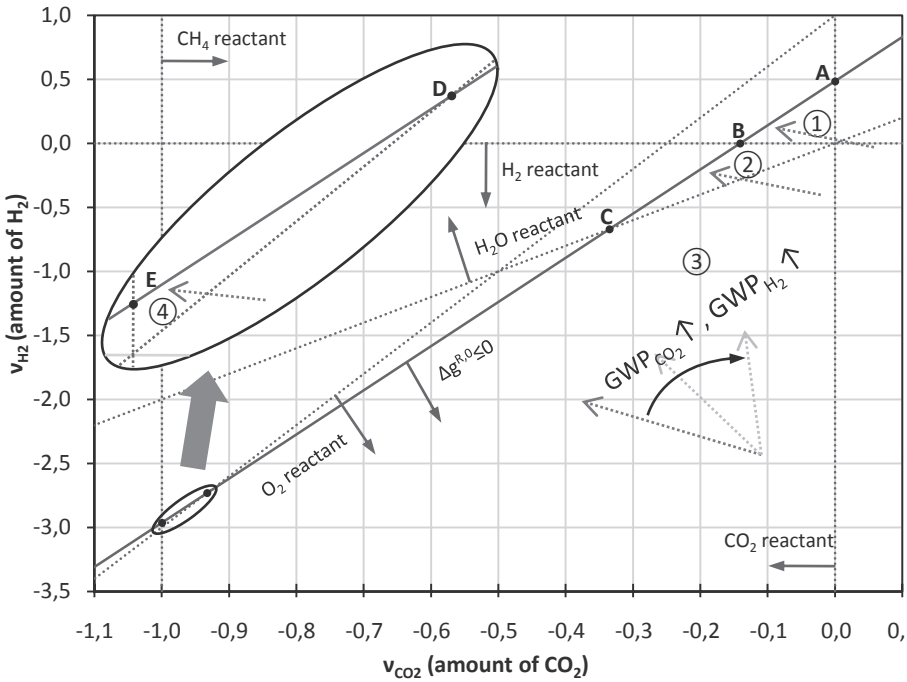

Figure 1: Solution space of (MI)LP for methanol synthesis with CO_2 as a potential feedstock. The (qualitative) dotted vectors pointing towards the regional optimal solution turn clockwise with increasing GWP values of CO_2 and H_2.

As for any LP, the optimal solution of every region is at a corner. A vector $\vec{n}_{OS,k}$ pointing towards the local (minimal) optimal solution (OS) can be defined as:

$$\vec{n}_{OS,k} = \begin{pmatrix} n_{OS,1,k} \\ n_{OS,2,k} \end{pmatrix} = \begin{pmatrix} -\partial OF / \partial v_{CO_2} \\ -\partial OF / \partial v_{H_2} \end{pmatrix} \quad (12)$$

For region 3, the vector $\vec{n}_{OS,3}$ is given by

$$\vec{n}_{OS,3} = \begin{pmatrix} \frac{\partial \nu_{CH_4}}{\partial \nu_{CO_2}} GWP_{CH_4} + \frac{\partial \nu_{O_2}}{\partial \nu_{CO_2}} GWP_{O_2} + GWP_{CO_2} \\ \frac{\partial \nu_{CH_4}}{\partial \nu_{H_2}} GWP_{CH_4} + \frac{\partial \nu_{O_2}}{\partial \nu_{H_2}} GWP_{O_2} + GWP_{H_2} \end{pmatrix} \approx \begin{pmatrix} -GWP_{CH_4} - 2GWP_{O_2} + GWP_{CO_2} \\ \frac{1}{2} GWP_{O_2} + GWP_{H_2} \end{pmatrix} \quad (13)$$

The global optimal solutions for given GWP values are obtained as follows: the vectors $\vec{n}_{OS,k}$ are plotted and the local optimal corners are identified. With the corners' reactant mixtures computed from (3) – (5), the objective function values OF_k (8) are compared to determine the global optimal solution.

2.3. Threshold values for the GWP of CO_2 and H_2

The GWP of CO_2 and H_2 are the critical factors in determining the environmental potential of a CCU scheme: How much additional CO_2 was produced in preparing the CO_2 feedstock? How was the – usually required – hydrogen produced? Most CCU proposals rely on projections about the future supply of the required feedstock. The presented graphical method allows for a convenient determination of GWP target values for future CO_2 capture and H_2 production technologies.

Eq. (13) shows, exemplary for k=3, that the vectors $\vec{n}_{OS,k}$ depend on the variable values GWP_{CO_2} and GWP_{H_2}. All vectors turn clockwise if GWP_{CO_2} or GWP_{H_2} increase. Only vector $\vec{n}_{OS,1}$ does not depend on GWP_{H_2}. This general behavior can be used to identify possible optimal corners. For example, the vector $\vec{n}_{OS,3}$ always points upwards in positive direction of ν_{H_2} since $(\frac{1}{2} GWP_{O_2} + GWP_{H_2}) \geq 0$.

The optimal solution moves from its current to a neighboring corner if the vector $\vec{n}_{OS,k}$ is orthogonal to the zero-line connecting these corners. This condition is fulfilled if:

$$m_{zero-line} = -\frac{n_{OS,k,1}}{n_{OS,k,2}} = -\frac{\partial OF_k / \partial \nu_{CO_2}}{\partial OF_k / \partial \nu_{H_2}}, \quad (14)$$

where $m_{zero\text{-}line}$ denotes the slope of the zero line. The derivatives of the OF depend on the GWP_i values. The GWP_i values fulfilling Eq. (14) are called *local GWP threshold values* since values just below or above the threshold values result in different optimal solutions in a region *k*. For the two degrees of freedom (GWP_{CO_2} and GWP_{H_2}), it is convenient to compute threshold lines.

The procedure for obtaining global GWP threshold values is as follows: the potential local optimal corners are identified using (12) with variable values for GWP_{CO_2} and GWP_{H_2}. By applying (14) to the zero-lines that connect these corners, relations for the local GWP threshold values are derived. Whether these local values are also global threshold values can be checked in analogy to the procedure in 2.2.

3. Results

The proposed method is used to determine the global GWP threshold values for CH_3OH production. In this case, five global environmentally optimal solutions can be found in dependence of GWP_{CO_2} and GWP_{H_2} (corners A to E in Figure 1). Hence, four threshold lines can be computed, see Figure 2. If GWP_{CO_2} is above 0.276 kg CO_2eq./kg CO_2, the use of CO_2 as a feedstock for methanol synthesis is environmentally not advisable and methane should be employed as carbon source. If GWP_{CO_2} is below that value, it is always preferential to (partially) use CO_2 as a feedstock. How much CO_2 should be used, depends also on GWP_{H_2}, see Figure 2.

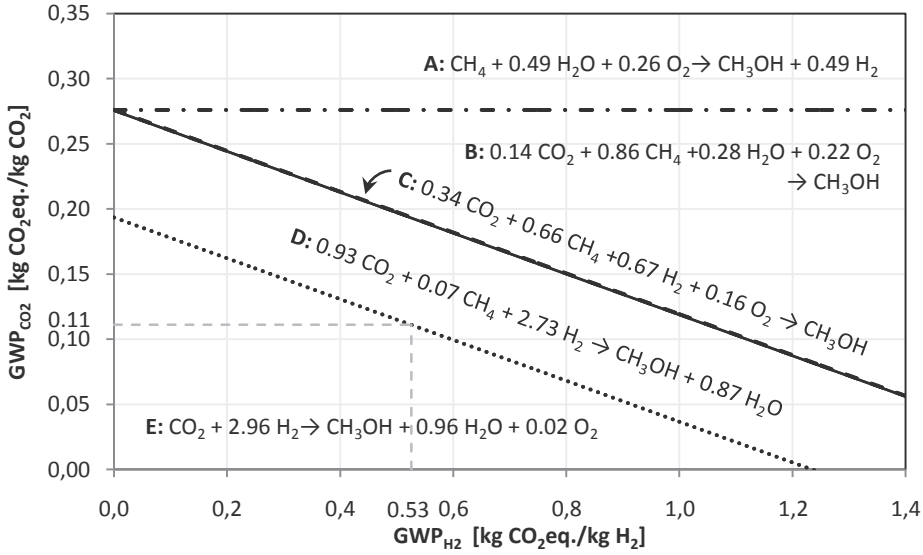

Figure 2: Environmentally optimal reactions as a function of the GWP of CO_2 and H_2.

Figure 2 can be used to define GWP targets for technologies. For example, in a power plant with a 90% CO_2 capture rate where all of the remaining 10% are allocated to the captured CO_2 stream, the GWP of CO_2 is 0.11 kg CO_2eq./kg CO_2 (=0.1/0.9). Please note that this allocation procedure provides a worst case value for GWP_{CO_2}. Still, with this worst case value, CO_2 should always be used as a feedstock. Moreover, CO_2 should be the only carbon source if GWP_{H_2} is below 0.53 kg CO_2eq./kg H_2.

4. Conclusions

Environmentally optimal reaction schemes for CCU can be obtained by introducing environmental impact coefficients into the process design framework by Patel et al. [3]. The resulting graphically-based targeting method gives further valuable insight into the process: threshold values for the GWP of CO_2 and H_2 can be derived that are tipping points between different reaction schemes. A worst case analysis shows that methanol production from CO_2 captured from power plants is a promising CCU scheme.

Abstract

Pulp and paper mills are huge consumers of water and energy. Hence, much research works have been dedicated to simultaneous reduction of water and energy in the past decades. However, none of those works are addressing the brown stock washing system (BSWS), which is the core processing section that determines the amount of energy required in black liquor (BL) concentration. The latter is the largest energy consumption in a typical pulp and paper mill. Therefore, minimizing water consumption in the BSWS will lead to energy saving too. In this work, mass balances of the BSWS is first analyzed in a process simulation software (Cadsim), and adopted as the base case model for the study. Next, a mixed integer non-linear programming (MINLP) optimization model is developed to minimize the total annualized cost incurred in the project. The synthesized water network features significant reduction in both energy and water consumption in the BSWS.

Keywords: water minimization; pulp and paper mill; optimization; process integration.

1. Introduction

In recent decades, the large-scale exploitation of resources i.e. energy and water by the process industries has exacerbated the imbalance between economic growth and environmental protection (OECD, 2008). Being one of the biggest consumers of these resources, the process industries are urged to adopt sustainable resource management strategies to minimize overexploitation and pollution (UNEP, 2009).

Energy is used for heating purposes in the process plants. Energy embedded in water creates an inextricable link between both resources, in which the conservation of water will directly translate into energy savings (Tellinghuisen, 2009). Various attempts have been reported on the application of process integration techniques for simultaneous energy and water reduction in pulp and paper mill. Wising et al. (2005) identify the potential of excess heat recovery in the mill utilising the grand composite curve. On the other hand, Nordman and Berntsson (2006) introduce a “tank curve” to identify the maximum excess heat in the mill. Savulescu and Alva-Argáez (2008) investigated the non-isothermal mixing point and direct heat transfer to achieve water and energy efficiency.

In this work, water network for a brown stock washing system (BSWS) in an existing pulp and paper mill is optimized. An MINLP is developed to minimize the total cost associated with water consumption in the BSWS and its piping cost incurred in the proposed water network design.

2. Problem Statement

By referring to Figure 1, a set of washers with fixed flowrates and displacement ratio (DR), is optimized for its water network system by effectively reused/recycled the filtrate (water source) in the showers (water sink) and in the dilution of pulp inlet stream (water sink). Table 1 tabulates the water flowrates and DR of each washing equipment in the base case (Bonhivers and Stuart, 2007).

Table 1.Washers flowrates and displacement ratio (DR)

Washers, k	**DR**	**Water flowrates, (kg/t pulp)**			
		Pulp inlet D_k	**Shower S_k**	**Filtrate F_k**	**Pulp outlet P_k**
Emcc	0.65	9457	4998	10505	3950
Diffuser 1	0.90	7612	12494	12852	7254
Diffuser 2	0.90	7254	12494	12494	7254
Decker	0.75	57439	9500	59803	7136

PreDO	0.70	71662	6000	71614	6048

3. Mathematical Model for Brown Stock Washing System

BSWS is the most important washing section in a pulp and paper mill. The main function of BSWS is to remove dissolved solids (DS) from the pulp. The filtrate generated during the washing process is known as black liquor (BL) and is concentrated in evaporator to become strong BL for recovery. The mathematical model for BSWS optimization is formulated as follows:

The objective function is set to minimize the total annualized cost, obj_{COST} as shown in Equation (1). This includes the fresh water (first term) cost which has been annualized to 330 operation days per year, with 600 ton of pulp produced daily and the annualized piping (second term) cost.

$$\min obj_{\mathrm{COST}} = \left(F_{\mathrm{FW}} \times F_{\mathrm{COST}} \times 600\ \text{ton pulp/day} \times 330\ \text{day/year}\right) + P_{\mathrm{COST}} \tag{1}$$

3.1. Washers Mass Balances

Equations (2) – (4) stated the flowrate balances for shower, dilution point and filtrate, respectively, while Equation (5) is the overall flowrate balance at washer k.

$$S_k = FW_k^S + \sum_{k' \in K} R_{k',k}^S + T_k^S \qquad k \in K \tag{2}$$

$$D_k = FW_k^D + \sum_{k' \in K} R_{k',k}^D + P_{k-1} + T_k^D \qquad k \in K \tag{3}$$

$$F_k = \sum_{k' \in K} R_{k,k'}^D + \sum_{k' \in K} R_{k,k'}^S + R_k^T + BL_k \qquad k \in K \tag{4}$$

$$D_k + S_k = P_k + F_k \qquad k \in K \tag{5}$$

where $R^{S}_{k',k}$ and $R^{D}_{k',k}$ denote filtrate flowrate sent for reused/recycled at the shower and pulp dilution point (from another washer *k'* to washer *k*), respectively. It is worthy of note that, in case of filtrate self-recycle, *k'* = *k*. Variables T^{D}_{k} and T^{S}_{k} denote the pressate flowrate from TRP; P_{k-1} represents flowrate of pulp liquor from washer *k*-1 entering into washer *k*; variable $BL_k$is the lean black liquor which will be sent for heat treatment; FW^{S}_{k} and FW^{D}_{k} denote fresh water that makes up shower and pulp dilution point, respectively.

On the other hand, DS balances for the shower stream and pulp dilution point are given by Equations (6) – (7), respectively. Equation (8) states the DR parameters in relationship with DS concentration.

$$FW^{S}_{k} C_{\mathrm{FW}} + \sum_{k' \in K} R^{S}_{k',k} C^{F}_{k'} + T^{S}_{k} C_{T} \le S_{k} C^{S}_{k} \qquad k, k' \in K \quad (6)$$

$$FW^{D}_{k} C_{\mathrm{FW}} + \sum_{k' \in K} R^{D}_{k',k} C^{F}_{k'} + P_{k-1} C^{P}_{k-1} + T^{D}_{k} C_{T} \le D_{k} C^{D}_{k} \qquad k, k' \in K \quad (7)$$

$$\mathrm{DR}_{k} = \left(C^{D}_{k} - C^{P}_{k}\right) / \left(C^{D}_{k} - C^{S}_{k}\right) \qquad k \in K \quad (8)$$

where $C^{S}_{k}, C^{F}_{k}, C^{D}_{k}, C^{P}_{k}, C_{T}, C_{\mathrm{FW}}$ represent the concentration at shower, filtrate, pulp dilution, pulp outlet, TRP and fresh water, respectively.

3.2. Twin Roll Press (TRP) Mass Balance

Pressate from TRP is sent for reuse/recycle, and Equations (9) and (10) stated the flowrate and DS balances, respectively. The total flow rate of fresh water, F_{FW} is given in Equation (11).

$$D_{\mathrm{T}} = FW^{T} + \sum_{k \in K} R^{T}_{\mathrm{k}} + P^{in}_{\mathrm{T}} \quad (9)$$

$$FW^{\mathrm{T}} C_{\mathrm{FW}} + \sum_{k \in K} R^{T}_{\mathrm{k}} C^{F}_{k} + R_{T} C^{out}_{T} + P^{in}_{\mathrm{T}} C^{P}_{Dec} \le D_{T} C^{in}_{T} \quad (10)$$

$$F_{\mathrm{FW}} = \sum_{k \in K} FW^{S}_{k} + \sum_{k \in K} FW^{D}_{k} + FW^{T} \quad (11)$$

where variables D_{T} and C^{in}_{T} denote the inlet flowrate and concentration at TRP, respectively. Variable FW^{T} denote the fresh water flowrates at TRP. It is further note that P^{in}_{T} is identical to $P_{k\text{-}1}$ in Equation (3), where in this case P^{in}_{T} and C^{P}_{Dec} are referring to the pulp outlet flowrate and DS concentration from decker washer.

3.3. Energy Consumption

Energy is consumed in three identified sections, e.g. multiple-effect evaporator (MEE), H_{evap}, BL concentration heater, H_{conc} and O_2 delignification reactor, H_{react} (see Fig. 1); their respective energy balance equations are shown in Equations (12) – (14). Equation (15) denotes the total BL sent to the MEE for heat treatment. As shown in Equation (13), the lean BL is preheated to 100 °C whereas in Equation (14) the pulp stream is heated to the reaction temperature of 115 °C.

$$H_{\mathrm{Evap}} = \left(BLE - SBL\right) \times \overline{H} \div a \quad (12)$$

$$H_{\mathrm{conc}} = \left(BLE - BL_{EMCC}\right) \times C^{\mathrm{BL}}_{\mathrm{P}} \left(100 - T_{BL}\right) \quad (13)$$

$$H_{\mathrm{React}} = F_{\mathrm{R}} \times C^{\mathrm{R}}_{\mathrm{P}} \left(115 - T_{R}\right) \quad (14)$$

$$BLE = \sum_{k \in K} BL_k - RBL \tag{15}$$

where parameters *RBL* and *SBL* denote the recycled BL to the EMCC washer, and strong BL exit at the MEE; parameters $\overline{H}$ and *a* represent the specific heat and efficiency of the MEE. Variable BL_{EMCC} is the BL flowrate at the EMCC washer, while variable T_{BL} is the average BL inlet temperature at the concentration heater while T_R is the inlet temperature at the reactor. Variable F_R denotes the pulp outlet flowrate at TRP (before entering the reactor). In this work, heat capacity for black liquor, C_P^{BL} and pulp mat in reactor, C_P^R are assumed at 3.5 kJ/kg°C and 4 kJ/kg°C, respectively.

3.4. Annualized Piping Cost

Equations (16) - (17) give the upper (UB) and lower (LB) bounds of the reused/recycled filtrate. Binary variable $x_{k',k}$in Equation (16) indicates the existence of piping connection between the filtrate of washer *k'* and shower of washer *k*; binary variable $y_{k',k}$ in Equation (17) indicates the existence of piping connection between the filtrate of washer *k'* and dilution point of washer *k*. Note that in this case, the *LB* is set at zero while the *UB* is set at the filtrate flowrate, F_k (see Table 1).

$$LB \times x_{k',k} \le R^S_{k',k} \le UB \times x_{k',k} \qquad k, k' \in K,\ k \ne k' \tag{16}$$

$$LB \times y_{k',k} \le R^D_{k',k} \le UB \times y_{k',k} \qquad k, k' \in K,\ k \ne k' \tag{17}$$

Capital cost for piping (P_{COST}) in Equation (1) is adapted from Kim and Smith (2004) and is given in Equation (18). The piping cost considers the use of carbon steel pipes (given in USD), with the cost parameters of p = 7200 and q = 250 (CE plant index = 318.3). It is further assumed that the stream flowrate velocity, ν = 1 m.s^{-1} and water density, ρ = 1000 kg.m^{-3} throughout this study. An equal Manhattan distance, *D* is assumed for all pipelines.

$$P_{\text{COST}} = D\left[\left(p \sum_{k' \ne k \in K} \frac{R^S_{k',k}}{3600\rho\nu} + q x_{k',k}\right) + \left(p \sum_{k' \ne k \in K} \frac{R^D_{k',k}}{3600\rho\nu} + q y_{k',k}\right)\right] AF \tag{18}$$

An annualised factor (*AF*) is used to annualise the piping capital cost, defined as:

$$AF = \frac{m(1+m)^n}{(1+m)^n - 1} \tag{19}$$

where m = fractional interest rate per year, n = number of years.

4. Case Study

In the case study illustratation, the following assumptions are in place:-

F_{COST} is set at \$ 1/ton; C_{FW} = 0; *RBL* = 2000 kg/ton pulp; *SBL* = 2900 kg/ton pulp; $\overline{H}$ = 2200 kJ/kg; a = 4; D = 10 m; TRP pulp inlet, filtrate and pulp outlet flowrates are 26829, 23807 and 3022 kg/ton pulp, respectively; T_R and T_{BL} are set at 80 °C; The upper limit of DS concentration leaving PreDO washer ≤ 0.094 %.

The MINLP model in this work entails a total of 221 continuous variables, 119 binary variables and 441 constraints with solution found in 3 CPU second.

5. Conclusion

Objective function in Equation (1) is solved subject to the constraints in Equations (2) – (19) yields the minimum total annualized cost of USD$1.94 million. Fig. 1 shows one of the possible optimal water network configurations. Table 2 summarizes the total fresh water, BL and heat consumption of the base case and the optimized BSWS.

Table 2. Comparison of fresh water and energy consumption

	Base case (Cadsim simulation)	MINLP
Fresh water (kg/ton pulp)	12321	9644
Black liquor (kg/ton pulp)	13948	13053
Energy (GJ/ton pulp)	6.74	5.05

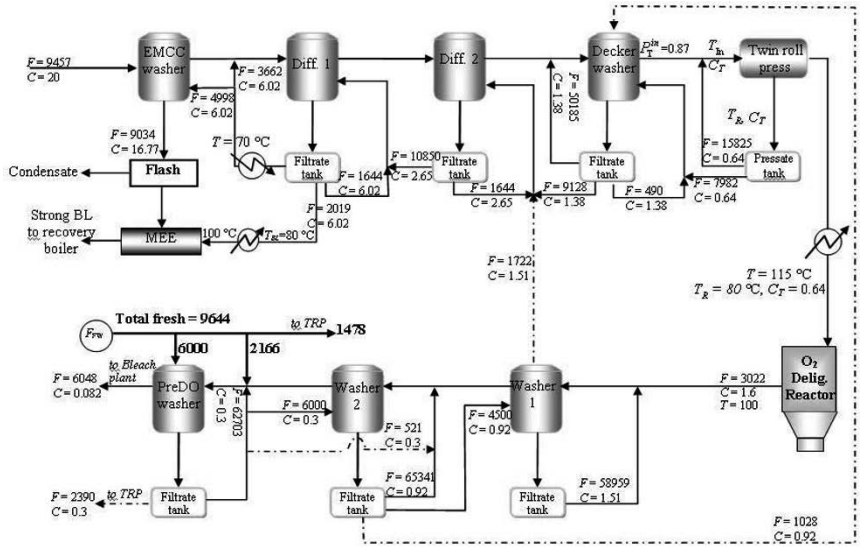

Figure 1: Process layout for optimized BSWS with F (kg/ton pulp), C (%) and T (°C)

Abstract

A heuristic design method is presented in this paper for batch water-using networks with *multiple* contaminants. A systematic procedure is developed on the basis of the performance measures originally used for evaluating the continuous systems. Specifically, the well-established *concentration indices*, i.e., Concentration Potential of Demand (CPD) and Concentration Potential Source (CPS), are adopted as primary criteria and the *time priority* as secondary criterion to match the water sources with demands sequentially. For illustration purpose, an example is given at the end of this paper. The results show that this manual approach can be easily implemented to produce a near optimal batch water-using network, which consumes a reasonable amount of freshwater with relatively low level of storage capacity.

Keywords: Batch water-using network, Multiple contaminants, Concentration index.

1. Introduction

Water integration in the batch plants has gained increasing attention in recent years(Gouws et al., 2010). The available integration methods can be classified into two kinds. The first can be considered as the graphic-based(Chen & Lee, 2008) or pinch-based(Hallale, 2002; Majozi et al., 2006; Kim, 2011) approach which can be applied only to the single-contaminant systems, while the other is the model-based strategy(Li & Chang, 2006; Chen et al., 2008). The main feature of the pinch-based approach is that the target amount of freshwater is first determined and the network design can then be synthesized accordingly. With a graphic-based approach(Chen & Lee, 2008), the design task can be performed directly without a targeting step, while the minimum freshwater consumption and the maximum water recovery is ensured by following the necessary condition of optimality(Salvelski & Bagajewicz, 2000) and the nearest neighbors algorithm(Prakash & Shenoy, 2005). On the other hand, since in general time limitation of unmatched operation periods may be the primary barrier for resource integration in batch processes, storage facilities are often installed to enhance the opportunities for water recovery. As a result, the corresponding NLP or MINLP models can be very difficult to solve(Chen et al., 2008).

[1] To whom correspondence should be addressed. E-mail: ctchang@mail.ncku.edu.tw

The objective of this study is to develop a systematic heuristic procedure for designing the batch systems with multiple contaminants, which is analogous to the aforementioned graphic-based approach with *single* contaminant(Chen & Lee, 2008). Such an analogy is possible primarily owing to the fact that two concentration indices, i.e., Concentration Potential of Demand (CPD) and Concentration Potential Source (CPS), can be used to order the degrees of contamination of various water demands and sources respectively in a way just like that for the single-contaminant water streams(Liu et al., 2009). Two kinds of water-using units, *i.e*., the *fixed load* and *fixed flow rate* operations, are considered in this work. The concentration constraints are adopted as primary criteria and time priority as secondary criteria to match the water demands and sources sequentially and the needed storage facilities are simultaneously determined in the network synthesis process.

2. Problem Statement

A batch water-using network may consist of several different types of unit operations, and each consumes and/or generates certain quality and quantity of water. In addition, the starting and finishing times of every operation should be predefined. To overcome the mismatch between the operating periods of two chosen batch processes, a buffer tank may be introduced to facilitate water integration. It is assumed that freshwater is available at any time and wastewater can be discharged to the environment. The primary design objective is to minimize freshwater consumption by maximizing water reuse among water-using units. As a secondary objective, the total number of buffer tanks and the sum of their capacities should both be reduced as much as possible so as to cut down the overall capital investment. Finally, water recycle is forbidden in this work to avoid accumulation of trace contaminants that may result in operational difficulties.

3. Concentration Potentials

Liu et al.(2009) proposed to use the *concentration potentials* for characterizing the reuse capabilities of sources and demands. The concentration potential of demand D_j (CPD) was defined as

$$CPD(D_j) = \sum_{i=1}^{NS} R_{i,j} = \sum_{i=1}^{NS} \min_{k=1,2,\cdots NC} \left[\frac{C_{D_j,k}^{\lim}}{C_{S_i,k}} \right] \qquad (i \neq j) \tag{1}$$

where, the subscripts i, j and k represent the labels of demands, sources and contaminants respectively; NS and NC denote the total numbers of sources and contaminants respectively; $R_{i,j}$ is the maximum amount of S_i that can be used to satisfy 1 ton of D_j; $C_{D_j,k}^{\lim}$ is the maximum allowable concentration of contaminant k in demand D_j; $C_{S_i,k}$ is the concentration of contaminant k in source S_i. Here $i \neq j$ because it is forbidden to recycle a water stream to the process where it is produced. Obviously, the overall reuse capability of demand D_j is proportional to CPD(D_j). On the other hand, the concentration potential of source S_i (CPS) was defined as

$$\frac{1}{CPS(S_i)} = \sum_{j=1}^{ND} R_{i,j} = \sum_{j=1}^{ND} \min_{k=1,2,\cdots NC} \left[\frac{C_{D_j,k}^{\lim}}{C_{S_i,k}} \right] \quad (i \neq j) \tag{2}$$

where, *ND* is the total number of demands. It can be inferred that the overall reuse capability of S_i is inversely proportional to CPS (S_j).

From equations (1) and (2), it can be observed the concentration potentials are functions of the contaminant concentrations only. Note also that multiple demands (or sources) with the same concentrations should be treated as one stream in calculating these potentials.

4. Allocation Principles

When the demands are satisfied by sources in a cyclic batch process, a total of seven allocation principles should always be observed, only two of principles are given below because of space limitation and interested readers are referred to our full paper(Li et al., 2012):

(1) When there are multiple source streams available, the source with largest value of maximum R should be reused first to reduce the freshwater usage. If there is more than one source with identical R value, the source with the highest CPS should be reused to reduce downstream freshwater consumption, where the CPS value of the sources should be calculated only for the unmatched processes.

(2) If a demand cannot be totally satisfied with a single source, another source should be used. The remainder of the mass loads in the demand can be calculated by subtracting the mass load in the allocated source from the maximum mass load of the demand. Similarly, the remainder of the limiting flow rate of the demand can be calculated by subtracting the flow rate of the allocated source from the present limiting flow rate, and the allowable maximum concentration can be calculated by dividing the remainder of the mass load by the remainder of the limiting flow rate. The allocation procedure will continue till the concentrations of at least one contaminant reach the maximum(s) or the reminder of the limiting flow rate becomes zero.

5. A Case study

This example is adopted to illustrate the effectiveness of the proposed design method. The processing data considered in this case study is given in Table 1. From the starting and ending times given in this table, it can be observed that units 1, 2 and 4 are operated in truly batch mode while units 3 and 5 in semi-batch mode.

Before exploring water reuse, let us consider a base case in which all units are satisfied with freshwater. For the fixed-load operations (i.e., units 1, 2 and 4), the required amounts of water can be determined to be 30, 55 and 15 ton respectively. On the other hand, both units 3 and 5 require 40 ton of water. Therefore, the freshwater consumption level in the base case is 30+55+15+40+40=180 ton in a single period (8.5h).

Let us next arrange these five units in ascending order of the limiting inlet concentration potential (CPD) which are calculated by using the limiting concentration values. By applying the proposed allocation principles, the network configuration in Figure 1 can be identified. The detailed implementation steps are omitted here due to space limitation, interested readers are referred to our full paper(Li et al., 2012). Note that in this figure

the duration of each batch operation is expressed in a color bar and, moreover, the time periods of water intake and discharge are indicated by the shaded and blank bars. The charging and discharging periods of the storage tanks are also marked with angled solid lines. Notice that the total freshwater usage has been reduced to 83.1 ton, which means a 53.8% saving from the base case. Certainly, three buffer tanks must be installed to achieve this goal. The required storage capacities can be easily determined to be 30, 75 and 26.9 ton respectively according to the corresponding time profiles of their inventories.

In order to check the optimality of Figure 1, the minimum freshwater usages for the case study when only one contaminant is considered and time is entirely ignored can be obtained by any availble method(Foo et al., 2005), which are all 80 ton. So the low bound of minumu freshwater usage is 80 ton and the freshwater consumption in Figure 1 is really near to this low bound value and the error is only 4%.

Table 1: Process data for the example problem

Unit	Time(h)		Contaminant	$C_{in,k}^{max}$	$C_{out,k}^{max}$	m^{load}	F^{lim}
	intake	discharge		ppm	ppm	kg	ton
1	0.0-1.0	1.0-5.0	A	0	100	3.0	30
			B	0	90	2.7	
			C	0	50	1.5	
2	0.0-0.5	4.5-5.0	A	40	150	8.25	75
			B	60	80	1.5	
			C	20	70	3.75	
3	5.0-6.5	5.0-6.5	A	170	170	0	40
			B	120	120	0	
			C	100	100	0	
4	2.0-2.5	6.5-7.0	A	110	210	3.0	30
			B	135	200	1.95	
			C	60	120	1.8	
5	7.0-8.5	7.0-8.5	A	170	170	0	40
			B	120	120	0	
			C	100	100	0	

6. Conclusions

A systematic heuristic design procedure for batch water-using network with multiple contaminants is proposed in this paper. Two allocation principles and the corresponding network synthesis steps are illustrated with a simple example. The implementation results show that this manual design strategy is quite effective for producing near optimal water-using networks.

Abstract

This work presents a new mathematical programming model for the optimal integration of an industrial water network and its supporting watershed. In particular, the model determines the optimal location of a new industrial facility considering the sustainable integration of its wastewater discharges with the surrounding watershed through a disjunctive formulation. The behavior of the watershed impacted by the new discharges is described by the material flow analysis (MFA) technique in terms of property balances. The MFA technique considers all inlet and outlet streams in the watershed (i.e., residential, sanitary, industrial discharges and extractions). Therefore, for a new industrial plant, the proposed model allows to track the water properties throughout the watershed and determine the allowable level of discharges. The objective function involves the minimization of the total annualized cost that includes the costs for the installation of the new plant (including the transportation for raw materials, products and services, as well as the land cost), wastewater treatment, piping, and the purchase of the fresh sources. The resulting model is a mixed-integer nonlinear program (MINLP) and a case study for one of the most important watersheds of Mexico is presented to demonstrate the advantages of the proposed formulation. The results show that the environmental regulations are not enough to satisfy the sustainability of the integrated system (i.e. new industrial plant, watershed and other elements of the environment). Hence, unlike previous approaches, the proposed model yields sustainable water networks by taking into consideration simultaneously in-plant water integration and its interaction with the surrounding watershed including various environmental elements such as neighboring plants, cities and agricultural areas.
Keywords: Property-Based, Material Flow Analysis, Optimal Plant Location, Sustainable Systems, Watershed, Water Integration.

1. Introduction

Industrial facilities consume large quantities of fresh water and, at the same time, produce considerable amounts of wastewater. Over the last years, economic competition, scarcity of fresh water and the increasingly strict environmental regulation on industrial effluents have driven the process industry to develop a variety of techniques for the integrated management of water resources. Among them, the water process integration, which is based on water reuse/recycle and wastewater regeneration strategies, has been proven as an effective approach to reduce both fresh water consumption and wastewater discharge of industrial facilities (El-Halwagi, 2011). While this approach is beneficial, its application has only focused on water integration in individual plants and eco-industrial parks without explicitly addressing the sustainability problem of the surrounding watersheds. Recently, Lira-Barragán et al.

*jmponce@umich.mx

(2010a; 2011b) presented two mathematical programming models to account simultaneously for the optimum water integration of a new industrial plant and the sustainability of its watershed. It should be noted that this integrated approach is based on mass concentration of water streams (i.e. constraints for environment and process units are in terms of composition of the pollutants). Therefore, it cannot handle constraints (i.e. environmental regulations) imposed on water quality in terms of properties such as pH, toxicity, turbidity, chemical oxygen demand (COD) and others.
Therefore, this work presents a mathematical programming formulation based on properties for water network synthesis of new plants with multiple pollutants, which allows the simultaneous consideration of the integration of their discharges with macroscopic watershed systems. The Material Flow Analysis (MFA) technique is used to determine the environmental impacts of material flows caused by new plants on the watersheds. Since different plant locations will have different environmental impact and may entail different treatment costs, the plant location is incorporated as a design variable into the model using disjunctive programming and a set of discrete variables. The proposed formulation identifies the optimal property-based water network and location of a new plant that meet the sustainability requirements of the watershed system.

2. Model Formulation

The model proposed in this paper is based on the representation shown in **Figure 1**, where the integration of the wastewater effluent from the new plant is integrated with the surrounding watershed through the determination of the optimal location of the new plant and the quantity and quality (given in terms of specific values for the properties) of the wastewater discharged to the watershed. Notice in this figure that each process source inside the new industrial plant is segregated to be treated for a set of interceptors in several treatment stages. Once the treatment is completed, these streams and the fresh sources are sent to the process sinks and to the wastewater discharge. The process sinks and the wastewater discharge include property constraints. This allows to integrate the process wastewater discharge with other discharges to the watershed (i.e., water for agricultural use, wastewater discharged to the river with and without treatment, industrial and residential effluents, etc.), in addition to natural phenomena like precipitation, filtration and vaporization, as well as the quality for the water in the final disposal to avoid accumulation of hazardous pollutants.
To determine the properties of the water in different sections of the watershed, the river is sectioned in parts (reaches) where the properties can be considered constant (ovals in **Figure 1**). The discharges to the watershed contain compounds that interact chemically and biochemically with the system thought the flora and fauna established in the watershed; in addition, the properties of these discharges modify the properties of the water in the watershed. To ensure the sustainability of the surrounding watershed, it is required to carry out an analysis prior to the optimization respect to the capacity of the final disposal to decompose chemically and biochemically the pollutants and, as consequence, it is necessary to quantify these processes in terms of properties. The analysis yields the sustainability constraints, which ensures that the pollutants will not be accumulated in the system and to maintain the properties of the watershed under reasonable limits.
To solve this problem, the mathematical programming model consists of four main elements: the material flow analysis model for the watershed, the water network inside the new industrial facility, the disjunctive model to integrate the new discharge to the watershed and the objective function.

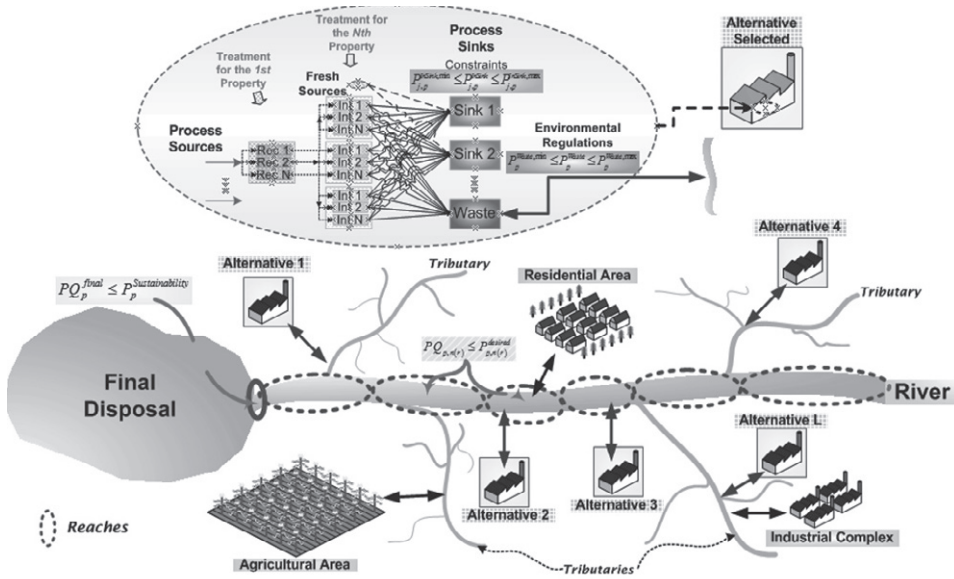

Figure 1: Problem addressed in this paper including the mass integration inside the new plant.

Watershed model based on properties. The overall and component balances for the different sections of the river (**Figure 1**) state that the outlet flowrate in a reach Q_r is equal to the inlet flowrate Q_{r-1} plus precipitation P_r, direct discharge D_r, residential discharges H_r, the sum of tributaries $FT_{r,t}$ and the possible discharge from the new plant $QPNEW_r$ minus the losses L_r and uses U_r.

$$Q_r = Q_{r-1} + P_r + D_r + H_r + \sum_{t=1}^{N_{t(r)}} FT_{r,t} + QPNEW_{r(l)} - L_r - U_r, \quad \forall r \in R \tag{1}$$

The property balances of each reach are based on equation (1), but this also includes a reactive term $r_{p,r}$ to account for the chemical and biochemical reactions that change the properties of the streams. In addition, the mixing rules for different properties are stated in similar way that the component balances (i.e., proportional to the flowrate). However, some properties do not follow a direct relation with the flowrate, so specific property operators ψ_p determined experimentally are used for these cases (see Shelley and El-Halwagi, 2000).

$$\psi_p\left(P_{p,r}^{Reach}\right)Q_r = \psi_p\left(P_{p,r-1}^{InReach}\right)Q_{r-1} + \psi_p\left(P_{p,r}^{Prec}\right)P_r + \psi_p\left(P_{p,r}^{Ind}\right)D_r + \psi_p\left(P_{p,r}^{Resid}\right)H_r + \sum_{t=1}^{N_{t(r)}}\psi_p\left(P_{p,r,t}^{Trib}\right)FT_{r,t} \tag{2}$$

$$+\psi_p\left(P_{p,r(l)}^{PNEW}\right)QPNEW_{r(l)} - \psi_p\left(P_{p,r}^{Loses}\right)L_r - \psi_p\left(P_{p,r}^{Uses}\right)U_r - \int_{V=0}^{V_r} r_{p,r}\,dV_r, \ \forall p \in P, r \in R$$

Similar balances are established for the tributaries of the river.

Location of the new plant. There are several alternatives (L) to locate the new industrial facility specified prior to the optimization process. For each alternative, it is necessary to consider the possible discharge of the new wastewater ($QPNEW_l$) with its properties. Thus, if the new industrial plant is located in the alternative 1, the wastewater flowrate and their property associated to this site must be greater than zero; otherwise, if the new plant is not located in the position 1, the wastewater flowrate and their property operators discharged are zero. This is included in the following disjunction:

$$\begin{bmatrix} Y_1 \\ \psi_p\left(P_{p,1}^{PNEW}\right) \geq 0, QPNEW_1 \geq 0 \\ \psi_p\left(P_{p,2}^{PNEW}\right) = 0, QPNEW_2 = 0 \\ \vdots \\ \psi_p\left(P_{p,I}^{PNEW}\right) = 0, QPNEW_I = 0 \end{bmatrix} \vee \begin{bmatrix} Y_2 \\ \psi_p\left(P_{p,1}^{PNEW}\right) = 0, QPNEW_1 = 0 \\ \psi_p\left(P_{p,2}^{PNEW}\right) \geq 0, QPNEW_2 \geq 0 \\ \vdots \\ \psi_p\left(P_{p,I}^{PNEW}\right) = 0, QPNEW_I = 0 \end{bmatrix} \vee \cdots \vee \begin{bmatrix} Y_I \\ \psi_p\left(P_{p,1}^{PNEW}\right) = 0, QPNEW_1 = 0 \\ \psi_p\left(P_{p,2}^{PNEW}\right) = 0, QPNEW_2 = 0 \\ \vdots \\ \psi_p\left(P_{p,I}^{PNEW}\right) \geq 0, QPNEW_I \geq 0 \end{bmatrix}, \quad \forall p \in P$$

The previous disjunction is reformulated using the convex hull technique.

In-plant water integration. The in-plant mass integration is based on **Figure 1**. The size of this formulation increases exponentially according to the number of treated properties (*N*); however, the major advantage for the model obtained from this representation is that it is linear. As it can be seen in **Figure 1**, for each property to be treated there is a set of treatments units; therefore, there are *N* treatment units. The balances for describing the in-plant water integration include the overall and property balances in the segregating and mixing points as well as the models for the property interceptors.

Environmental constraints. The model requires a set of constraints that include upper and lower limits for specific properties in the wastewater discharged to the environment (i.e., pH, COD, toxicity, color, etc.). These are stated in form of property operators as:

$$\psi_p\left(P_p^{Waste,\min}\right) \leq \psi_p\left(P_p^{Waste}\right) \leq \psi_p\left(P_p^{Waste,\max}\right), \quad \forall p \in P \tag{3}$$

Constraints for the quality of specific reaches. It is necessary a set of property constraints for some reaches of the river where water is required for specific uses:

$$\psi_p\left(P_{p,m(r)}^{DesiredMIN}\right) \leq \psi_p\left(P_{p,m(r)}^{\text{Re}ach}\right) \leq \psi_p\left(P_{p,m(r)}^{DesiredMAX}\right), \quad \forall p \in P, m(r) \in M(R) \tag{4}$$

Sustainability constraints. The model considers the following constraints to assure the sustainability of the watershed and avoid environmental risks of the final disposal:

$$\psi_p\left(P_p^{SustainableMIN}\right) \leq \psi_p\left(P_{p,final}^{\text{Re}ach}\right) \leq \psi_p\left(P_p^{SustainableMAX}\right), \quad \forall p \in P \tag{5}$$

Objective Function. The objective function consists in the minimization of the total annual cost (*TAC*), which is constituted by the installation cost for the new plant, the fresh sources cost, the treatment cost (including operational cost, variable and fixed capital cost) and the piping cost. The installation cost ($Cland_l$) takes into account the land cost and the transportation costs for raw materials, products and services.

$$\begin{aligned} Min\ TAC = & \sum_{l \in L} Cland_l y_l + H_Y \sum_{k \in K} FreC_k F_k + H_Y \sum_{i \in I} \left[\sum_{int^1 \in INT^1} VarC_{op}^{int^1} w_i^{int^1} + \cdots \sum_{int^N \in INT^N} \left(VarC_{op}^{int^N} w_i^{int^1, \cdots, int^N} \right) \right] \\ & + H_Y \sum_{i \in I} \left[\sum_{int^1 \in INT^1} VarC_{cap}^{int^1} w_i^{int^1} + \cdots \sum_{int^N \in INT^N} \left(VarC_{cap}^{int^N} w_i^{int^1, \cdots, int^N} \right) \right] + k_f \sum_{i \in I} \left[\sum_{int^1 \in INT^1} FixC_{cap}^{int^1} z_i^{int^1} + \cdots \sum_{int^N \in INT^N} \left(FixC_{cap}^{int^N} z_i^{int^1, \cdots, int^N} \right) \right] \\ & + H_Y \left[\begin{array}{l} TrPipC \sum_{i \in I} \left(\sum_{int \in INT} w_i^{int^1} + \cdots \sum_{int^N \in INT^N} w_i^{int^1, \cdots, int^N} \right) + WaPipC \sum_{i \in I} \sum_{int^1 \in INT^1} \cdots \sum_{int^N \in INT^N} g_{i,Waste}^{int^1, \cdots, int^N} \\ + EqPipC \sum_{i \in I} \sum_{int^1 \in INT^1} \cdots \sum_{int^N \in INT^N} \sum_{j \in J} g_{i,j}^{int^1, \cdots, int^N} + FrPipC \sum_{k \in K} \sum_{j \in J} f_{k,j} \end{array} \right] \end{aligned} \tag{6}$$

3. Results and Discussion

This case considers the Balsas watershed that is one of the biggest systems in Mexico (**Figure 2**). This system transports several types of discharges until the Pacific Ocean (CONAGUA, 2010). The properties restricted for the stream discharged to the environment are composition, toxicity, COD, odor and color, while the process sinks limit the composition and density. In this sense, the environmental regulations for the properties restricted in the wastewater stream are the following: for composition is 50, for the toxicity is 0.1, for COD is 75, for odor is 2.7 and for color is 100. The system has twenty possible locations to install the new industrial facility. This example was

implemented in GAMS using the solver DICOPT and the optimal solution found by the proposed model shows that the new facility must be placed in alternative 6 with a total annual cost of $\$14.9x10^6$/yr, composed by $\$9x10^6$/yr for installation cost, $\$3.6x10^6$/yr for treatment cost, $\$1.52x10^6$/yr for fresh source cost and \$779,040/yr for piping cost. In this solution, the mass integration shows that the values for some of the properties in the discharged wastewater stream need to be lower than their corresponding environmental regulations to fulfill the constraints in the watershed. For example, the value of toxicity in the wastewater stream is zero, satisfying the constraint in the reach 8, where is not allowed the existence of this property.

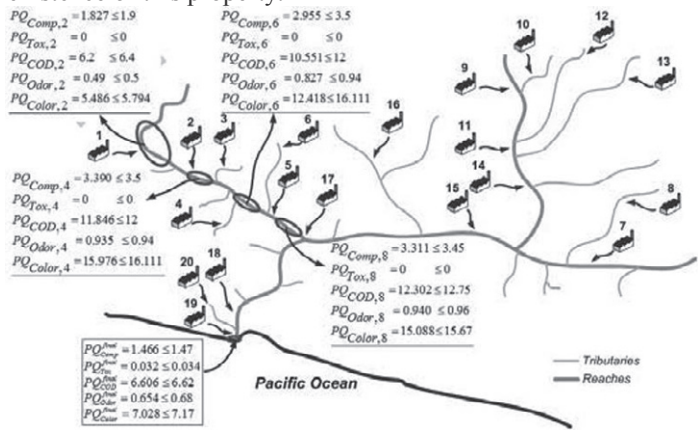

Figure 2. Balsas watershed system.

4. Conclusions

This work presents a new water integration approach to consider simultaneously the water integration inside a new plant and the sustainability of the associated watershed. The results show that the traditional water integration schemes that do not consider the watershed system yield inappropriate solutions, because the environmental regulations are not enough to satisfy the sustainability of the system. To satisfy the sustainability, the interaction of the wastewater streams discharged to the environment with other discharges through the watershed must be considered in conjunction to the chemical and physical phenomena that happen in the watershed. In addition, a model based on properties like the one proposed is suited for this problem because the large set of compounds present in these macroscopic systems.

Abstract

The impact of climate change, particularly drought, places an enormous pressure on the synthesis of process systems that use freshwater resources efficiently. This paper presents the synthesis of water-based polygeneration system to minimize freshwater consumption. A comprehensive model is formulated through a superstructure, featuring the possible configurations of simultaneous heat and power generations, re-circulating cooling water system, wastewater treatment options, as well as reaction and separation technologies for chemical production. Process units are modeled using Aspen Hysys 2006. A case study on the synthesis of optimum water polygeneration system is developed for an ethylene glycol production. The superstructure model is a mixed integer non-linear programming problem (MINLP) consisting of 305 equations, 326 variables and 20 binary variables. The objective of the model is to minimize freshwater make-up subject to 85 constraints. The model is subsequently solved using DICOPT++ in GAMS 20.7 with the optimum solution showing nearly 50% savings of freshwater consumption.

Keywords: water conservation, heat and power, cooling water, 3R, ethylene glycol.

1. Introduction

Climate change creates pressure on the sustainability of future water supplies. The problem of declining freshwater resources due to population and industrial needs is further elevated by the impact of climate change such as drought. The problem is further compounded with the generation of industrial waste water. A recent strategy to address the problem of declining resources, such as water, is polygeneration. Polygeneration is an integrated approach to generates multiple products from a single resource [1-2]. In the case of water-based polygeneration, water is the main input material for the generation of multiple outputs from a single industrial plant, such as hot utility, power, cold utility and chemical products. As a result, water-based polygeneration minimizes the consumption of limited natural resources and energy as well as reducing the generation of waste water [2].

Previous works have addressed the design and analysis of polygeneration system from the perspective of energy conservation [3-4]. The search for an optimum polygeneration energy system is computationally demanding due to the complex combination of options that are built in large superstructure representation. Liu et al. [5-8] developed mathematical programming models for the design and analysis of polygeneration energy systems. The investment planning for the polygeneration system was formulated as a mixed integer linear programming (MILP) model and solved in GAMS [5]. The authors later developed mixed-integer nonlinear programming (MINLP) models to address design and operational variables [6] with multi-objective optimization function [7] and

polygeneration energy systems design under uncertainty using decomposition based stochastic programming approach [8]. Optimum polygeneration system of a combined energy and water production has been presented by Rubio-Maya et al. [9]. Choices of possible technologies are represented using MINLP superstructure. Although the focus of the work was on desalinated and cooling water production associated with the production of heat and power, it did not investigate the minimization of freshwater consumption and wastewater generation.

In this study, optimum polygeneration system incorporating 3R water conservation concept, i.e. regenerate, reuse and recycle, is investigated. An MINLP model is developed through a superstructure that simultaneously addresses heat and power generations, re-circulating cooling water system, wastewater treatment options, and reaction and separation technologies for chemical production. A water polygeneration system for ethylene glycol production is presented as a case study.

2. Superstructure Representation

The mathematical programming problem for a process network synthesis is formulated using a superstructure that incorporates many alternative design paths. The idea of a superstructure is to establish the interaction between intermediate inputs and outputs for every unit operation represented as a network comprising process streams and equipment. Yeomans and Grossmann [10] presented a state-task-network (STN) in which three basic elements of superstructure syntheses are states, tasks, and equipment. As shown in Fig. 1, a circle represents the state of a process stream, such as raw material composition, or product flow rate. In addition, a task corresponds to momentum, mass and energy transfer that take place in equipment such as heat exchanger, reactor, or absorber. States and tasks are connected with arrow lines building the network superstructure. The identification of states and tasks helps in determining the type of equipment to be applied for each task. For complex process synthesis problem, such as the water-based polygeneration system, the superstructure is further divided into subsystems comprising different unit operations.

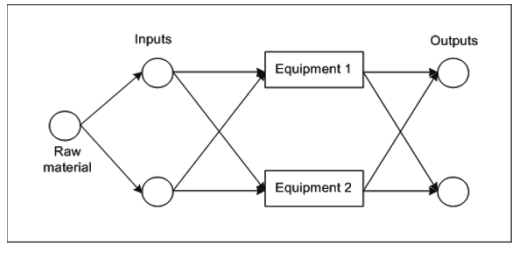

Fig.1. General superstructure representation.

3. Model Formulation

A mixed integer nonlinear programming (MINLP) model for the selection of optimum water-based polygeneration system is formulated based on superstructure representation. Binary variable, $y \in Y = \{0,1\}$, is introduced as a logical constraint that provides yes-no decision. The selection of process technology option is represented as

$$\sum_{i \in I} y_i = 1 \qquad (1)$$

where i is index of unit operation. For a specific unit operation i, variable $y_i = 1$ if unit i is selected in the optimal structure or 0 otherwise.

For heat and power generation subsystem, mass and energy balances are expressed as

$$\sum_j \sum_i F_{j,i}.y_i - \sum_k \sum_i F_{k,i}.y_i = 0 \tag{2}$$

$$\sum_j \sum_i F_{j,i}.H_j.y_i - \sum_k \sum_i F_{k,i}.H_k.y_i = 0 \tag{3}$$

where F and H are flowrates and enthalpy values of inlet streams j and outlet streams k, respectively. For the energy balance around steam boiler, an efficiency factor, η_B, is also included. For the energy balance around steam turbine, the power demand, $W_{st,i}$, and the steam enthalpy at steam pressure level, $\Delta H_{st,i}$, is correlated to the flowrate intake of the steam turbine, $FT_{st,i}$, as shown below [11]:

$$F_{stB} - \sum_{i \in I} FT_{st,i} = 0 \tag{4}$$

$$FT_{st,i} = W_{st,i} / \Delta H_{st,i} \tag{5}$$

In Eq. (4), F_{stB} refers to steam flowrate coming from the boiler of the selected steam generation technology.

In the cooling water subsystem, mass balance around the cooling tower is given by

$$F_{in} + F_m - F_{out} - F_b = 0 \tag{6}$$

where F_{in} is the inlet water flowrate to cooling tower, F_{out} is outlet water flowrate of cooling tower, F_m is the cooling water makeup and F_b is the cooling tower blowdown. Water loss through evaporation, F_{ev}, is correlated to blowdown and makeup as per Eq. (7) and (8), in which π_c is the cooling tower cycles of concentration.

$$F_b = F_{ev} / (\pi_c - 1) \tag{7}$$

$$F_m = F_{ev} \left[\pi_c / (\pi_c - 1) \right] \tag{8}$$

The chemical production subsystem is simulated in Aspen HYSYS 2006 using the UNIQUAC property model. The constraints for the supply of cooling, heating and power requirement in the chemical production are formulated as per process demands. For example, the steam supply to a distillation column, St_{supply}, is equal to the steam demand by the reboiler, St_{Dem}.

$$ST_{supply} \geq ST_{Dem} \tag{9}$$

The objective for the water-based polygeneration system is to optimize the flowrate of freshwater consumption (FW) at minimum total annualized cost. The objective function (z) includes the cost of freshwater intake, C_{fw}, and the cost of water recovery, $OP_{recovery}$, as shown in Eq. (10).

$$\min z = \left[(FW \times C_{fw}) + OP_{recovery} \right] \times AOT \tag{10}$$

The cost of water recovery takes into consideration the pumping cost as well as cost associated with water recycle, reuse and regeneration (3R). Water recycling involves post-treatment process of the water quality to meet the next water-user specification.

However, water reuse does not require additional treatment and is possibly sent to the next user in its water effluent condition. The cost is calculated on annual basis assuming annual operation time, *AOT*, of 8000 hrs/year.

4. Case Study: Water-based polygeneration system in ethylene glycol production

An ethylene glycol production follows the reaction between ethylene oxide and water at temperature of 200^{o}C and pressure of 20 bars to produce mono-ethylene glycol and other higher glycols derivatives. The product recovery and purification consume water for the heating and cooling of the separation processes. An MINLP model based on the superstructure generated in Fig. 2. is demonstrated for the synthesis of an optimum water-based polygeneration system in an ethylene glycol production.

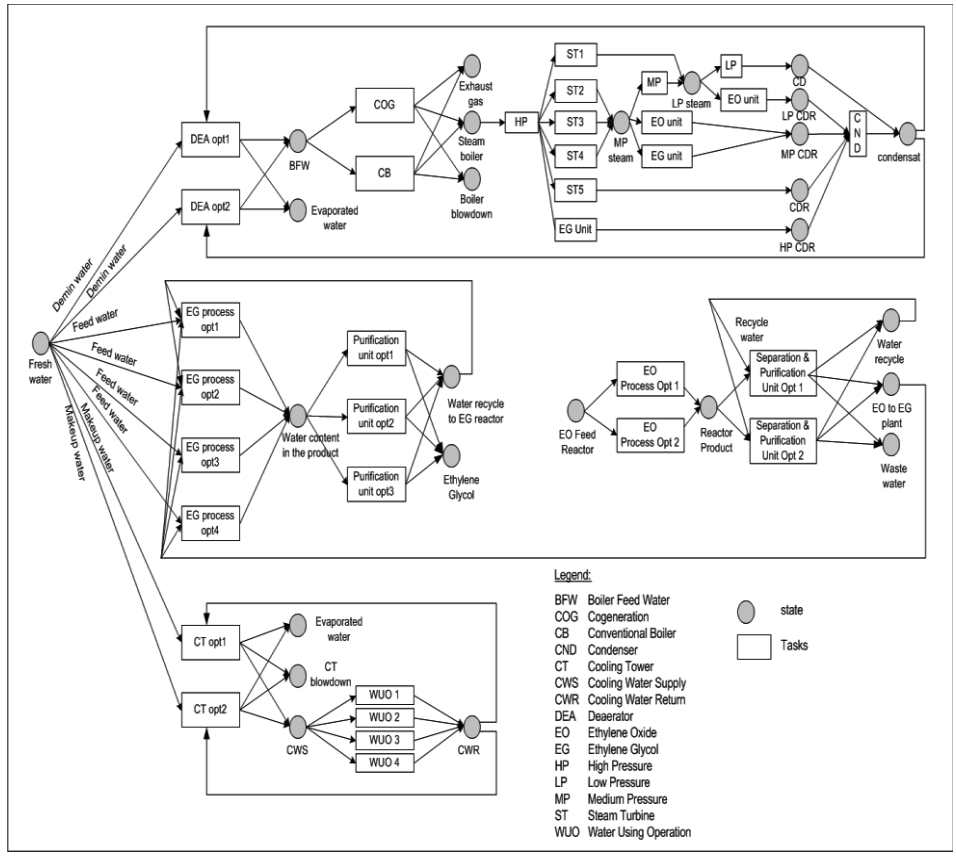

Fig.2. Superstructure representation of water-based polygeneration system.

The superstructure for water-based polygeneration system is presented with three subsystems, namely heat and power generation, recirculating cooling water and chemical production. The heat and power generation subsystem features power generation option from either gas turbine or steam turbine, while the option for boilers include a conventional boiler or a cogeneration system that recovers hot gas turbine exhaust to raise steam. Gas turbines options are simple or regenerative gas turbines, while steam turbines options are back-pressure or condensing steam turbines. For recirculating cooling water system, choices of cooling tower include the forced or the

induced mechanical drafts types. For the chemical production subsystem, two options of ethylene glycol (EG) synthesis are ethylene oxide (EO) hydrolysis and the Shell's OMEGA process. Options for the separation system include direct sequence, indirect sequence or dividing wall distillation column.

The model is developed in GAMS and solved using DICOPT++. It is a nonconvex MINLP model comprising 20 binary variables, 326 continuous variables and 305 equations. The optimum results indicate the power generation unit employs a cogeneration system comprising a gas turbine with HRSG and three steam turbines. Simple gas turbine cycle and back-pressure steam turbine are selected to meet the heat and power demands. For EG production, the EO hydrolysis process is selected with minimum freshwater consumption. For separation unit, the dividing wall column is selected resulting in significant reduction in capital cost from the distillation columns arrangement and considerable energy savings in condenser and reboiler loads.

Table 1. Optimum results of water-based polygeneration system

	Freshwater consumption (t/hr)	Wastewater generation (t/hr)	Objective Function ($/yr)
Base case	447.674	228.453	931,161.08
Optimised case	219.221	0	637,587.84

The 3R strategy for water recovery is also implemented in the optimum solution. As shown in Fig. 2, freshwater is consumed as makeup for demineralized water in the heat and power subsystem, feed to the EG reactor, and makeup water for the cooling tower. The cost of water consumption is minimized through water regeneration and recycle from boiler and cooling tower blowdown as well as from wastewater produced in the EG plant. Comparison between the base case and the optimized case is summarized in Table 1. The optimized case showed a significant reduction of freshwater consumption by almost 50% and total elimination of wastewater generation.

5. Conclusion

A comprehensive model for the synthesis of an optimum water-based polygeneration system was formulated through superstructure representation. The application of the model was demonstrated on an ethylene glycol production case study. The optimum solution highlighted that water-based polygeneration system may potentially bring significant savings in freshwater consumption.

Abstract

This paper proposes a multi-objective genetic algorithm for optimal synthesis of integrated water networks. The framework is based on formulating a superstructure that incorporates all feasible design alternatives for the water network and solves it for minimum freshwater and treatment costs. It considers also selection of treatment units and piping cost in the formulation. The framework is illustrated by solving a literature case study.

Keywords: water reuse, wastewater minimization, superstructure, NSGA-II.

1. Introduction

In chemical plants, the water that is used for processing and non-processing purposes would lead to wastewater that needs to be treated to acceptable level prior to being discharged to the environment. With growing pressure to become more sustainable, chemical plants are looking for alternatives to minimize their freshwater consumption as well as wastewater generation. This is especially important in region with constrained water resources. In this regard, process modifications through water saving technologies and optimal design of water networks need to be promoted.

The problem of optimal synthesis of an integrated water network can be described as follows: given a set of processing units that requires water, synthesize an optimal network of water flows over the set of processing units subject to contaminant mass load, allowable contaminant concentrations, maximum flowrates, and wastewater treatment efficiencies. This optimization problem is known to be highly nonlinear and nonconvex. Over the past decades, various solution methods have been proposed and these can be differentiated into deterministic and stochastic. The former formulates the water network synthesis problem as MINLP and solves it for global optima. The drawback of this approach is that it is limited to formulating the water network synthesis as single objective problem involving either minimization of freshwater or cost. Further, solution to MINLP problem is difficult and cannot be guaranteed by the conventional gradient-based algorithm (Hul et al., 2007). To mention a few, Karuppiah and Grossmann (2006) proposed an advanced search strategy by combining deterministic spatial branch and contract algorithm and General Disjunctive Program for optimizing water network superstructure. Rubio-Castro et al. (2010) solved the MINLP superstructure by first discretizing it to MILP (mixed integer linear programming).

Stochastic optimization techniques such as genetic algorithm (GA) have been applied to solve the integrated water network problem. Tsai and Chang (2001) applied a GA technique to identify minimum freshwater consumption and cost-optimal water usage and treatment network. Tudor and Lavric (2011) proposed a GA method for

simultaneous minimization of freshwater consumption and piping cost. The advantage of stochastic approach over the deterministic method is that the former is able to explore the trade-off surface of multiple objectives efficiently. Another advantage of stochastic technique is its ability to solve the inherently nonlinear and nonconvex problem with optimal consistency (Thunyawart et al., 2011). However, such advantage comes at the expense of longer computing time (Hul et al., 2007).

In this paper, we apply a multi-objective GA for simultaneous minimization of freshwater consumption and total water treatment cost including the piping cost. We include a choice for selection of treatment units in the formulation and explore the trade-off surface of the two objectives.

2. Integrated water network model

The water network model is based on the superstructure shown in Figure 1 (Karuppiah and Grossmann, 2006). It shows an integrated water network with four process units (PUs) and two groups of treatment units (TUs). Each PU requires water and would pick up a certain load of contaminants from the processing. The resulting wastewater stream from each PU must be treated in the TUs prior to discharge. In this case, one TU from each treatment group needs to be selected. To minimize the amount of freshwater usage, water from the TUs needs to be reused. However, this is subject to maximum allowable inlet contaminant concentrations of the PUs.

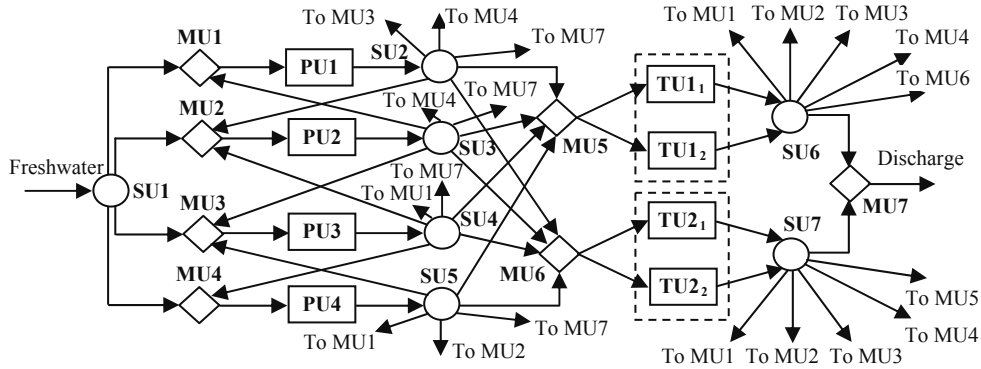

Figure 1. Superstructure of water network with selection of treatment units

The mass balance over a process unit p is written as:

$$F_i\, C_{i,j} + L_j \times 1000 = F_k\, C_{k,j} \tag{1}$$

where F_i and F_k are the flowrates of the input i and output k streams of unit p (ton/h), $C_{i,j}$ and $C_{k,j}$ are the concentrations of contaminant j in the input i and output k streams of unit p (ppm), and L_j is the loading of contaminant j in unit p (kg/h). In this case, F_i and F_k are assumed as equal. The removal of contaminant j from a treatment unit t is described as:

$$C_{i,j} = (1 - RR_j) C_{k,j} \tag{2}$$

where RR_j is the removal ratio for contaminant j in unit t.

The objective functions are described as follows:

$$\text{Min } HC_{FW} FW \tag{3}$$

$$\text{Min } \Phi = AR \sum_{t=1}^{T_{total}} IC_t F_{out,t}^{\ \alpha} + H \sum_{t=1}^{T_{total}} OC_t F_{out,t} + PC \tag{4}$$

where FW is the freshwater flowrate to all process units (ton/h), C_{FW} is the freshwater cost ($/ton), H is plant operating hours per annum (h/yr), AR is the annualized

investment factor (/yr), IC_t is the investment cost coefficient for treatment unit t, $F_{out,t}$ is the flowrate of wastewater from treatment t (ton/h), OC_t is the operating cost coefficient for treatment unit t (ton/h), and PC is the piping cost expressed as follows (Rubio-Castro et al., 2010):

$$PC = AR \times PP \times [\frac{D_{k,i}F_{k,i}}{3600\rho\upsilon} + D_{k,i} \times CU_p] \quad (5)$$

where PP is the pipe parameter, $D_{k,i}$ is the piping distance between point k and i (m), $F_{k,i}$ is the flowrate between point k and i (kg/h), ρ is the water density (kg/m^3), υ is the velocity of water inside the pipe (m/s), and CU_p is the unit cost of the pipe ($). Here, we set a minimum flow of 0.1 ton/h in each pipe, except for the flow to the discharge.

3. Multi-objective Genetic Algorithm

We have applied Non-Dominated Sorting in Genetic Algorithm-II, NSGA-II, (Deb et al., 2002) for multi-objective optimization. The procedure is as follows:

Step 1. A random initial population of size N is generated within the variable ranges and the objective functions for each chromosome are evaluated.

Step 2. The initial population is sorted based on the objective values using fast sorting method to generate several non-dominated fronts. Each member in each front is assigned a fitness value (rank).

Step 3. The crowding distance for each member in each front is calculated and sorted according to its objective values.

Step 4. Based on the rank and crowding distance, the parent population is selected from the initial population using binary tournament selection.

Step 5. Crossover and mutation are performed to the parent population to generate offspring population.

Step 6. The parent and offspring population are combined to generate a population size of 2N. Elitism is performed to select the best population of size N according to its objective function value.

Step 7. The stopping criterion is checked. Step 2 to 7 is repeated if necessary.

The decision variables in this water network problem are various water flows – Freshwater to PU, PU to another PU, PU to TU, PU to Discharge, TU to PU, TU to another TU, and TU to Discharge. Other decision variable is selection of treatment technology for each treatment group. These flows together with treatment selection constitute a chromosome. The GA is coded in such a way that mass balance constraints will always be satisfied. As concentration limits may be violated, a penalty function proportional to the difference from the limit is applied on the objective values.

4. Case study

We have solved the case study of Karuppiah and Grossmann (2006) shown in Figure 1. It involves two contaminants A and B, for which the PU and TU data are shown in Table 1 and 2, respectively. The discharge limits for both contaminants are 10 ppm. The freshwater cost is $1/ton and the annualized factor for investment is taken to be 0.1/yr. The plant is operated for 8000 h/yr. Table 3 shows the distances between PUs and TUs.

The Pareto plot in Figure 2 shows a trade-off between freshwater and treatment costs. It shows that for a network with less freshwater flow, it needs to be compensated with more flow of reused water. Consequently, this leads to higher treatment cost. The figure also shows a minimum total operating cost of $655,110 which corresponds to minimum freshwater case. Figure 3 compares two different water networks involving minimum freshwater and treatment costs. The former corresponds to freshwater flowrate of 40

ton/h while freshwater flowrate in the later is 75.16 ton/h. In both cases, the selected treatment technologies are $TU1_2$ and $TU2_1$ – this is in line with the results of Karuppiah and Grossmann (2006). Comparison between Figure 2 and 3 highlights that a change to the network structure would lead to significant repercussion in the freshwater demand. This explains a series of "jumps" in the freshwater cost shown in Figure 2.

Table 1. Process unit data

Unit	Flowrate (kg/h)	Contaminant load (kg/h)		Max. inlet concentration (ppm)	
		A	B	A	B
PU1	40	1	1.5	0	0
PU2	50	1	1	50	50
PU3	60	1	1	50	50
PU4	70	2	2	50	50

Table 2. Treatment unit data

Group	Treatment technology	α	Removal ratio (%)		Investment cost coeff.	Operating cost coeff.
			A	B		
TU1	$TU1_1$	0.7	95	0	16800	1
	$TU1_2$	0.7	90	0	4800	0.5
TU2	$TU2_1$	0.7	0	90	12600	0.0067
	$TU2_2$	0.7	0	95	36000	0.067

Table 3. Distances (in meters) between plant units

	PU1	PU2	PU3	PU4	$TU1_1$	$TU1_2$	$TU2_1$	$TU2_2$	Discharge
Fresh	150	170	180	200	–	–	–	–	–
PU1	–	50	50	50	60	60	60	60	70
PU2	50	–	50	50	60	60	60	60	70
PU3	50	50	–	50	60	60	60	60	70
PU4	50	50	50	–	60	60	60	60	70
$TU1_1$	60	60	60	60	–	–	20	20	10
$TU1_2$	60	60	60	60	–	–	20	20	10
$TU2_1$	60	60	60	60	20	20	–	–	10
$TU2_2$	60	60	60	60	20	20	–	–	10

5. Conclusions

A multi-objective optimization framework for integrated water network is proposed using NSGA-II. The framework takes into account selection of treatment technologies and piping cost. The framework is tested using a literature case study. Pareto plot of the optimization results highlights trade-off between the freshwater and treatment costs. Our future work is to extend the framework to batch process by exploring both the structural and variable aspects of the synthesis problem.

Synthesis of water networks for processes with mixed batch and continuous units

Cheng-Liang Chen, Chun-Yen Lin, Hui-Chu Chen, Jui-Yuan Lee

National Taiwan University, No. 1, Sec. 4, Roosevelt Rd., Taipei 10617, Taiwan

Abstract

This paper presents a mathematical model for the synthesis of water networks, where both batch and continuous units are involved. For cases where the number of batch units is greater than that of continuous units, a dividing approach is proposed. By treating continuous operation as a combination of batch operations, the original design problem is simplified and the remaining task is almost to synthesize a batch water network. The model is formulated as a mixed-integer nonlinear program based on a superstructure including all feasible network interconnection. A modified literature example is solved to illustrate the proposed approach.

Keywords: process integration, water network synthesis, batch and continuous units, mathematical optimization.

1. Introduction

Water is one of the most important natural resources widely used in various process industries. However, rapid industrial growth has led to serious water pollution in the world. In addition, the growing concern about high consumption and waste of water for industrial applications calls for efficient and responsible use of water in industry. Other reasons tied to this need include the predicted scarcity of industrial water, increasingly stringent environmental regulations for wastewater disposal, and the rising costs of fresh water and effluent treatment.

To make efficient use of water, water recovery via *water network synthesis* has been commonly accepted as an effective means, with *reuse*, *recycle*, and *regeneration* as options for reducing industrial water withdrawals and discharges. Over the past decades, various *process integration* techniques for water network synthesis were developed for continuous and batch processes (Foo, 2009; Jeżowski, 2010; Gouws et al., 2010) based on *pinch analysis* and *mathematical optimization* approaches. The latter is preferred when a systematic strategy leading to an optimal solution is required.

While previous works on water network synthesis are restricted to addressing systems with all continuous or batch units, there are cases where both types of units exist. In this work, a mathematical model is developed for the synthesis of water networks involving batch and continuous units, focusing on the particular case where batch units are in the majority. Application of the model is demonstrated through an illustrative example.

2. Problem Statement

Given is a set of water-using units $i \in \mathcal{I}$ consisting mostly of batch process units ($i \in \mathcal{I}^{b}$) with a few continuous ones ($i \in \mathcal{I}^{c}$). These units require water to pick up a set of contaminants $c \in \mathcal{C}$ with fixed mass loads from the process streams. Available for service are a set of fresh water sources $w \in \mathcal{W}$ supplying water of different purity levels. Prior to

the use of fresh water, reuse/recycle of effluent from the process units is considered. To facilitate water recovery, a set of storage tanks $s \in \mathcal{S}$ for intermediate water storage may be used. The objective is to synthesize an optimal water network that achieves the minimum fresh water consumption, while satisfying all process constraints.

3. Solution Approach

Since the problem addressed in this work involves batch and continuous units, the main challenge is to integrate the units of different operating modes. While continuous units operate uninterruptedly for a long duration, batch units are often operated shortly (for a few hours) and cyclically. In addition, water intake and discharge of a batch unit are found at the start and end of the operation respectively. The inlet and outlet water of a continuous unit, by contrast, is continuously fed and discharged during the operation.

To deal with the case where the number of batch units is greater than that of continuous units, it is proposed to treat continuous operation as a combination of batch operations. This can be achieved by dividing the operating time of continuous units into a number of time intervals, according to the start and end of operation of the batch units. Through water storage, in any time interval (t, $t + 1$) the inlet water of a continuous unit is treated as if charged only at time point t, as illustrated in Figure 1. Meanwhile, the outlet water from the unit is treated as if discharged only at time point $t + 1$. The original problem can thus be converted into a simpler one where only batch units are involved in water network synthesis.

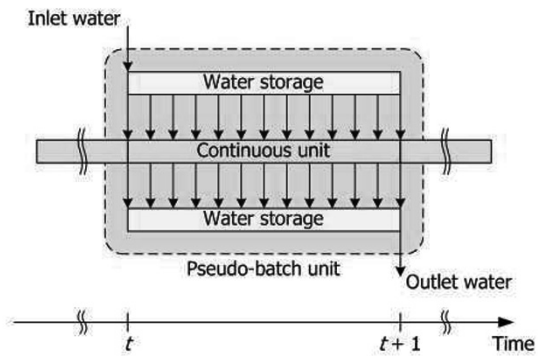

Figure 1: Illustration of a pseudo-batch unit

4. Superstructure and Model

Having treated all continuous units as pseudo-batch units, the remaining task is almost to synthesize a batch water network. In this work, the model developed by Chen et al. (2009) is extended to perform the synthesis task. The modified model consists of basic mass balance equations, flow/concentration limits of water-using units, capacity limits of storage tanks, and logical constraints, and is based on a superstructure including all feasible network connections between units and tanks. To address the time dimension in batch processes, a set of time points $t \in \mathcal{T}$ are defined.

Figure 2 shows the schematic diagram of a water-using unit i. As shown, its inlet water may come from other water-using units i', storage tanks s, and/or fresh water sources w;

its outlet water may be sent to other water-using units *i′*, storage tanks *s*, and/or waste disposal systems *d*.

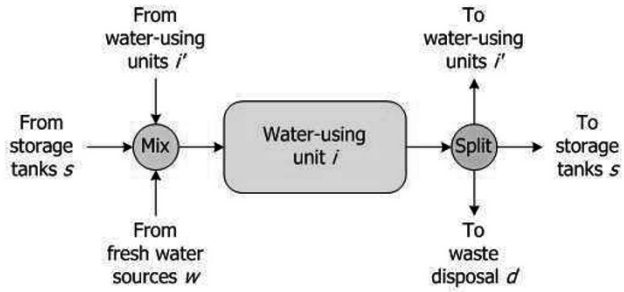

Figure 2: Schematic diagram of a water-using unit

Figure 3 shows the schematic diagram of a storage tank *s*. As shown, its inlet water may come from water-using units *i* and/or other storage tanks *s′*; its outlet water may be sent to water-using units *i* and/or other storage tanks *s′*.

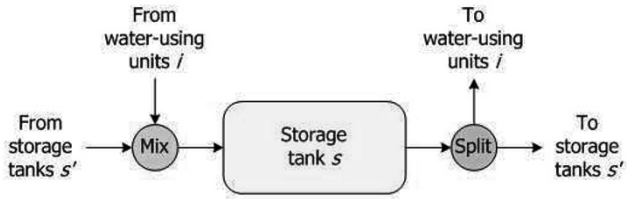

Figure 3: Schematic diagram of a storage tank

Additional constraints that need to be considered are as follows.

- No direct water reuse/recycle is allowed for the continuous units.

This is because treating continuous units as pseudo-batch units involves water storage to change the pattern of water intake and discharge (Figure 1).

- A continuous unit is not allowed to send water to a tank at a time point (t) if the unit received water from the tank at the previous time point ($t - 1$).

In other words, the inlet and outlet water flows of a storage tank must be prevented from occurring in the same time interval. This is to provide sufficient time for perfect water mixing in the tank.

- The inlet and outlet water flow rates of a continuous unit should be constant.

For maximum water recovery, the objective function is set to minimize the consumption of fresh water for water-using operations. Due to the bilinear terms in the contaminant balance equations and binary variables used to indicate the connections between units and tanks, the model is a mixed-integer nonlinear program (MINLP).

5. Illustrative Example

A two-plant example is solved to analyze in-plant and inter-plant water integration. This example involves two plants, nine batch units, and two continuous units. The operating data for the water-using units in both plants are shown in Tables 1 and 2, adapted from Majozi (2005) and Kim and Smith (2004) respectively. From the Gantt charts shown in Figs. 4(a) and (b), it can be seen that seven time points are defined for plant 1 and five time points for plant 2, according to the start and end times of the batch operations. Also,

the operation of unit F is divided into six batch sub-operations and the operation of unit K four sub-operations. A single pure fresh water source is available for use.
The optimization is carried out in the General Algebraic Modeling System (GAMS) on a Core 2, 2.00 GHz processor, with BARON as the solver for MINLP.

Table 1: Operating data for the water-using operations in plant 1

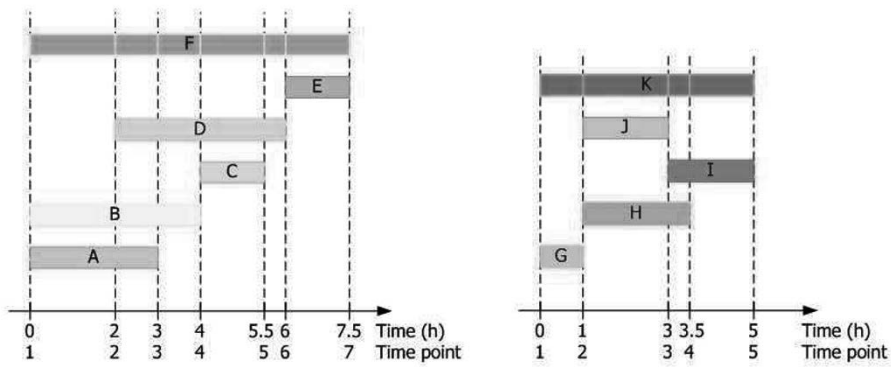
Unit	$C^{in,max}$ (kg salt/ton water)	$C^{out,max}$	M^{load} (kg)	Duration (h)
A	0	0.1	100	0-3
B	0.25	0.51	72.8	0-4
C	0.1	0.1	0	4-5.5
D	0.25	0.51	72.8	2-6
E	0.1	0.1	0	6-7.5
F	0.1	0.25	*187.5	0-7.5

Cycle time = 7.5 h. *Total mass load over the 7.5-h cycle time; the instantaneous mass load of unit F is 187.5 kg/7.5 h = 25 kg/h.

Table 2: Operating data for the water-using operations in plant 2

Unit	$C^{in,max}$ (kg salt/ton water)	$C^{out,max}$	M^{load} (kg)	Duration (h)
G	0	0.1	2	0-1
H	0.05	0.1	12.5	1-3.5
I	0.05	0.8	60	3-5
J	0.4	0.8	8	1-3
K	0.2	0.4	*100	0-5

Cycle time = 5 h. *Total mass load over the 5-h cycle time; the instantaneous mass load of unit K is 100 kg/5 h = 20 kg/h.



(a) (b)

Figure 4: Gantt charts for (a) plant 1 and (b) plant 2 operations

5.1. In-plant Water Integration

Two storage tanks are available in both plants to facilitate water recovery. The model for plant 1 involves 856 constraints, 746 continuous variables, and 168 binary variables, and is solved in 9 CPU s. The minimum fresh water consumption is determined as 1150 ton/cycle. This corresponds to a 56.4% reduction compared with the base case (2635.49 ton/cycle) where no water is recovered. The optimal network configuration is not shown because of space limitation. Both tanks are used and the capacities required are 1000

and 280 ton. The plant 2 model involves 527 constraints, 429 continuous variables, and 100 binary variables, and is solved in 7 CPU s. The minimum fresh water consumption is determined as 356.25 ton/cycle. This corresponds to a 25.8% reduction compared with the base case (480 ton/cycle; without water recovery). Both tanks are used and the required capacities are 125 and 20 ton.

5.2. Inter-plant Water Integration

When the two plants are considered together, a common cycle time of 15 h is assumed, where plant 1 operates two cycles and plant 2 three. Before inter-plant water integration is carried out (in-plant integration only), the total fresh water consumption over the 15-h cycle time is calculated as $1150 \times 2 + 356.25 \times 3 = 3368.75$ ton. By performing pinch analysis for the two plants, one can find out the pinch points for plant 1 and plant 2 are at 0.25 and 0.4 kg salt/ton water, respectively. This indicates sending wastewater of the pinch concentration from plant 1 to plant 2 can lead to further fresh water reduction. From the solution to plant 1, the total amount of wastewater at 0.25 kg salt/ton water is 590 ton/7.5 h. By introducing this wastewater as an additional water source into plant 2 and resolving its model, it is obtained the minimum fresh water consumption of plant 2 is reduced to 222 ton/5 h, and the minimum consumption of the additional water source is 358 ton/5 h. The total fresh water consumption now becomes 2966 ton/15 h, which corresponds to a further 12% reduction through inter-plant integration.

6. Concluding Remarks

A mathematical model has been developed for synthesizing water networks involving batch and continuous units. For the particular case where batch units are in the majority, a dividing approach is proposed. It converts the original problem into a simpler one that is almost to synthesize a batch water network. An example was solved to illustrate the proposed approach. Note that only a preliminary analysis for inter-plant integration has been performed in the present work. A more systematic method should be developed for optimizing connections and operations within individual plants and between different plants. This is the subject of future work. Other cases where the number of continuous units is large compared to that of batch units also remain for future work.

Optimal operation of reverse osmosis plant driven by solar power without batteries

Senthil.K, Shankar Narasimhan, Sridharakumar Narasimhan

Department of Chemical Engineering,
Indian Institute of Technology Madras, Chennai, India

Abstract

Ensuring adequate supply of clean drinking water and electricity in several parts of the world continues to be a formidable challenge. In coastal areas facing this problem, desalination of sea water using Reverse Osmosis (RO) driven by solar power without batteries can be an appropriate technological solution. Variability in incident solar power is a significant operational issue. The focus of this work is optimal operation and control of the RO plant with guaranteed water purity. A steady state model is developed and validated using 'ROSA', a black-box software programme commonly used for simulating RO plants. Analysis of the optimal solution reveals that the feasible space (of available power) consists of two regions where different set of constraints are active. In one region salt concentration constraint is active and in another, the pressure constraint is active. Hence the optimal operation strategy can be implemented by active constraint control.

Keywords: Reverse osmosis, Desalination, Solar power, Optimization, Active constraint control, Without batteries.

1. Introduction

In remote coastal areas where electricity and drinking water are not available, reverse osmosis plants driven by non conventional energies like wind, solar are attractive. Photovoltaic cells provide power that varies with the intensity of sunlight. Since the solar incidence radiation shows significant variability during the day and across months, batteries are used as energy storage devices. However, the main disadvantage with batteries is that they require regular maintenance. This is a major drawback for the plants in remote places. Secondly, efficiency of these batteries is less than 80%. In such a situation, optimal operation of the RO plant without the use of batteries is an excellent option. Some experience of operating and simulating RO unit without batteries can be found in the works of Riffel & Carvalho (2009) and Keefer et al. (1985). Operation of such a plant with guaranteed purity and production is a challenging control problem and this is the focus of this work.

A typical solar powered reverse osmosis plant consists of solar panel, DC-DC converter, three phase bridge, three phase induction motor, reciprocating pump, and membrane unit. The DC-DC converter boosts the voltage from 50 volts to 550 volts. The three phase bridge converts 550 volts DC to a three phase AC power of variable frequency and voltage which is fed to the induction motor. Reciprocating pump driven by the induction motor delivers feed water at a pressure of 60-69 bars to the membrane unit. Permeate that diffuses through the membrane and the reject are collected in separate tanks. In a battery-less solar powered reverse osmosis plant, power available to run the plant varies with intensity of sunlight. The objective of the project is to

maximize permeate production rate for this time varying power subject to the constraint of keeping the salt concentration in permeate at any time less than 500 ppm. The various other constraints considered are water balance, salt balance, salt diffusion equation, water diffusion equation, maximum working pressure of the system and the power constraint.

2. RO membrane Model

An RO membrane model is required to solve the optimization problem. A static lumped parameter model (Dow's Technical manual) can be used for optimization purpose. The various assumptions made in the RO model are

- Temperature of the water is assumed to be 25 deg Celsius
- Frictional pressure drop in the membrane unit is assumed to be negligible

The RO model has two equations, one describing the rate of water diffusion and the other describing the rate of salt diffusion through the membrane. The rate of water diffusion is proportional to the difference between the pressure in excess of the osmotic pressure on the feed side and the pressure in excess of the osmotic pressure on the permeate side.

$$Q_p = A \times S_a \times \{(P_{af} - \pi_{avg} \times PF) - (P_{ap} - \pi_p)\} \tag{1}$$

where Q_p, A, S_a, P_{af}, π_{avg}, PF, P_{ap}, π_p refer to permeate flow rate, permeability of water, active surface area of the membrane (constant for a given membrane), absolute feed pressure, average osmotic pressure of the water on the feed side, concentration polarization factor, absolute permeate pressure and permeate osmotic pressure, respectively. Pressure on the permeate side is approximately atmospheric and so equation (1) can be rewritten as

$$Q_p = A \times S_a \times \{P_f - \pi_{avg} \times PF + \pi_p\} \tag{2}$$

where P_f is the feed water gauge pressure. The concentration polarization factor (PF) [3] is given by

$$PF = \exp\left(K \times \frac{Q_p}{Q_f}\right) \tag{3}$$

where Q_f is the feed flow rate. As water diffuse through the membrane, the concentration of salt near the surface of the membrane becomes considerably higher than the salt concentration of the bulk solution. Concentration polarization factor is used as a correction factor to account for this concentration gradient effect. The mass rate of diffusion of salt (J_s) through the membrane is proportional to salt concentration difference between the feed and the permeate side (C_p).

$$J_s = B \times S_a(C_{avg} \times PF - C_p) \tag{4}$$

where C_{avg} and B refer to average salt concentration on the feed side and salt permeability of the membrane respectively. Here also the factor 'PF' plays the same role as it did in the water diffusion equation. Equation (4) can be rewritten by dividing both sides by Q_p as follows

$$C_p = \frac{J_s}{Q_p} = \frac{B \times S_a(C_{avg} \times PF - C_p)}{Q_p} \tag{5}$$

In equation (5), C_p is very less compared to C_{avg}, and so C_p term on the right hand side is neglected and the resulting equation is

$$C_p = \frac{B \times S_a\left(C_{avg} \times PF\right)}{Q_p} \tag{6}$$

The equations (2) and (6) constitute the RO model.

3. Parameter estimation and validation

The RO model described above has three unknown parameters namely permeability of water (A), permeability of salt (B) and proportionality constant (K) which can be determined using the plant input/output data. The input data include feed water concentration (C_f), feed water pressure (P_f), feed water flow rate (Q_f) and the output data are permeate flow rate (Q_p) and the permeate concentration (C_p). Currently an experimental facility is not available with us for obtaining the data. DOW™ developed a software called 'ROSA' which is used primarily to design membrane units. This software has an inbuilt model of the membrane unit, but integration of 'ROSA' with the optimization program cannot be done easily. So 'ROSA' is used as a substitute for an RO plant in order to generate the input/output data which are then used to estimate model parameters. Feed water flows in the range of 2.4-6 m^3/day and feed pressure in the range of 50-69 bars are chosen for the simulation of the 'ROSA' software. The feed concentration is kept constant at 35000 ppm. The estimates of A, B and K are found by least squares technique and are 0.0148 m/day/bar, 0.0027 m/day and 0.0491 respectively. Then the model is simulated with test data set (within the same range of the training data set) and found to predict the permeate flow rates within an accuracy of ±2% and the permeate concentration within ±4% on an average. The cases where maximum deviation between the model and ROSA occur are shown in Fig-1 & 2.

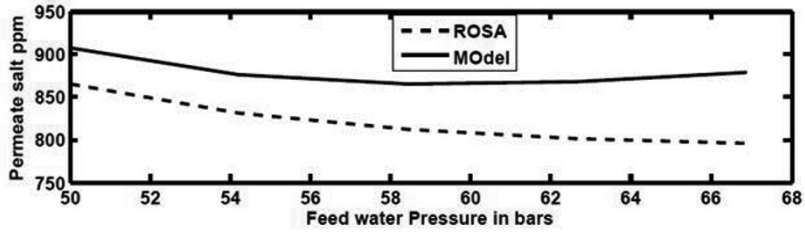

Figure-1: Comparison of permeate salt concentration prediction between the developed model and ROSA at constant feed flow of 6m^3/day.

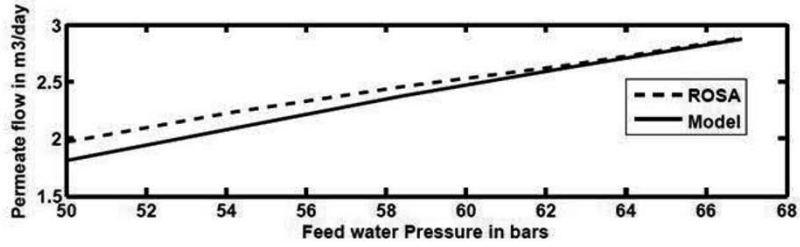

Figure-2: Comparison of permeate flow rate prediction between the developed model and ROSA at constant feed flow of 2.4 m^3/day.

4. Optimization

Given the power available, an analysis of the system shows that they are two degrees of freedom i.e. feed water flow rate and feed pressure. As the solar radiation varies throughout the day, it is not feasible to operate the plant at constant feed flow rate and constant feed pressure. So a formal optimization problem needs to be formulated and solved to determine the optimal feed flow rate and feed pressure for each solar radiation intensity. The objective of the optimization problem is to maximize permeate flow rate subject to the constraints of (i) permeate salt concentration being less than 500 ppm, (ii) power available being less than or equal to the product of feed pressure and feed flow rate, (iii) feed pressure being less than the maximum design pressure of the membrane (69 bar), and (iv) salt balance, water balance & salt diffusion equations being satisfied. The optimization problem can be formulated as follows:

$$\underset{Q_f, Q_c, P_f, C_c, C_p}{\text{Maximize}} \; Q_p = A \times S_a \times \{P_f - \pi_{avg} \times PF + \pi_p\} \tag{7}$$

Subject to

$$C_p - B \times S_a \times \frac{C_{avg}}{Q_p} exp\left(\frac{K \times Q_p}{Q_f}\right) = 0 \tag{8}$$

$$Q_f - Q_c - Q_p = 0 \tag{9}$$

$$Q_f \times C_f - Q_c \times C_c - Q_p \times C_p = 0 \tag{10}$$

$$C_p - 500 \leq 0 \tag{11}$$

$$P_f - 69 \leq 0 \tag{12}$$

$$\text{PW} - P_f \times Q_f \times \frac{100}{(24 \times 60^2)} \leq 0 \tag{13}$$

In the above formulation, equation (7) refers to the water diffusion equation of the membrane model. Equations (8), (9) and (10) refer to salt diffusion equation of the membrane, overall material balance and salt balance, respectively. Equation (12) ensures that the feed pressure does not exceed the maximum permissible pressure of the membrane Equation (13) ensures that the power consumed by the pump does not exceed the power available (PW). The above mentioned optimization problem is solved using Matlab's fmincon function which is a local optimizer. The results of the optimization presented in Fig. 3, show that the optimal policy is to maintain either the pressure or the permeate concentration active at its maximum permissible value. The critical power point at which the active constraint shifts depends on the feed water salt concentration. If the feed water concentration is 35000 ppm, the shift occurs at 0.333 kilowatt. For a feed water salt concentration of 32000 ppm and 36000 ppm, the shift occurs at 0.3060 kilowatt and 0.3430 kilowatt respectively.

In order to implement the above optimal policy, an active constraint control strategy can be used which does not require knowledge of the critical power point or the available input power. Only the feed pressure and the permeate concentration have to be measured and monitored. If the pressure is less than its maximum value, the plant is operated such that permeate salt concentration is maintained at the maximum

permissible limit. If the pressure reaches its maximum limit, the plant is operated such that the pressure is maintained at its maximum limit. The manipulated variable is the position of a valve which is placed at the reject line of the RO module whose stem position is changed to either keep the pressure or the permeate concentration at its maximum value. This optimal strategy is robust to uncertainties in the model parameters. Additionally, the feedback solution to the optimal operation problem can be implemented easily without the need to perform real time optimization

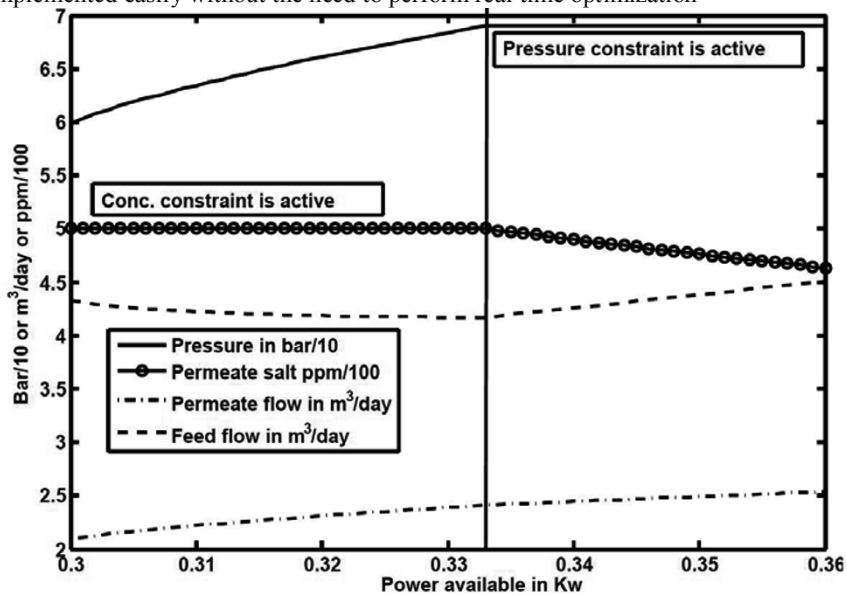

Figure-3: Optimal feed water flow rate & feed water pressure that correspond to various powers levels (at constant feed water salt conc. of 35000 ppm)

5. Conclusion

An appropriate optimization problem for operation of an RO desalination plant driven by solar power without batteries subject to input variability has been formulated and solved. Analysis of the solution reveals that a simple active constraint control strategy can realize the optimal solution. This control strategy is robust with respect to parametric changes. Replacing the present RO model with a detailed model to study whether the same concept holds good, to study the influence of a product buffer tank on permeate production, study of dynamics of the system, controller design and implementation of active constraint control in plant will constitute our future work.

Optimization of the scheduling and water integration in batch processes based on the Timed Petri net

Li Huan, Xiao Wu*, He Gaohong, Du Jian

State Key Laboratory of Fine Chemical, R&D Center of Membrane Science and Technology, Dalian University of Technology, Dalian 116024, Liaoning, China

Abstract

A approach based on the Timed Petri net (TPN) for incorporating water integration in batch process scheduling was presented in this paper. Firstly, the Petri net model of process scheduling was built and the scheduling can be obtained using the incidence matrix analysis method. Then the Petri net model of the water integration was established according to the water cascading analysis, the principles of water network design and the water matching rules. Finally, based on the facility of multiple view integrated modeling, the Petri net models of the scheduling and water-using network synthesis were combined to achieve the optimization of the scheduling and water integration in batch process. An example was presented to demonstrate the validity and advantages of the proposed approach.

Keywords: batch processes; Timed Petri net; scheduling; water integration;

1. Introduction

Batch processes are used for high-value-added products in process industries widely, and the wastewater often has a bad influence on environment, so the water integration with certain scheduling in batch processes has got more attention[1-3]. However, to a great extent, the optimal water-using network and the economic benefits in batch processes rely on the production and scheduling. So the scheduling optimization is also an important problem in batch processes[4,5]. The optimization of the scheduling and water integration of batch process, as two separate problems, were taken into consideration in recent years[6,7], and most of the approaches were based on the mathematical programming[8-10], but it was often hard to get the optimal solution due to the multiple solution of the model, which was resulted in by the no-linear and integrality constraints and the non-convexity of the problem.

With the Petri net has been the primary tool to be used in the activities of modeling, performance analysis and simulation of the discrete event systems as its outstanding ability in graphic description and mathematical analysis. The Petri net has gained widely application in the scheduling-model problem of batch processes[11,12]. As the Petri net is a good representation of conflict situations, shared resources, precedence constraints and explicit time constraints, it has been a availably modeling tool suited to model the scheduling and water integration of batch system. Hence, a new approach for optimization of the scheduling and water integration in batch process was presented based on time Petri net (TPN) in this paper, which can obtain the targets avoiding the solution complexity of the mathematical programming.

* wuxiao@dlut.edu.cn (W. Xiao).

2. Optimization of the scheduling and water integration

2.1. Scheduling model based on the time Petri net

When a Petri net was used to formulate a scheduling problem, the state equation of the Petri net model ,which was expressed by Eq. (1), calculated the new state.

$$M_k = M_0 + A^T X \tag{1}$$

where A is the incidence matrix which represents the preceding relationships between places and transitions, X is a firing sequence of transitions.

The scheduling model was built based on the TPN, the transitions t/t' respectively represent the start/stop of the operation, which is expressed by the places of the TPN. So the sub-process accomplished in the R device can be described by the subnet shown in Fig. 1. The places P'/P'' respectively represent the feed/product of the operation, the P place represents the operating procedure of the operation and its delay time is the operating time in the device R. The tokens in the places indicate the current state of the operation or device.

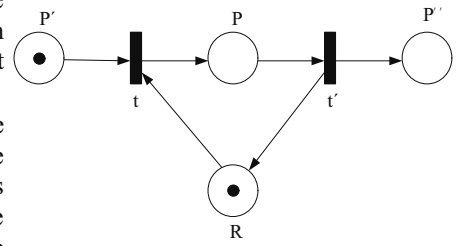

Fig. 1 PN model of the sub-process in R device.

The delayed vector was defined $DT = (d\tau_0, d\tau_1, d\tau_2, \cdots, d\tau_m)$, the element $d\tau_i$ is the delayed time of the place P_i. In the state vector $S(\tau_k) = (s_0(\tau_k), s_1(\tau_k), s_2(\tau_k), \cdots, s_m(\tau_k))$, the element $s_i(\tau_k)$ means the transient-time that the tokens arrive at the place P_i in the k step. In the enabling vector $T(\tau) = (t_0(\tau), t_1(\tau), t_2(\tau), \cdots, t_n(\tau))$, the element $t_j(\tau)$ is the earliest time that the transition t_j was triggered. As a result, the transition set T^*, which is called optimization transitions sequence, is constituted by the transitions corresponded with the minimum elements in the enabling vector. Then the N-vector X_{k+1} was determined, because the j element in the X_{k+1} is the times that the transitions appeared in T^*. And then the new state could be gained by Eq. (1). When M_k=M_0, the calculation was end. The τ_k was the make-span of the operation and the T^* was the operation sequence. In the simulation algorithm process, the heuristic scheduling rules described in the literature [13] was used to solve the conflicts.

2.2. Water integration model based on the TPN

The Petei net model of water integration was built using the water cascading analysis

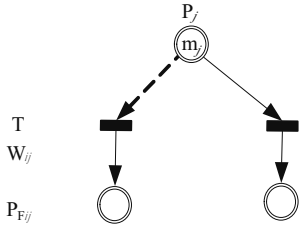

Fig. 2 PN model controlled by time interval.

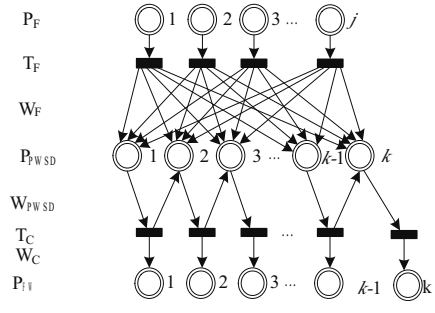

Fig. 3 PN model of pinch analysis.

(WCA)[14]. And the time is the critical factor and the same stream can be found in different time intervals in batch processes, thereby, the Petri net model controlled by time interval, shown in Fig. 2, was built then. The tokens in P_j place are the total mass

flowrate of the *j* stream and the places P_{Fj} are the *j* streams in time intervals *i*. And a common model of pinch analysis, shown in Fig. 3, was firstly established based on the time Petri net using WCA.

Once the minimum fresh water demand and the water pinch location were obtained, the Petri net model of water network synthesis can be established according to the water cascading analysis, the principles of water network design and the water matching rules[15], shown in Fig. 4, there were 3 operation units in the synthesis model, unit 1 was above the pinch purity, unit 2 was below the pinch purity and unit 3 was across the pinch purity.

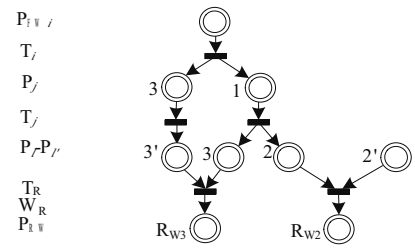

Fig. 4 PN model of water network synthesis.

2.3. Optimization model of the scheduling and water integration

To optimize the batch process scheduling and water integration, the Petri net model for incorporating pinch analysis in scheduling should be constructed first. In the Fig. 1, the tokens in place P obtained after the transition t was fired are the material in R device, while in the Fig. 2, the tokens in place P_j are the total mass flowrate of the *j* stream, which also could be treated as a material. That, in turn, makes the place P has the same physical significance to the place P_j. So the Petri net model for incorporating pinch analysis in scheduling was built by combining the place P with the place P_j, shown in Fig. 5, where m_j was the limiting mass flowrate of stream *j* and the significance of other variables are the same as the above models.

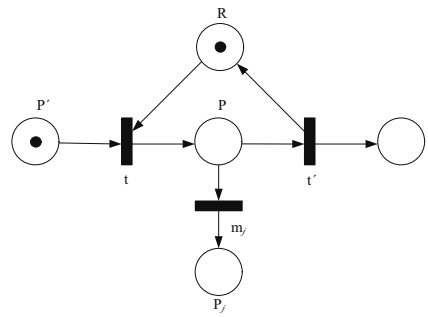

Fig. 5 Petri net for incorporating pinch analysis in scheduling

3. Example

Following an example was presented to illustrate the validity of the proposed approach.

Table 1 Stream data for the batch process example

Operation	Process	Cin	Cout	Limiting mass flowrate	Time of duration
		ppm	ppm	ton/h	h
$OP_{A,1}$	D_1/S_1	0	100	20	2
$OP_{A,2}$	D_2/S_2	50	100	250	2
$OP_{B,1}$	D_3/S_3	50	800	90	3
$OP_{B,2}$	D_4/S_4	400	800	20	2

Consider a batch process with two devices R_1 and R_2, two different products (P_A/P_B) were produced according to the same order in the devices. In the process, it need 2 hours and 2 hours respectively in devices R_1 and R_2 to produce one product, 3 hours and 2 hours respectively in devices R_1 and R_2 to produce the other product. It was assumed that every operation needed water-using process. Table 1 summarize the data for the water stream corresponding with the operation.

The Petri net model for incorporating pinch analysis in scheduling of example was built based on the model of Fig. 5, shown in Fig. 6, the meanings of the places and transitions are the same as before. The model of water integration considering the scheduling was obtained by combining the model of Fig. 6 and the model of Fig. 3.

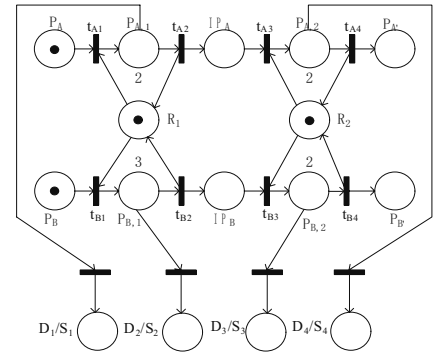

Fig. 6 Petri net model for incorporating pinch analysis in scheduling of example

The results could be obtained using the scheduling calculation and the application software of Petri net, which were shown in Table 2. In the Table 2, the operation sequences of branch 1 (Fig. 7(a)) and branch 2 (Fig. 7(b)) were shown in Fig. 7. It was known from the results in the table, although the make-span of the two branches were same, the total fresh water flow of branch 1 was much less than the branch 2. So the operation sequence corresponding with the branch 1 was adopted in this paper.

And then, based on the model of Fig. 5, according to the determined operation sequence and the total fresh water flow demanded in the example, the water-using network diagram without storage was designed shown in Fig. 8.

Table 2 The results data for the example

Branch	The total fresh water flow/t·h^{-1}	Make-span/h
1	213.13	7
2	309.38	7

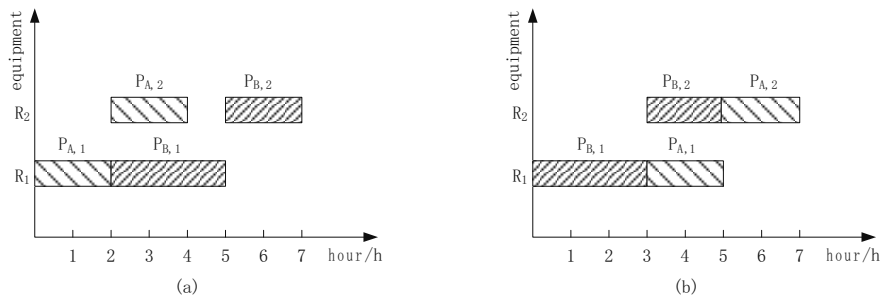

Fig. 7 The Gantt for the example of branches

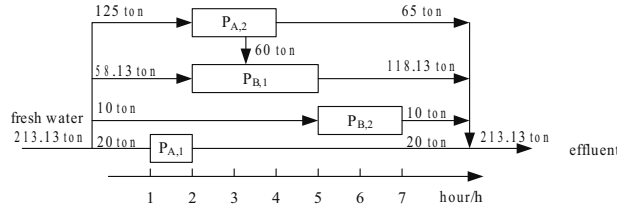

Fig. 8 Water-using network diagram for example without storage

4. Conclusion

A new approach was developed in this paper for optimizing the scheduling and water integration in batch process synchronously, the time factor in batch process was

translated into the delayed time of the places, which was one of objects in Petri net. And the optimization of the scheduling and water integration in batch process was obtained by using the simulation calculation of the Petri net model, which was validated effectively by an example. Compared with the mathematical programming, the models based on the TPN were simple and intuitive and the solution of the models was also simple and efficient avoiding the complicated calculation of the mathematical programming. Not only was the successful implementation of the approach conducive to the development of the study on the water integration but also it provided the foundation for the synchronous optimization of the scheduling and other mass transfer processes in batch process.

Abstract

A method to find a draw solute for forward osmosis desalination is developed. The economics of a forward osmosis process is largely influenced by the selection of a draw solute and energy consumed for its separation from the fresh product water. The proposed method evaluates a vast number of possible draw solutes by predicting the production rate of fresh water, investment cost and energy consumption in the separation process. The possible draw solutes are confined to electrolytes and its separation processes to thermal systems. Subsequently, a cost-minimizing draw solute is determined subject to any necessary constraints. The developed method will contribute to designing commercially viable forward-osmosis desalination processes.

Keywords: Draw Solute, Forward Osmosis, Desalination, Screening, Property Database

1. Introduction

Water scarcity problem has been intensified in many regions all over the world by climate change, and expanding industrial and agricultural demand for water. In many of such areas of drought, desalination is often the only solution. Current commercial desalination technologies such as multi-stage flash (MSF) and reverse osmosis (RO), however, consume large thermal energy (200~400 MJ/ton in MSF process) (Borsani et al., 2005), or expensive electrical energy (4~6 kWh in RO process) (Fritzmann et al., 2007). In this regard, forward osmosis (FO) desalination is recently drawing attention to reduce the energy consumption in desalination processes.

An FO desalination system consists of a membrane process and a draw solute recovery process. In the membrane process, the driving force for water permeation is the chemical potential difference between draw solution and seawater. Therefore, the osmotic pressure of draw solution should be higher than that of seawater to enable spontaneous permeation of water molecules. The draw solution diluted with the permeated water then enters the recovery process to produce fresh water while reconcentrating the solution. Note that the total energy efficiency is determined by the energy requirement of the recovery process (McGinnis et al., 2007).

The design of an FO desalination system is mainly determined with selection of a draw solute. The draw solute should have high solubility and high osmotic pressure which would lead to high water flux through the membrane. At the same time, it should be readily separable from water consuming low energy.
In previous researches, several candidate compounds have been assessed for their application to desalination. The water flux at a fixed concentration is measured in those studies, often to figure out the performance of the membrane. These candidates include ammonium bicarbonate, magnesium sulfate, sodium sulfate, potassium sulfate, potassium nitrate, potassium chloride, ethanol, glucose and fructose (Cath et al., 2006) (Achilli et al., 2010). A systematic approach is proposed in this study for optimal design of a forward osmosis desalination system. This approach considers all components in the property database not to overlook any candidate of high potential. Moreover, both membrane and draw solute recovery processes are optimized for respective candidates considering water flux and energy consumption, both of which vary depending on the selection of the draw solute. In the first step, a chemical database is established to calculate solubilities and osmotic pressures. Secondly, draw solute candidates are selected by exploring the established chemical database. Lastly, the optimal desalination system is designed for each candidate draw solute and the costs of those systems are compared to find the optimal draw solute.

2. Screening method

Property information of total 4,058 compounds is gathered to establish a property database from the OLI stream analyzer which is developed by OLI systems, Inc. The analyzer provides properties such as pH, ORP, viscosity, density, enthalpy based on property models and experimental data. Subsequently, the compounds are screened in hierarchical order. The screening criteria are shown in Fig 1. At first, components whose maximum osmotic pressures are lower than that of seawater (24 bar) are screened. Then, rare metals, radioactive substances and the compounds of low solubilities below 0.5 molal concentration are screened. Boiling points of the candidates are set to be below 100°C to find the components more volatile than water because boiling water requires large latent heat energy. Finally, toxic components whose concentrations should be less than 1 ppm in drinking water are screened.

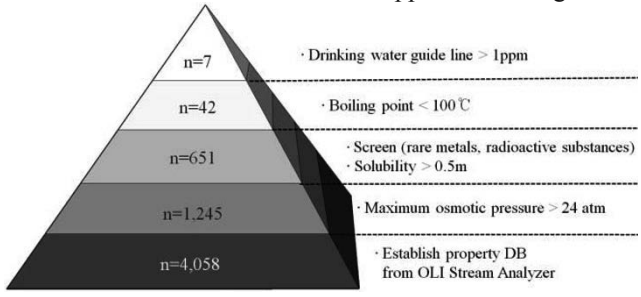

Figure 1: Screening criteria

3. Mathematical models

3.1. FO membrane process model

FO membrane consists of a selective layer and a support layer (Loeb et al., 1997). Water flux through the membrane (J_w) is proportional to the osmotic pressure difference between those of seawater and draw solution, and to the pure water permeability

coefficient (A). A can be experimentally determined. The effective osmotic pressure difference is less than that of bulk solutions($\pi_{ds.b}$-$\pi_{sw.b}$) due to the effect of internal concentration polarization (ICP) in the support layer and external concentration polarization (ECP) at the outer wall of selective layer. The actual water flux, therefore, should be calculated as below (Tan et al., 2008).

$$J_w = A\left\{\pi_{ds,b}\exp(-J_w K) - \pi_{sw,b}\exp(J_w / k)\right\} \quad (1)$$

where K is solute resistivity for diffusion within the support layer, k is the mass transfer coefficient, $\pi_{ds.b}$ is osmotic pressure of the bulk draw solution and $\pi_{sw.b}$ is osmotic pressure of the bulk seawater.

3.2. Draw solute recovery process model

In this study, the draw solute recovery is confined only to thermal separation with a distillation column. Aspen Plus® is used to simulate distillation columns. As this process only concerns about the purity of product water, i.e. the bottom product, the column is designed as a stripping column.

The minimum number of trays at the specified design pressure is calculated while the purity of bottom product is kept below the target concentration. At each tray, physical and chemical equilibrium states are assumed. The vessel height is calculated by multiplying the number of trays with the tray spacing. The vessel radius is decided from the vessel height and the flowrates of vapor and liquid.

4. System optimization

4.1. Investment cost model for the FO membrane process

To assess the integrated performance of the FO membrane process and the draw solute recovery process, a cost minimization problem needs to be established. The six-tenth rule is applied to calculate investment cost of the FO membrane process because currently there is no commercial-scale FO membrane process established (Williams et al., 1947). This relationship has been found to provide reasonable results for individual pieces of equipment and for entire plants. The investment cost for the FO membrane process ($C_{inv.M}$) is calculated from Eq. (2).

$$C_{inv.M} = C_{ref.M}\cdot\left(\frac{Q/J_w}{Area_{ref}}\right)^{0.6} \quad (2)$$

where $C_{ref.M}$ is the investment cost for the reference process, $Area_{ref}$ is the membrane area of the reference process. The term (Q/J_w) means required membrane area to meet target production.

4.2. Investment cost model for the draw solute recovery process

To calculate the investment cost for the distillation column, Mulet-Corripio-Evans's method is applied (Mulet et al., 1947). The method calculates the purchase costs of the vessel, the platform, ladders, and trays from the vessel weight and size.

4.3. Cost minimization

The cost minimization problem for unit mass of product water is as follows.

$$\min C = \frac{1}{Q}\left(\frac{C_{inv.DC}}{L_{DC}} + \frac{C_{inv.M}}{L_M}\cdot U_M\right) + \left(U_{steam}\cdot r_{steam} + U_{electricity}\cdot r_{electricity}\right) \quad (3)$$

where C is the total production cost to produce a ton of product water. U_{steam} and $U_{electricity}$ are the unit utility & maintenance costs for steam and electricity. r_{steam} and $r_{electricity}$ are the required amounts of steam and electricity to produce a ton of product water, $C_{op.DC}$ is the operation cost for the distillation column to produce a ton of product

water, L_M is the lifespan expectancy and U_M is the utility & maintenance cost coefficient for the FO membrane process which includes the costs for maintenance and operation. It is assumed that the operation cost for FO membrane process is negligible.

5. Case study

The optimal system design is also influenced by several cost parameters. The variance in the operation cost is represented by the steam price change while that in the investment cost is expressed with the production capacity. Several cases are studied for U_{steam} value of 0.008$/MJ and 0.0001$/MJ, and Q value of 1 million imperial gallons per day (MIGD : 4,546 tons per day) and 100 MIGD. Note that the capacity of a typical RO plant is 0.1~35 MIGD and that of MSF plant is 20~200 MIGD. The maximum concentration is limited to 10m(molal concentration) to compensate the negligence of the back diffusion in this model. The target purity of product water is set to follow the drinking water guidelines.

5.1. Normal steam price(0.008$/MJ), small plant capacity(1MIGD)

The best candidate in this case is 2-Butanone (methyl-ethyl-ketone : MEK) with vacuum operation of the distillation column. Although 2-Butanone offers relatively low water flux, it is selected because the energy requirement to satisfy the purity standard is less than the half of the 2nd best candidate, ammonium hydroxide. Meanwhile, ammonium hydroxide ranks higher than ammonium bicarbonate even though the carbonic acid ion provides additional osmotic pressure with low energy consumption. This is because the solubility of ammonium bicarbonate is relatively low. On the other hand, high solubility of ammonium hydroxide contributes to enhancing the water flux.

5.2. Low steam price(0.0001$/MJ), large plant capacity(100MIGD)

Desalination systems are often located close to power plants. When the waste heat from the power plants can be utilized, the utility cost may be significantly reduced. This case searches for the best solution with steam price of $0.0001/MJ which is much lower than the market price. Because the plant capacity of this case is small, investment cost becomes a dominant factor to decide the optimal draw solute and operation condition. Accordingly, ammonium hydroxide, which requires the smallest membrane area, is also selected as the optimal solute with 2-butanone.

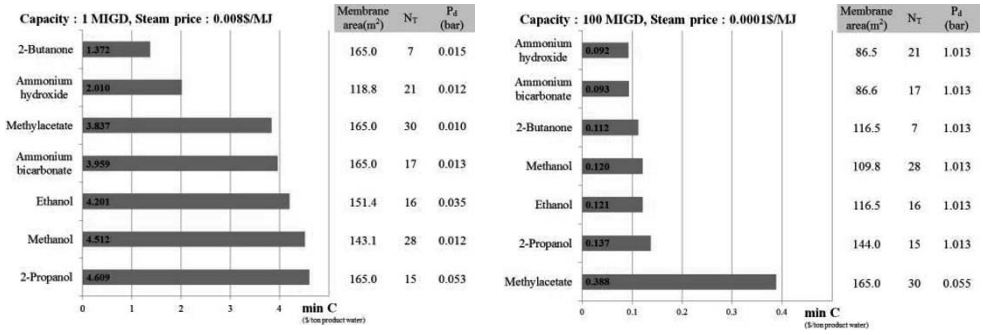

Figure 2: Optimization results.

6. Conclusions

In this study, a systematic approach has been proposed to finding the optimal draw solute and process design. Draw solute candidates have been selected by a hierarchical

screening method. Models for the FO membrane process and the draw solute recovery process have been established to calculate water permeability and energy consumption. A cost function integrating operation and investment costs have enabled comparing the production costs of the draw solute candidates. The cost is minimized to find the optimal draw solute, the diluted concentration of the draw solution, required membrane area, as well as the number of trays and pressure in the distillation column. In case studies, production costs at different steam prices and plant capacity conditions are evaluated.

The proposed approach provides an evaluation tool to compare draw solute candidates when new candidates are suggested. Moreover, the application is not limited to the production of potable water using distillation. Membrane distillation or nanofiltration can also be used in the recovery process. The target purity of product water can be set for agricultural or industrial purposes. Furthermore, this approach can be applied to systems for solution concentration or wastewater reuse with minor modifications.

Abstract

This work addresses integrated water network synthesis problems by proposing detailed yet computationally efficient models for the design of membrane separation-based water regenerators. The resulting tighter formulation incorporates major physical parameters for the membrane regenerators. The resulting nonconvex mixed-integer nonlinear program (MINLP) based on a source–regenerator–sink superstructure is implemented on a case study and solved to global optimality using GAMS/BARON.
Keywords: Optimization; Superstructure; MINLP; Water network synthesis; Water reuse; Water regeneration

1. Introduction

Water network synthesis problems have received increasing attention in the process systems engineering literature as evidenced by a flurry of recent publications (among others, see Ahmetović and Grossmann, 2011; Faria and Bagajewicz, 2010; Misener et al., 2011), including fairly recent resurgence in water pinch analysis (see the reviews by Jezowski (2010) and Foo (2009)). We extend our recent work on the industrially-favored pressure-driven membrane separation-based water regenerators by postulating computationally-efficient models (Khor et al., in press) yet with more detailed representations (Khor et al., 2011). The approach gives rise to precise tighter formulations in investigating the interactions between non-membrane and membrane-based regenerators for an integrated water network. The goal is to synthesize an optimal water network given the three elements of: (i) water sources with fixed flowrates and contaminant concentrations; (ii) water sinks with fixed flowrates and maximum allowable inlet concentration (MAIC) limits; and (iii) water regenerators. To this end, we develop a source–regenerator–sink superstructure that allows all feasible interconnections of the elements to embed numerous alternative configurations for direct reuse/recycle, regeneration–reuse, and regeneration–recycle. The rest of the paper mainly discusses the proposed model formulation and gives a flavor of its implementation and solution on a case study.

2. Optimization-Based Model Formulation for Water Network Synthesis

The formulation adopts a fixed-flowrate representation for water-using units that caters for both mass transfer- and non-mass transfer-based operations (Foo, 2009). Such a representation is amenable to a source–sink model with the additional component of water regeneration subnetwork that pools the sources for treatment before directing them to the sinks for reuse/recycle. For non-membrane regenerators, we employ the conventional model of linear water treatment units (Karuppiah and Grossmann, 2008).

On the other hand, for membrane regenerators, the permeator and the rejector are decomposed into two separate entities, in which each is treated as a regenerator to ensure the permeator concentration is lower than that of the rejector (Khor et al., in press). To incorporate the important physical parameters for a membrane regenerator, we employ the more detailed representation afforded by knowledge-driven first-principles models (Khor et al., 2011). Figure 1 shows the superstructure around the water regeneration subnetwork that is representative of the entire network in general.

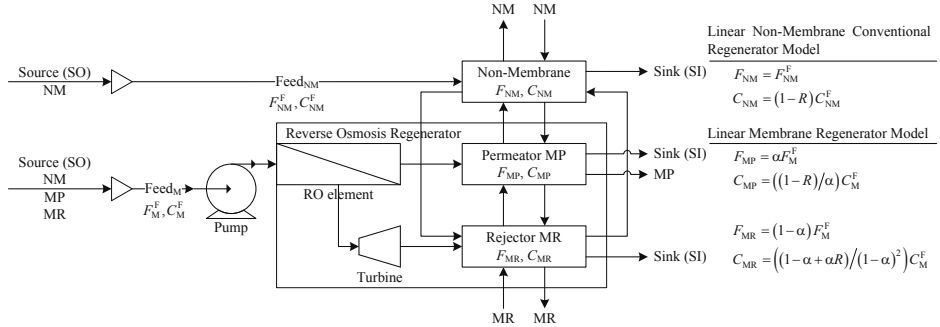

Figure 1. Superstructure for the water regeneration subnetwork

The superstructure and regenerator models lead to a nonconvex MINLP that globally optimizes the capital and operating costs for the interconnections in terms of total stream flows and concentrations. The nonlinearity is due to contaminant mixing while the integrality pertains to discrete decisions on selection of the interconnections and the regenerators.

The following notation will be used in the formulation. Flow in an interconnection from the subscript representing the origin entity A (as indexed by β) is sent to the destination entity B (as indexed by α) at the rate $F_{A,B}(\beta,\gamma)$. For example, $F_{SO,SI}(i,j)$ indicates flowrate from a source (SO) $i \in I$ to a sink (SI) $j \in J$. Concentrations for a set of contaminants $q \in Q$ is defined for each network entity. K_{NM} denotes the set of non-membrane regenerators k, while the set K_M contains ordered pairs of the permeator MP and the rejector MR of membrane regenerators k. The formulation is as follows:

(a) Linear mass balance for a source:

$$F_{SO}(i) \geq \sum_{k \in K_{NM}} F_{SO,NM}(i,k) + \sum_{k' \in K_M} \left(F_{SO,MP}(i,k') + F_{SO,MR}(i,k')\right) + \sum_{j \in J} F_{SO,SI}(i,j), \quad \forall i \in I$$

This balance is formulated as an inequality for the numerical purpose of accounting for the direct discharge flow of any excess water source into the following three terminal sinks: the waste sink representing an effluent treatment plant (ETP); the discharge sink for safe removal into the environment; and the incineration sink for handling untreated wastes that do not meet discharge regulations and contaminants whose fate do not end up in any sink for reuse/recycle.

(b) Linear mass balance around the feed point for a non-membrane regenerator:

$$\sum_{i \in I} F_{SO,NM}(i,k) + \sum_{\substack{k' \in K_{NM} \\ k' \neq k}} F_{NM,NM}(k',k) + \sum_{k'' \in K_M} \left(F_{MP,NM}(k'',k) + F_{MR,NM}(k'',k)\right) = F^F_{NM}(k), \quad \forall k \in K$$

where F^F_{NM} is the feed flowrate to a non-membrane regenerator.

(c) Nonconvex bilinear concentration balance around the feed point for a non-membrane regenerator:

$$\left(\begin{array}{l}\sum_{i\in I}F_{\mathrm{SO,NM}}(i,k)C_{\mathrm{SO}}(i,q)+\sum_{\substack{k'\in K_{\mathrm{NM}}\\k'\neq k}}F_{\mathrm{NM,NM}}(k',k)C_{\mathrm{NM}}(k',q)\\+\sum_{k''\in K_{\mathrm{M}}}\left(F_{\mathrm{MP,NM}}(k'',k)C_{\mathrm{MP}}(k'',q)+F_{\mathrm{MR,NM}}(k'',k)C_{\mathrm{MR}}(k'',q)\right)\end{array}\right)=F_{\mathrm{NM}}^{\mathrm{F}}(k)C_{\mathrm{NM}}^{\mathrm{F}}(k,q),\forall k\in K,q\in Q$$

(d) Linear mass and concentration balances for a non-membrane regenerator:

$$F_{\mathrm{NM}}^{\mathrm{F}}(k)=\sum_{j\in J}F_{\mathrm{NM,SI}}(k,j)+\sum_{\substack{k'\in K_{\mathrm{NM}}\\k'\neq k}}F_{\mathrm{NM,NM}}(k,k')+\sum_{k''\in K_{\mathrm{M}}}\left(F_{\mathrm{NM,MP}}(k,k'')+F_{\mathrm{NM,MR}}(k,k'')\right),\quad\forall k\in K$$

$$\left(1-R(k,q)\right)C_{\mathrm{NM}}^{\mathrm{F}}(k,q)=C_{\mathrm{NM}}(k,q),\quad\forall k\in K,\forall q\in Q$$

(e) Linear mass balances around the feed point to the permeator and the rejector of a membrane regenerator:

$$\sum_{i\in I}F_{\mathrm{SO,MP}}(i,k)+\sum_{k'\in K_{\mathrm{NM}}}F_{\mathrm{NM,MP}}(k',k)+\sum_{\substack{k''\in K_{\mathrm{M}}\\k''\neq k}}\left(F_{\mathrm{MP,MP}}(k'',k)+F_{\mathrm{MR,MP}}(k'',k)\right)=F_{\mathrm{M}}^{\mathrm{F}}(k),\quad\forall k\in K$$

$$\sum_{i\in I}F_{\mathrm{SO,MR}}(i,k)+\sum_{k'\in K_{\mathrm{NM}}}F_{\mathrm{NM,MR}}(k',k)+\sum_{\substack{k''\in K_{\mathrm{M}}\\k''\neq k}}\left(F_{\mathrm{MP,MR}}(k'',k)+F_{\mathrm{MR,MR}}(k'',k)\right)=F_{\mathrm{M}}^{\mathrm{F}}(k),\quad\forall k\in K$$

Note that the membrane regenerator feed flowrate $F_{\mathrm{M}}^{\mathrm{F}}(k)$ is not related to a permeator or a rejector. This is appropriate to ensure the formulation naturally and consistently represents entities of the actual physical configuration of a membrane regenerator.

(f) Nonconvex bilinear concentration balances around the feed point to a permeator and a rejector:

$$\left(\begin{array}{l}\sum_{i\in I}\left(F_{\mathrm{SO,MP}}(i,k)\right)C_{\mathrm{SO}}(i,q)+\sum_{k'\in K_{\mathrm{NM}}}F_{\mathrm{NM,MP}}(k',k)C_{\mathrm{NM}}(k',q)\\+\sum_{\substack{k''\in K_{\mathrm{M}}\\k''\neq k}}F_{\mathrm{MP,MP}}(k'',k)C_{\mathrm{MP}}(k'',q)+\sum_{\substack{k''\in K_{\mathrm{M}}\\k''\neq k}}F_{\mathrm{MR,MP}}(k'',k)C_{\mathrm{MR}}(k'',q)\end{array}\right)=F_{\mathrm{M}}^{\mathrm{F}}(k)C_{\mathrm{M}}^{\mathrm{F}}(k,q),\forall k\in K,q\in Q$$

$$\left(\begin{array}{l}\sum_{i\in I}\left(F_{\mathrm{SO,MR}}(i,k)\right)C_{\mathrm{SO}}(i,q)+\sum_{k'\in K_{\mathrm{NM}}}F_{\mathrm{NM,MR}}(k',k)C_{\mathrm{NM}}(k',q)\\+\sum_{\substack{k''\in K_{\mathrm{M}}\\k''\neq k}}F_{\mathrm{MP,MR}}(k'',k)C_{\mathrm{MP}}(k'',q)+\sum_{\substack{k''\in K_{\mathrm{M}}\\k''\neq k}}F_{\mathrm{MR,MR}}(k'',k)C_{\mathrm{MR}}(k'',q)\end{array}\right)=F_{\mathrm{M}}^{\mathrm{F}}(k)C_{\mathrm{M}}^{\mathrm{F}}(k,q),\forall k\in K,q\in Q$$

(g) Linear mass balances for a permeator and a rejector with liquid recovery factor α:

$$\alpha(k)F_{\mathrm{M}}^{\mathrm{F}}(k)=\sum_{j\in J}F_{\mathrm{MP,SI}}(k,j)+\sum_{k'\in K_{\mathrm{NM}}}F_{\mathrm{MP,NM}}(k,k')+\sum_{\substack{k''\in K_{\mathrm{M}}\\k''\neq k}}\left(F_{\mathrm{MP,MP}}(k,k'')+F_{\mathrm{MP,MR}}(k,k'')\right),\quad\forall k\in K$$

$$\left(1-\alpha(k)\right)F_{\mathrm{M}}^{\mathrm{F}}(k)=\sum_{j\in J}F_{\mathrm{MR,SI}}(k,j)+\sum_{k'\in K_{\mathrm{NM}}}F_{\mathrm{MR,NM}}(k,k')+\sum_{\substack{k''\in K_{\mathrm{M}}\\k''\neq k}}\left(F_{\mathrm{MR,MP}}(k,k'')+F_{\mathrm{MR,MR}}(k,k'')\right),\forall k$$

(h) Linear concentration balances for a permeator and a rejector with removal ratio *R*:

$$\left(1-R(k,q)\right)C_{\mathrm{M}}^{\mathrm{F}}(k,q)=\alpha(k)C_{\mathrm{MP}}(k,q),\quad\forall k,q$$

$$R(k,q)C_{\mathrm{M}}^{\mathrm{F}}(k,q)=\left(1-\alpha(k)\right)C_{\mathrm{MR}}(k,q),\quad\forall k,q$$

It is noteworthy that a more general expression for the rejector concentration is adopted.

(i) Linear mass balance for a sink:

$$\sum_{i\in I}F_{\mathrm{SO,SI}}(i,j)+\sum_{k\in K_{\mathrm{NM}}}F_{\mathrm{NM,SI}}(k,j)+\sum_{k'\in K_{\mathrm{M}}}\left(F_{\mathrm{MP,SI}}(k',j)+F_{\mathrm{MR,SI}}(k',j)\right)=F_{\mathrm{SI}}(j),\quad\forall j$$

(o) Quality requirement for a sink as dictated by its MAIC limits:

$$\sum_{i\in I} F_{\mathrm{SO,SI}}(i,j)C_{\mathrm{SO}}(i,q)+\sum_{k\in K_{\mathrm{NM}}} F_{\mathrm{NM,SI}}(k,j)C_{\mathrm{NM}}(k,q)+\sum_{k'\in K_{\mathrm{M}}}\begin{pmatrix}F_{\mathrm{MP,SI}}(k',j)C_{\mathrm{MP}}(k',q)\\+F_{\mathrm{MR,SI}}(k',j)C_{\mathrm{MR}}(k',q)\end{pmatrix}$$
$$\le F_{\mathrm{SI}}(j)\cdot C^{\mathrm{MAIC}}(j,q),\quad \forall j,q$$

(p) Logical constraints on existence of piping interconnections:

$$F^{\mathrm{L}}_{\mathrm{A,B}}(\beta,\gamma)\,y_{\mathrm{A,B}}(\beta,\gamma)\le F_{\mathrm{A,B}}(\beta,\gamma)\le F^{\mathrm{U}}_{\mathrm{A,B}}(\beta,\gamma)\,y_{\mathrm{A,B}}(\beta,\gamma),$$
$$\forall(\beta,\mathrm{A})\in(I,\mathrm{SO})\cup(K_{\mathrm{NM}},\mathrm{NM})\cup(K_{\mathrm{M}},\mathrm{MP})\cup(K_{\mathrm{M}},\mathrm{MR}),$$
$$\forall(\gamma,\mathrm{B})\in(K_{\mathrm{NM}},\mathrm{NM})\cup(K_{\mathrm{M}},\mathrm{MP})\cup(K_{\mathrm{M}},\mathrm{MR})\cup(J,\mathrm{SI})$$

where $F^{\mathrm{U}}_{\mathrm{A,B}}(\beta,\gamma)$ is the maximum capacity of the interconnection between A and B.

3. Detailed Nonlinear First-Principles Model Formulation for Membrane Regenerators

As mentioned, we consider regeneration subnetwork models based on first-principles for the membrane regenerators that account for their major physical parameters including the types, sizes, number of modules, and orientations. Such a representation is more rigorous than models considered for water treatment units in Misener and Floudas (2010) and Karuppiah and Grossmann (2008). We illustrate such a formulation for a single-stage hollow fiber type reverse osmosis network (RON). Constraints on the RON operating condition is enforced by considering pressure difference across the membrane:

$$\left(\frac{\omega}{A\gamma}\sum_{q\in Q}C^{\mathrm{F}}_{\mathrm{M}}(k,q)+\pi_{\mathrm{F}}\sum_{q\in Q}C_{\mathrm{MP}}(k,q)\right)\left(\sum_{q\in Q}C^{\mathrm{F}}_{\mathrm{M}}(k,q)+\sum_{q\in Q}C_{\mathrm{MR}}(k,q)\right)$$
$$=\left(P_{\mathrm{F}}(k)+P_{\mathrm{R}}(k)-2P_{\mathrm{P}}(k)\right)\sum_{q\in Q}C^{\mathrm{F}}_{\mathrm{M}}(k,q)\sum_{q\in Q}C_{\mathrm{MP}}(k,q),\quad \forall k\in K$$

where ω is the contaminant flux constant, A is the water permeability coefficient, γ is a membrane- and water- related physical coefficient, and π_{F} is the osmotic pressure at feed side. The additional decision variables denoted by $P_{\mathrm{F}}(k)$, $P_{\mathrm{R}}(k)$, and $P_{\mathrm{P}}(k)$ are pressures of the feed, rejector, and permeator of a membrane regenerator k, respectively.

For the total annualized costs (TAC) of the RON, the following components are taken into account:

(a) capital cost of the RO modules as a function of the shell side and stream pressures, which is nonconvex in the linear fractional terms:

$$\frac{C_{\mathrm{module}}\sum_{j\in J}F_{\mathrm{MP,SI}}(k,j)}{AS_m\gamma\left(P^{\mathrm{F}}_{\mathrm{M}}(k)-\frac{\Delta P_{\mathrm{shell}}}{2}-P_{\mathrm{MP}}(k)-\frac{b}{e(q)}\sum_{q\in Q}C_{\mathrm{MP}}(k,q)A\gamma\left(P_{\mathrm{F}}(k)-\frac{\Delta P_{\mathrm{shell}}}{2}-P_{\mathrm{MP}}(k)-\Delta\pi_{\mathrm{RO}}\right)\right)},$$

(b) capital cost of the pump as a function of the feed pressure and flow, which is bilinear and concave in the power terms:

$$C_{\mathrm{pump}}\left(\left(P_{\mathrm{F}}(k)-P_{\mathrm{atm}}\right)F^{\mathrm{F}}_{\mathrm{M}}(k)\right)^{0.65}$$

(c) capital cost of the energy-recovering turbine as a function of the pressures and rejector flow, which is bilinear and concave in the power terms:

$$C_{\mathrm{turbine}}\left(\left(P_{\mathrm{F}}(k)-\Delta P_{\mathrm{shell}}-P_{\mathrm{atm}}\right)\sum_{j\in J}F_{\mathrm{MR}}(k,j)\right)^{0.43}$$

(d) linear operating cost of pump:

$$\frac{1}{\eta_{\text{pump}}} C_{\text{electricity}} H \left(P_{\text{F}}(k) - P_{\text{atm}} \right) F_{\text{M}}^{\text{F}}(k)$$

(e) linear operating cost of using pretreatment chemicals:

$$C_{\text{chemicals}} H \cdot F_{\text{M}}^{\text{F}}(k)$$

(f) linear operating revenue of the turbine:

$$\left(P_{\text{F}}(k) - \Delta P_{\text{shell}} - P_{\text{atm}} \right) \eta_{\text{turbine}} C_{\text{electricity}} H \sum_{j \in J} F_{\text{MR}}(k, j)$$

4. Case Study: Water Network in a Petroleum Refinery

The MINLP model is applied on a refinery case study that involves 28 sources including freshwater; 2 regenerators: mud trap–corrugated plate interceptor and a single-stage RON; and 14 sinks including two terminal sinks (ETP and discharge to the environment). Full details of the case study can be found in Khor et al. (2011). We use a set of base operating values obtained from available plant data to initialize the solution procedure. We utilize the general purpose global optimization solver GAMS 23.3.3/BARON 9.0.2 to avoid obtaining an unreliable local optimal solution. Using BARON requires good variable bounds for tight relaxations, which we supply in the form of general equations based on analyzing the source–regenerator–sink network topology (Ahmetović and Grossmann, 2011). To tighten the formulation and enhance solution convergence, we add linear logical constraints using 0–1 variables on certain design and structural specifications derived from physical insights of the problem. These logic cuts remove undesirable fractional solutions in a branch-and-bound search tree by deducing as many values for the 0–1 variables as possible. An optimal water network configuration is attained in 3970 iterations requiring an acceptable CPU time of 282.5 s with promising results of more than 50% annual savings in freshwater use. Future work is geared towards solving a realistic multicontaminant problem involving uncertainty in the flowrates, concentrations, and removal ratios by employing customized strategies for handling model nonconvexities.

Abstract

We present a methodology for optimally locating disinfectant booster stations for response to contamination events in water distribution systems. A stochastic programming problem considering uncertainty in both the location and time of the contamination event is formulated resulting in an extensive form that is equivalent to the weighted maximum coverage problem. Although the original full-space problem is intractably large, we show a series of reductions that reduce the size of the problem by five orders of magnitude and allow solutions of the optimal placement problem for realistically sized water network models.

Keywords: optimal placement, weighted maximum coverage, water distribution systems

1. Introduction

Unintentional or malicious contamination of water distribution systems poses significant health risks to consumers. Early-warning detection systems have been proposed to detect the presence of contaminant using a fixed grid of sensors throughout the network, and several researchers have studied the problem of optimal sensor layouts within these drinking water distribution systems (Ostfeld and Salomons, 2004; Berry et al., 2005; Murray et al., 2010). However, adequate emergency response mechanisms must also be developed. If the sensor grid flags a warning, a manual water sample will be drawn and sent for laboratory analysis. Following analysis (which can take several hours or more), a positive confirmation of contaminant will likely result in a no-drink order. However, during the time between the first detection and the laboratory confirmation, contaminant will be spreading throughout the network. Disinfectant booster stations can help mitigate the effect of potential contamination by injecting additional (but safe) amounts of disinfectant immediately following the initial warning (Parks et al., 2009).

Here, we address the optimal placement of disinfectant booster stations to mitigate the effect of a contamination event. This is a particularly challenging problem for two reasons. First, the interaction between the contaminant and the disinfectant are often described using nonlinear reaction kinetics. In addition to this nonlinearity, since the particular contaminant is not known a priori, the specific structure and values for the kinetic parameters

*Corresponding Author, carl.laird@tamu.edu

are not known. Second, the water network model itself is large, and since the time and location of the contamination event is not known a priori, considering potential contamination events from every network node and all possible timesteps leads to an extremely large number of scenarios.

In this paper, we make simplifying assumptions on the contaminant-disinfectant interaction that allow us to precompute the effect of disinfectant booster stations and toxin scenarios independently, removing the need to embed the large-scale water quality model within the problem formulation. These simulations provide input data to a very large mixed-integer linear programming formulation with hundreds of thousands of scenarios and discrete decision variables corresponding to the placement of booster stations within the network. While the initial formulation is intractably large, we show a series of reductions that significantly decrease the problem size, while yielding an exact mathematical transformation of the original stochastic programming problem. With these techniques, we demonstrate effective, optimal booster station placement using a real water network model with over 3000 nodes.

2. Problem Formulation

To remove the complexities associated with the disinfectant-toxin reaction kinetics, we use the simplifying assumption that a sufficient concentration of disinfectant is injected to completely and instantaneously neutralize the toxin if they come into contact. With this assumption, the problem can be formulated using independent precomputed simulations for all possible booster station locations and all possible contamination scenarios.

The extensive form of the stochastic programming formulation is given by the following mixed-integer linear programming problem,

$$\min \sum_{s\in S} \alpha_s \sum_{\substack{n\in N\\ t\in T}} \delta_{n,t,s}\, m_{n,t,s} \tag{1}$$

$$\text{s.t.} \quad \sum_{b\in B} y_b \le \mathbf{M} \tag{2}$$

$$\delta_{n,t,s} \ge 1 - \sum_{b\in B} y_b Z_{b,n,t,s} \qquad \forall\ n\in N,\ t\in T,\ s\in S \tag{3}$$

$$0 \le \delta \le 1, \quad y \in \{0,1\} \tag{4}$$

This problem is equivalent to the weighted maximum coverage problem, where S, N, T, B are sets representing the scenarios, network nodes, timesteps, and potential booster locations, respectively. The mass of toxin consumed from node n at time t for scenario s is given by the parameter $m_{n,t,s}$ (calculated from the precomputed toxin simulations). Assuming each scenario s has probability α_s, the objective function is the expected value of the mass of toxin consumed from the entire water distribution system over all scenarios. The binary variable y_b is 1 if node b is selected as a booster station location, and Equation 2 restricts the number of booster stations that can be placed to be no more than $\mathbf{M}$. The indexed parameter Z is determined from the precomputed booster station simulations and captures the node-time pairs in each scenario that are disinfected as a result of each potential booster station location. The parameter $Z_{b,n,t,s} = 1$ only if a booster station installed at node b supplies sufficient disinfectant to node n and time t for scenario s (otherwise, $Z_{b,n,t,s} = 0$). The continuous variable $\delta_{n,t,s}$ indicates whether or not toxin is consumed at node n and time t for scenario s. Equation 3 ensures that $\delta_{n,t,s}$ is only allowed to be 0 if

at least one selected disinfectant booster station location provides neutralization of node n at time t for scenario s. This continuous indicator variable is guaranteed to have a value of either 0 or 1 at the solution (where 0 indicates the complete neutralization of toxin for that combination of n, t, and s).

The input parameters for this problem formulation are calculated using simulations computed by the Merlion (Wong et al., 2010) water quality modeling package. Given a particular sensor layout in the network we perform a toxin simulation for each scenario s to determine $m_{n,t,s}$ the mass of toxin consumed from node n at time t and the contaminant detection time. Assuming that the booster station injections begin immediately following sensor detection, we can simulate the effect of every booster station location for this scenario, starting the disinfectant injection at the detection time, and continuing injection for 8 hours (when the laboratory results would confirm a positive or false alarm).

For large water network models, the full mixed-integer linear problem formulation is still intractable. Fortunately, there are a number of reductions that significantly decrease the problem size while providing an exact mathematical transformation of the full problem.

1. For any particular contamination scenario, there are a number of node-time pairs where toxin will not be present (the value of $m_{n,t,s} = 0$) and the corresponding $\delta_{n,t,s}$ can be removed from the problem. Likewise, there are node-time pairs where toxin exists ($m_{n,t,s} > 0$), but no disinfectant can reach the node ($Z_{b,n,t,s} = 0 \; \forall \; b$). This is true, for example, for all times prior to the detection time of a particular scenario since no disinfectant is injected as yet. In this situation, we can set the corresponding $\delta_{n,t,s}$=1 and again remove the variable from the problem.

2. Consider the constraints shown in Eq. (3). When the right-hand-sides of multiple constraints are identical, we can aggregate the corresponding indices in the δ variables. This would occur, for example, if $Z_{b,1,2,3} = Z_{b,4,5,6} \; \forall \; b$. Then, the corresponding variables $\delta_{1,2,3}$ and $\delta_{4,5,6}$ are indistinguishable from each other and can be aggregated to a single variable, $\delta_{1/4,2/5,3/6}$. With this aggregation, the new coefficient in the objective function is determined using the probability weighted sum of the original coefficients ($m_{1/4,2/5,3/6} = \alpha_3 m_{1,2,3} + \alpha_6 m_{4,5,6}$). Notice also that the parameter Z is calculated using disinfectant simulations from every potential booster station location with the injection starting at the detection time of the corresponding scenario. Any two scenarios that have the same detection time will also have the same calculated values for Z. While the number of scenarios is very large, there can only be as many possible detection times as there are time discretizations (i.e. $|T|$). Therefore, we only need to perform booster station simulations, at most, over all timesteps and not all scenarios, significantly reducing both the size of the problem and the computational time required to calculate the parameters.

As seen in the numerical results presented in the next section, these reductions are necessary for reasonable memory usage and solution times for larger water network problems.

3. Numerical Results

In this case study we examine the optimal placement of 5 booster stations in the water distribution network shown in Figure 1. This network has $3,358$ nodes and $3,829$ pipes. $1,621$ nodes have been selected as booster station candidates (all nodes with non-zero demand). We assumed 20 fixed sensors in the network, which were optimally placed

using the TEVA-SPOT toolkit (Berry et al., 2008). These sensor locations are shown in Figure 1. The water quality model was generated using a 30 minute water quality timestep and a full simulation horizon of 72 hours. For contamination scenarios, we considered contaminant injections from every junction and every timestep during the first 24 hours of the simulation horizon, resulting in a total of 159,504 contamination scenarios. The Merlion water quality model (Wong et al., 2010) was used to perform all of the toxin and booster station simulations, and the total simulation time, including writing of the data files for the problem formulation, was about 2 minutes for the required 170,310 simulations.

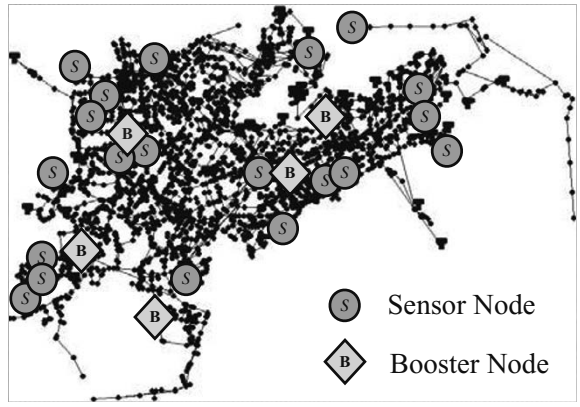

Figure 1. Network schematic showing network nodes and pipes, where sensors are indicated by `S` *and the optimal booster station locations indicated by* `B`

The size of the full problem is shown in Figure 2 (vertical axis is in logarithmic scale). The large number of scenarios results in a mixed-integer linear problem that has over 10 billion variables and constraints. Following the application of reduction (1), the problem size has been reduced by almost two orders of magnitude, but is still prohibitively large. The memory required to store the nonzeros in the constraint jacobian alone (as 8-byte doubles) is over 600 gigabytes. Applying reduction (2) reduces the problem by another three orders of magnitude, giving a reasonably sized problem with approximately half a million variables. Solving this problem using CPLEX 12.2 required approximately 45 minutes and 70 gigabytes of RAM on a machine with 8 Intel(R) Xeon(R) processors (X5570 @ 2.93GHz).

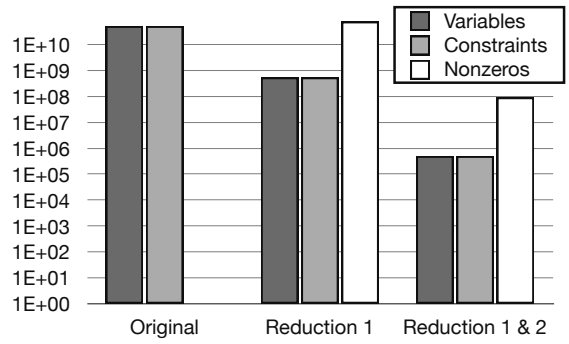

Figure 2. Problem size (log scale) for the original full space problem, the problem following reduction (1), and the problem following reductions (1) and (2).

Figure 1 shows the optimal solution for the booster station placement. With this booster station placement, the expected value of the mass of toxin consumed by the public is reduced by 62% over the value for the network with sensors only (no booster stations), where 64% of the expected consumption occurs before detection.

4. Summary and Conclusions

In this paper, we have proposed a stochastic programming formulation for the optimal placement of disinfectant booster stations in a large-scale water distribution system. This problem formulation considers uncertainty in both the time and location of contamination events. Given large water

network models and the number of scenarios, the extensive form of this problem is intractably large.

There is a tremendous amount of structure in the problem induced by the scenario-based formulation and the network model itself. This allows for a series of problem reductions that dramatically decrease the size of the formulation. Indeed, in the case study considered here, the problem size was reduced by over five orders of magnitude. This problem formulation includes an extremely large number of scenarios (all junctions and timesteps for an entire day), nevertheless, with these reductions, solution is possible considering realistic network models. While commercial modeling and solver packages have a presolve phase, the original problem is far too large to even fit in memory on a reasonable workstation. Furthermore, even with smaller test problems, we did not see significant reduction in the problem size using the presolve in both AMPL or CPLEX 12.2.

Incorporating Complex Fiscal Rules in Strategic Planning of Offshore Oil and Gas Fields

Vijay Gupta and Ignacio E. Grossmann

Dept. of Chemical Engineering, Carnegie Mellon University, Pittburgh, PA 15213, USA

Abstract

In this paper, we extend a recently proposed multi-field site strategic planning model for offshore oil and gas fields to include the complex fiscal rules, specifically sliding scale production sharing agreements (PSAs). The proposed multiperiod MINLP model maximizes NPV after paying royalties, profit share, etc. to the host government. The model can be reformulated into an MILP using linearization techniques to solve it to global optimality. It is shown that the computational cost increases significantly by adding the sliding scale PSA contracts in contrast to a simple NPV based optimization. However, the model yields improved investment and operations decisions due to the explicit consideration of the fiscal terms within development planning.

Keywords: Multiperiod Optimization, Oil exploration, Production sharing agreements.

1. Introduction

Strategic planning of offshore oil and gas fields involves capital intensive decisions pertaining to the installation of exploration and production facilities, subsea structures, pipeline connections, well drilling, etc. that are taken at the early stages of the project. However, there is a very large number of alternatives that are usually available to make these decisions under the given physical and practical restrictions. This necessitates optimizing the investment and operations decisions to ensure the highest return on the investments over the given time horizon. Furthermore, fiscal rules of the agreements between oil company and the host government usually determine the share of each of these entities in the total oil production or gross revenues and the timing of these payments. Hence, including fiscal considerations as part of the oilfield development problem can impact the optimal decisions and revenue flows over the planning horizon, as a large fraction of the total oil produced is paid as royalties, profit share, etc.

There are several deterministic (Iyer et al. 1998, Gupta and Grossmann 2011a), and stochastic (Goel and Grossmann 2004, Tarhan et al. 2009) models that have been proposed for the oil/gas field planning problem. However, the models and solutions approaches in the literature that consider the fiscal rules within development planning are either very specific or simplified. Van den Heever and Grossmann (2001) considered optimizing the complex economic objectives including royalties, tariffs, and taxes for the multiple gas field site where number of wells were used as parameters (fixed well schedule). Moreover, the fiscal rules presented were specific to the gas field site considered, but not in generic form. Based on a continuous time formulation for gas field development with complex economics of similar nature as Van den Heever and Grossmann (2001), Lin and Floudas (2003) presented an MINLP model and solved it with a two-stage algorithm. Simulation based approaches (Blake and Roberts 2006) are also considered for the analysis of the different fiscal terms.

In this paper, we address the optimal development planning of offshore oil and gas fields under complex fiscal rules considering as a basis the deterministic model for

multi-field site by Gupta and Grossmann (2011a), which includes sufficient level of details to be realistic as well as computationally efficient. We first discuss the basic elements of the various types of contracts with particular focus on the progressive PSA terms, and then the way to include these contracts in the model. Numerical results on an instance of the development planning problem with a typical PSA terms are presented.

2. Background

There are a variety of contracts that are used in the offshore oil and gas industry. These contracts can be classified into two main categories:

2.1. Concessionary System

A concessionary (or tax and royalty) system usually involves royalty, cost deduction and tax. Royalty is paid to the government at a certain percentage of the gross revenues. The net revenue after deducting costs becomes taxable income on which a pre-defined percentage is paid as tax. The total contractor's share involves gross revenues minus royalty and taxes. The basic difference as compared to the production sharing agreement, is that the oil company obtains the title to all of the oil and gas at the wellhead and pay royalties, bonuses, and other taxes to the government.

2.2. Production Sharing Agreements (PSAs)

The revenue flow in a typical Production Sharing Agreement can be seen as in Figure 1, (World Bank 2007). Some portion of the total oil produced is treated as cost oil by the oil company to recover costs after paying royalties to the government at a certain percentage of the oil produced. There is a ceiling on the cost oil recovery to ensure revenues to the government as soon as production starts. The remaining part of the oil, called profit oil, is divided between oil company and the host government at a certain percentage. The oil company needs to further pay income tax on its share of profit oil. Hence, the total contractor's (oil company) share in the gross revenue comprises of cost oil and contractor's profit oil share after tax. The other important feature of a PSA is that the government owns all the oil and transfers title to a portion of the extracted oil and gas to the contractor at an agreed delivery point. Notice that the cost oil limit is one of the key differences with a concessionary system.

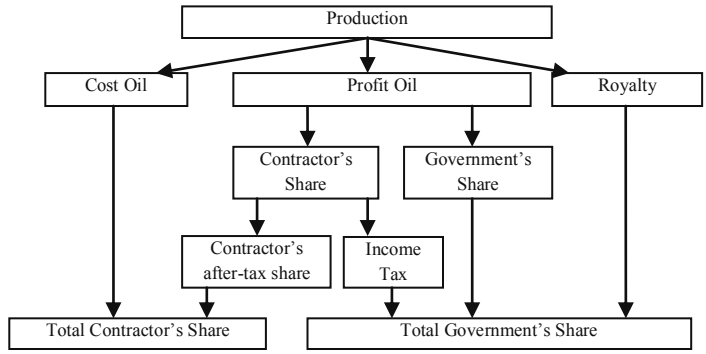

Figure 1: Revenue flow for a typical Production Sharing Agreement

The specific rules defined in such a contract (either concessionary or PSA) between oil company and host government determine the profit that the oil company can keep as well as the royalties and profit share that are paid to the government. These profit oil shares, royalty rates are usually based on the profitability of the project (sliding scale or progressive fiscal terms), where cumulative oil produced, rate of return, R-factor etc. are the typical profitability measures that determine the tier structure (levels) for these

contract terms. For instance, if the cumulative production is in the range of first tier, $L_1 \le xc_t \le U_1$, the royalty R_1 will be paid to the government, while if the cumulative production reaches in tier 2, royalty R_2 will need to be paid, and so on. In practice, as we move to the higher tier the percentage share of contractor in the total production decreases. Given that the resulting royalties and/or government profit oil share can represent a significant amount of the gross revenues, it is critical to consider these contract terms explicitly during oilfield planning to assess the actual economic potential of such a project. In the next section, we discuss how to include these sliding scale PSA rules in a development planning model which covers the key elements of the most of the available contracts, and represent one of the most general forms of fiscal rules.

3. Model

A typical offshore oilfield infrastructure consists of a set of oil fields *F = {1,2,..,f}* for producing oil using a set of FPSO (Floating, Production, Storage and Offloading) facilities, *FPSO = {1,2,...fpso},* (see Fig. 2) that can process the produced oil, store and offload it to the other tankers. Each oilfield consists of a number of potential wells to be drilled using drilling rigs, which are then connected to these FPSO facilities through pipelines to produce oil. The goal is to determine the optimum investment and operation decisions to maximize the NPV for a long-term planning horizon, which is discretized into a number of time periods *t,* typically each with 1 year of duration. Investment decisions in each time period *t* include which FPSO facilities should be installed or expanded, and their respective installation or expansion capacities for oil, liquid and gas, which fields should be connected to which FPSO facility, and the number of wells that should be drilled in a particular field *f*. Operating decisions include the oil/gas production rates from each field *f* in each time period *t*. It is assumed that the installation and expansion decisions occur at the beginning of each time period *t*, while operation takes place throughout the time period.

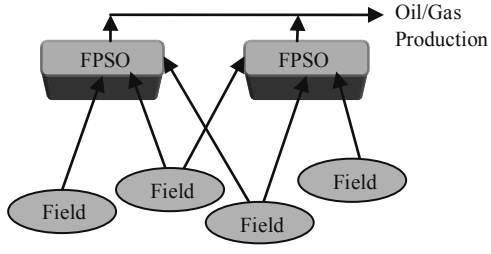

Figure 2. Typical Offshore Oilfield Infrastructure

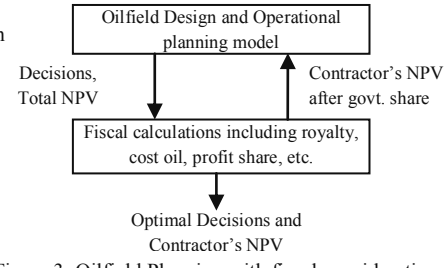

Figure 3. Oilfield Planning with fiscal considerations

Gupta and Grossmann (2011a) recently proposed an efficient multiperiod MINLP model (**Model 2**) for this development planning problem which is reformulated into an MILP (**Model 3**) to solve it to global optimality. The models were further reduced (**Model 2R** and **Model 3R**) to improve the computational efficiently in fullspace. We incorporate the sliding scale PSA terms in these MINLP/MILP models that are explained above. The proposed model considers the trade-offs involved between investment and operations decisions and resulting royalties, profit shares that are paid to the government, and yields the maximum overall NPV for the contractor, (see Fig. 3).

The objective function is to maximize the contractor's NPV where Economic Constraints, Reservoir Constraints, Field-FPSO Flow constraints, FPSO Capacity Constraints, Well drilling limitations and Logic Constraints are similar to the proposed MINLP/MILP models (see Gupta and Grossmann 2011a for details). This corresponds

to the design and operational planning model without fiscal considerations, (see Fig. 3). We describe below the constraints (1)-(8), that correspond to the fiscal part of the problem and these can be included in either of the proposed MINLP or its MILP reformulation. Notice that a detailed generic oilfield planning model with fiscal considerations and solution strategies are discussed in Gupta and Grossmann (2012).

$$TotalConSh_t = ConSh_t^{aftertax} + CO_t \qquad \forall t \qquad (1)$$

$$CO_t = \min(CR_t, f_t^{CR} \cdot REV_t) \qquad \forall t \qquad (2)$$

$$CR_t = CAP_t + OPER_t + CRF_{t-1} \qquad \forall t \qquad (3)$$

$$CRF_t = CR_t - CO_t \qquad \forall t \qquad (4)$$

$$PO_t = REV_t - CO_t \qquad \forall t \qquad (5)$$

$$\bigvee_i \begin{bmatrix} Z_{i,t} \\ ConSh_t^{beforetax} = f_i^{PO} \cdot PO_t \\ L_i \le xc_t \le U_i \end{bmatrix} \qquad \forall t \qquad (6)$$

$$Tax_t = f_t^{tax} \cdot ConSh_t^{beforetax} \qquad \forall t \qquad (7)$$

$$ConSh_t^{aftertax} = ConSh_t^{beforetax} - Tax_t \qquad \forall t \qquad (8)$$

Total contractor's share in time period *t*, (see Fig. 1), is calculated in constraint (1) as the sum of contractor's profit oil share (after paying income tax) and cost oil that it keeps to recover the expenses. We assume that there are no royalty provisions in this case. The cost oil in time period *t*, constraint (2), is calculated as the minimum of the cost recovery in that time period and maximum allowable cost oil (cost recovery ceiling), which is a given fraction f_t^{CR} of the gross revenue. Constraint (2) can further be rewritten as mixed-integer liner constraints. The cost recovery in time period *t*, constraint (3), is the sum of capital and operating costs in time period *t* and cost recovery carry forward from previous time period *t-1* which is calculated in constraint (4) as the difference between cost recovery and cost oil. Constraint (5) states that the total profit oil in time period *t* is the portion of the gross revenue that remains after subtracting the cost oil. Contractor receives a certain fraction, f_i^{PO}, of the total profit oil which is based on a sliding scale variable, for instance cumulative oil production. In particular, disjunction (6) is used to model this tier (levels) structure for profit oil fraction, which states that variable $Z_{i,t}$ will be true if cumulative oil production by the end of time period *t* lies between given tier thresholds $L_i \le xc_t \le U_i$; i.e. tier *i* is active and corresponding fraction f_i^{PO} is used to determine the contractor share in that time period. The disjunction (6) in the model is further reformulated into linear and mixed-integer linear constraints using the convex-hull formulation. The contractor pays income-tax, constraint (7), on its profit oil share at the given tax rate f_t^{tax} that is used in constraint (8) to calculate the contractor's after tax share.

4. Example

In this example, we consider 5 oilfields that can be connected to 3 FPSO's with 11 possible connections. There is a total of 31 wells that can be drilled and planning horizon is 20 years. There is a cost recovery ceiling and 4 tiers (see Fig. 4) for the profit oil fraction of the contractor linked to cumulative oil production, which defines the fiscal terms of a typical PSA. Table 1 compares the results of the proposed MILP (Model 3) and reduced MILP models (Model 3R) with PSAs, that are implemented in

GAMS 23.6.3 and run on Intel Core i7, 4GB RAM machine using CPLEX 12.2. Model 3 with PSA takes more than 10 hours with a 14% of optimality gap as compared to Model 3R, which terminates the search with a 2% gap in reasonable time (1,163.7s). In contrast, Model 3R without any fiscal terms can be solved in only 189.8 seconds. Interestingly, Model 3R with a flat 35% of the profit share of contractor is solved in 72.64s which is even smaller than model without any fiscal terms (189.8s).

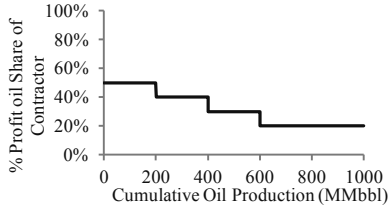

Figure 4. Contractor's Profit oil share for Example

Table 1. Computational Results for Example

	Model 3 with PSA	**Model 3R with PSA**
Constraints	9474	9363
Cont. Variables	6432	6223
Dis. Variables	727	551
NPV ($Million)	2,183.63	2,228.94
Time(s)	>36,000	1,163.7

Therefore, the increase in computational time while including fiscal rules in oilfield planning, is directly related to the number of tiers (levels) that are present in the model to determine the profit oil shares or royalties. This is due to the additional binary variables that are required to model tiers, and resulting weak relaxation, as good bounds on some of the key variables, e.g. profit oil, are not available a priori. The details of the optimal decisions for this example are discussed in Gupta and Grossmann (2011b).

5. Conclusions

In this paper, we have incorporated the complex fiscal terms of the contract between oil company and the host government in a recently proposed model for offshore oil and gas field infrastructure planning. Numerical results in an example show that the model can become expensive to solve with sliding scale fiscal terms due to the additional binary variables to model tiers. However, the model yields improved decisions due to the trade-offs involved between investments and actual contractor's profit share.

Abstract

The natural gas liquefaction process is an energy intensive process due to its low temperature. Compressor units are one of primary factors in minimizing energy consumption of natural gas liquefaction process. Among various natural gas liquefaction processes, C3-MR (Propane Pre-cooled Mixed-Refrigerant) process is the most commonly used in LNG market. C3-MR process uses two types of refrigerants such as mixed-refrigerant and pure-refrigerant. In this study, pure-refrigerant cycle is simulated, along with different compressing ratios and different pressure levels. The simulation of case studies shows that energy consumptions mainly depend on both compressing ratios and pressure levels.. This study has achieved the energy consumption savings by 27.7% through different case studies with an emphasis on compressing ratios and pressure levels.

Keywords: LNG, pure-refrigerant cycle, liquefaction process, propane pre-cooled mixed-refrigerant process

1. Introduction

Due to the tightening regulation of greenhouse gases and instability of demands and supplies of energy, the structure of world energy market is of large fluctuations.. As an alternative energy source against typical existing fossil fuels, the role of natural gas in the world's energy market has been growing now [1]. Moreover, a number of natural gas liquefaction plant have been built or under construction. This latest trend has a consequence that interest in the development of innovative natural gas liquefaction processes is rapidly growing [2].

In general, the liquefaction of natural gas yields huge volume reduction by 1/600 approximately.. For this reason, LNG can be generally used for long distances transportation. In order to liquefy natural gas, the liquefaction temperature must be cooled down below -162°C which is boiling point of methane, a main component of natural gas[3]. Therefore, the natural gas liquefaction process requires to operation under cryogenic conditions and huge amounts of energy. A Compressor is a most important unit in natural gas liquefaction process because it consumes most of energy of the process. Because of large energy consumption, a number of researches on natural gas liquefaction process optimization have been carried out [4]. Main optimization objectives can be classified into two categories such as the improvement of efficiency of the heat exchanger and reduction of the energy consumption of the compressor. [5].

The C3-MR process uses a pure-refrigerant for cooling mixed-refrigerant and pre-cooling natural gas. Many researches on mixed-refrigerants have been conducted, however, a small number of studies on pure-refrigerants. This study simulates pure-refrigerant cycle to find optimal set of compressing ratios and pressure levels of pure-

refrigerant cycle through case studies. Furthermore, the analyses of relationships of energy consumptions with pressure levels and compressing ratios, respectively.

2. Characteristics of C3-MR Process

A schematic diagram of C3-MR process using prue-refrigenrant for pre-cooling natural gas is shown Figure 1. . Propane is used as the pure-refrigerant, and it is also used to cool a mixed-refrigerant.

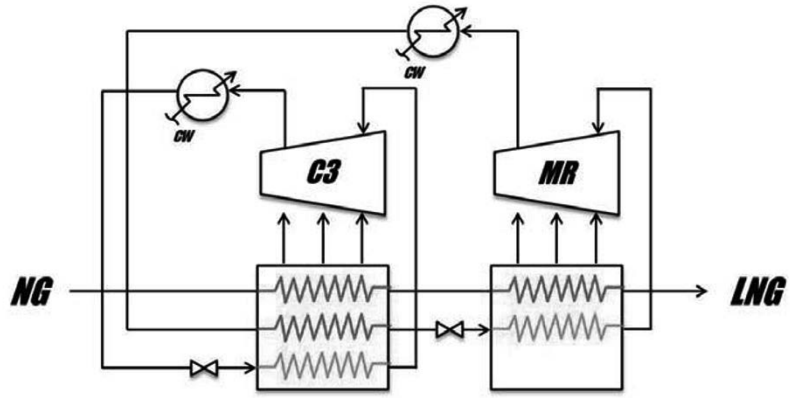

Figure 1. Propane pre-cooling mixed-refrigerant (C3-MR) process diagram

Propane is compressed through a compressor and then cooled by a cooler up to liquid sate. After that, it is expanded through valves. Cold propane is also used to cool natural gas and mixed-refrigerant, and it is vaporized again. Therefore, there is no temperature change of propane in the heat exchanger, only an evaporation heat is used for cooling natural gas and mixed-refrigerant. As shown in figure 2,Vapor propane goes to a compressor again and this series of steps are repeated. In this cycle, total energy consumption is changed by pressure levels and compressing ratios applied [6].

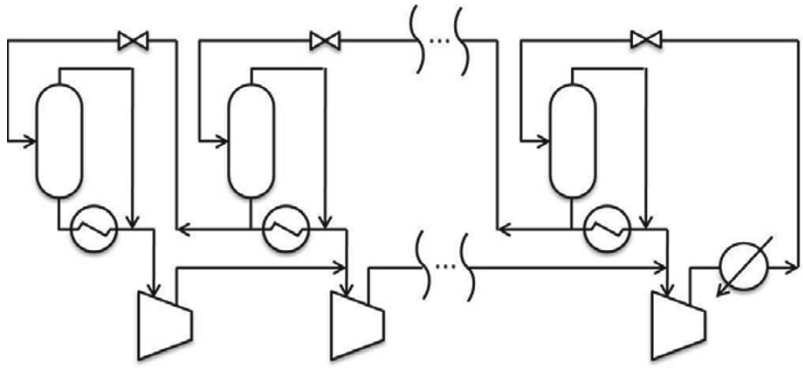

Figure 2. Propane cycle flow sheet

When using a pure-refrigerant for heat exchange, the temperature of cold stream remains constant. Due to this characteristics, heat exchange efficiency increases when using various temperatures of the cold stream. For this reason, pure-refrigerant cycle is

designed to be multi-stages. Compressor, heat exchanger, flash drum, and valves are needed to increase pressure level again. Thus, in general, 2 to 4 compressors are used for pure-refrigerant cycle due to the constraints of an investment cost and space as needed.

3. Mathematical Model

To cool a natural gas and mixed-refrigerant down to a desired temperature, flow rate of propane has to be determined. For this, the following energy balances are used.

$$\dot{Q}_h = \left(H_{h,i} - H_{h,c}\right) \times \dot{m}_h \quad (1)$$

$$\dot{Q}_c = \left(H_{c,i} - H_{c,o}\right) \times \dot{m}_c \quad (2)$$

$$\dot{Q}_h = -\dot{Q}_c \quad (3)$$

where $\dot{Q}$ denotes heat flow rate, H,enthalpy, and $\dot{m}$, mass flow rate, respectively. The subscript h represents a hot stream, c, cold stream, o an inlet and outlet streams of a heat exchanger, respectively.

4. Simulation results

4 types of compressing ratios for and 3 different pressure levels are taken into consideration. Pressure levels are divided into 3 parts; 3rd level with 2 compressors, 4th level with 3 compressors, and 5th level with 4 compressors. Peng-Robinson equation is used as the equation of state.

4.1. Operation Conditions of NG and MR for simulation

Other operating conditions remain as the same over each case. As shown in table 1, the mixed-refrigerant and natural gas conditions stay unchanged around the propane cycle. Minimum temperature difference between hot and cold streams in heat exchanger is within 5°C. Liquid propane is assumed to be perfectly vaporized through the heat exchanger.

Table 1. Conditions of natural gas and mixed refrigerant

	Feed NG	*Pre-cooled NG*	*MR In*	*MR out*
Temperature (°C)	15.00	-37.49	45.00	-37.49
Pressure (kPa)	6150	6150	6150	6150
Mass Flow (kg·mole/hr)	4973	4973	8761	8761

4.2. Simulation Conditions for Case Studies

A set of compressing ratios applied are follows. In case 1, compressing ratio is changed according to the propane temperature. Compressing ratio is high and low at lower and higher temperatures, respectivel.. Compressing ratio used in case 2 is also changed according to propane temperature, but it is used in opposite way to case 1; compressing ratio is low and high at low and high temperatures, respectively . Compressing ratio in case 3 is determined in a way that temperature differences of each pressure level

remiain same. In case 4, every compressor ratio keeps the same. Table 2 shows temperature and pressure conditions of propane.

Table 2. Temperature and pressure of propane

	Pressure Level 3		*Pressure Level 4*		*Pressure Level 5*	
	Temp. (°C)	Pressure (kPa)	Temp. (°C)	Pressure (kPa)	Temp. (°C)	Pressure (kPa)
Case 1						
Level 1	-42.49	100	-42.49	100	-42.49	100
Level 2	-19.34	250	-14.12	150	-37.28	125

Level 4	-	-	15.95	750	-7.41	375
Level 5	-	-	-	-	15.95	750
Case 2						
Level 1	-42.49	100	-42.49	100	-42.49	100
Level 2	-14.12	300	-19.34	250	-25.43	200
Level 3	15.95	750	1.79	500	-5.40	400
Level 4	-	-	15.95	750	7.98	600
Level 5	-	-	-	-	15.95	750
Case 3						
Level 1	-42.49	100	-42.49	100	-42.49	100
Level 2	-13.27	308.8	-23.01	218.9	-27.88	182.2
Level 3	15.95	750	-3.54	424.4	-13.27	308.8
Level 4	-	-	15.95	750	1.34	493.2
Level 5	-	-	-	-	15.95	750
Case 4						
Level 1	-42.49	100	-42.49	100	-42.49	100
Level 2	-16.74	274	-25.97	196	-30.44	165
Level 3	15.95	750	-6.68	384	-16.74	274
Level 4	-	-	15.95	750	-1.28	455
Level 5	-	-	-	-	15.95	750

4.3. Simulation Result

Simulation has been carried out for 12 different cases and comparedin tems of total energy consumptions. The result is shown in table 3.

Table 3. Total energy consumption

	level 3	level 4	level 5
Case 1	320.08 kW	281.30 kW	248.19 kW
Case 2	308.24 kW	256.32 kW	234.00 kW
Case 3	307.31 kW	255.44 kW	231.54 kW

Case 4	312.74 kW	259.17 kW	234.36 kW

5. Conclusion

This study had an objective of finding an optimal set of compressing ratio and pressure level throughcase studies. Each case is observed to be advantageous for cooling. Case 1 can cool down natural gas and mixed-refrigerant using propane at lower temperature. Case 2 can decrease an energy load at each compressors, using lower compressing ratio at higher flow rate of propane. In case 3, the efficiency of each heat exchanger can be increased by minimizing areas between hot and cold composite curves. Case 4 can keep compressing ratios at each compressor the same.

As the result, It was found that as the compressing level is getting higher, energy consumption is getting lower. Furthermore, it is identified that using lower compressing ratio at higher flow rate of propane is better than using lower temperature of middle pressure streams. The worst case is found to be pressure level 3 in case 1 with total energy consumption is 320.08 kW. On the other hand, the best case is identified as the pressure level 5 of case 3 consuming 231.54 kW which is 27.7% lower than that of worst case.

It can be concluded that compressing ration is a primary factor for saving energy consumption and required to be optimized as more than 20% energy savings can be improved by manipulating compression ratio.This work can contribute to minimizing energy consumption of natural gas liquefaction processes which use pure-refrigerant, such as C3-MR process and CASCADE process.

Monitoring and fault diagnosis system for LNG fractionation process

Hahyung Pyun, Hyunseok Jeong, Daeyeon Kim, Daegun Ha, Chonghun Han*

Seoul national university, Rm.712,Bldg.302, Seoul Nat'l Univ ,Gwanakgu,151-744, Korea

Abstract

LNG, the most common clean energy, has been consumed increasingly. Moreover it is expected to be over 50% of total energy source after 2030. Therefore, it is necessary for efficient monitoring and diagnosis system of LNG plant. This plant is very sensitive and correlated each other. If this plant is not operated appropriately, it causes a large amount of operating cost and damaged of equipment. Furthermore, it can propagate other process and cause its fail or risk. Previous monitoring and fault diagnosis system of this plant is based on univariate methodology. However univariate system is inconvenient to LNG plant because this system has so many sensors correlated each other.

It is necessary to apply multivariate monitoring and fault diagnosis methodology. In this study, PCA, one of the most common multivariate methodologies, is suggested as a monitoring method for a whole process. When fault is detected by this method, three steps methodology for diagnosis are suggested; fault propagation, fault magnitude and event analysis. This suggested methodology is demonstrated to application to LNG fractionation process. As a result, the application of this methodology has rapid detection and accurate performance compared to previous univariate monitoring system.

Keywords: LNG plant, PCA, Monitoring, Fault diagnosis

1. Introduction

In the future, echo-friendly energy will be spotlighted throughout the world. LNG is the most useful source of clean energy. For stable and cost-effective supply, monitoring and fault diagnosis system in LNG plant should be improved. The current system is based on univariate methodology. However, LNG plant has too many sensors to identify whole system. In order to these difficulties, multivariate statistical techniques should be applied. In this study, PCA, one of many multivariate statistical methodologies, is applied appropriately and event matrix for diagnosis is suggested.

2. Backgrounds

2.1. Propagation

Propagation is a signal path to identify a route of faults. This method is achieved by transforming new data to normalized data. Because the normalized data are different from the original data in terms of scale and deviation, the normalized data are more convenient for comparing with each sensor and visualization than the original data. After the data normalized, 3δ deviation is selected as the limit of the sensors. Exceeding the limit is recording in order. This recording is converted to the event matrix and this matrix is used for diagnosis.

2.2. PCA(Principal component analysis)

PCA is a method that reduced the dimension of a number of sensors. This method uses an orthogonal transformation to convert a set of sensors into a PC(principal components). First PC has as high a variance as possible, and each succeeding component is turn has the highest variance possible under the constraint that it be orthogonal to the preceding components. This method can properly describe the trend in whole system.

2.2.1. Fault magnitude

Fault magnitude is from PCA contribution result. This method shows which sensors contribute to the state in the spot of that time. There are two contributions; T-contribution and residual contribution. If fault is detected in T-score chart, than T-contribution interpret system. Otherwise, SPE chart detects fault, residual contribution is used to diagnosis. Fault magnitude is also converted to event matrix and used for diagnosis.

2.2.2. Correlation

PCA is based on decomposition of the covariance matrix of the process variables. So it can describe correlation sensors each other. This correlation is called loading. Loading plot is similar with contribution. The difference between contribution and loading is time-varying or one kind of indicator. So correlation is reflected trend of the system history which pre-set time interval. Likewise above methods, this method is converted to event matrix and used for diagnosis.

2.3. Event analysis

Event analysis is a method to interpret one's methodology. In other words, qualitative or quantitative result translates to standard description. Fig1 shows example of translation magnitude and correlation.

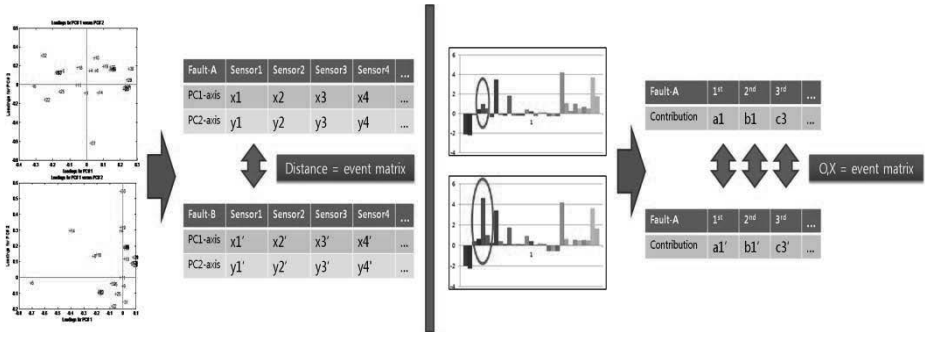

Fig 1 Event matrix for correlation(left) and magnitude(right)

2.4. Fractionation process

LNG plant has self refrigerant process to liquefy NG to LNG. Fractionation process is first section to make refrigerant. Preprocessing NG gas gets through scrubber and heavy gases become feed of the fractionation process. This process has 4 column; demethanizer, deethanizer, depropanizer, debutanizer. From each column methane, ethane, propane, butane+ are distillated. Since heat balance in liquefaction part is very sensitive as temperature of the cooling materials, high distillation performance in

fractionation is needed. In this study, dynamic simulation model for this process is used to verify the proposed methodologies.

3. Case study

3.1. Normal process

In order to monitor the process, normal state must be specified. In this study, aspen hysys simulator is used and the range of convergence dynamic model is defined as the normal state. Feed condition shows in table 1.

	Temperature [℃]	*Pressure [kPa]*	*Flow rate[kg/h]*
Normal process	-16.8~-14.8	6050~6250	51000~56000

Table 1. Normal operation condition

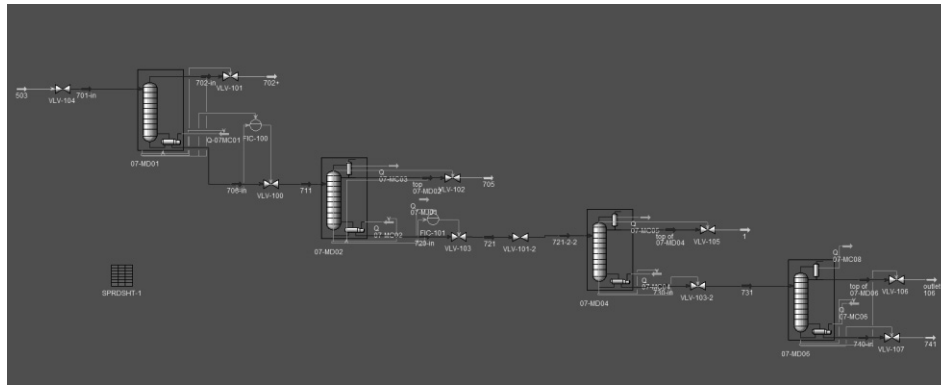

Fig 2 Dynamic model of fractionation process using aspen hysys

3.2. Abnormal process

In this study, 4 fault scenarios are used. Fist case is overheating in demethanizer's reboiler. Overheating in deethanizer reboiler is the second fault. Reboiler of deethanizer failure of the pressure controller is a third scenario. Last abnormal case is leaking of deethanizer bottom stream. Each scenario has 3 intensities; increased 5% , 10% and 20%.

Table 4. Correlation result

5. Conclusions

Suggested methodology; Propagation, Fault magnitude, Correlation, matches generated fault and past history fault. It is not perfect but very high performance. Misleading or incorrect case occurs each methodology. But if these methodologies are complementary, its accuracy should be improved. In this study, multivariable statistical methodologies are applied to LNG plant. Additional algorithms and correct idea for event matrix will be developed and should be improved the monitoring and diagnosis system.

Abstract

Well placement is a critical step with a permanent impact, and hence, finding the best location to drill the wells will have high economic benefits. This work utilizes the previous study of Tavallali et al. (2011) as the base platform and improves their model. It considers both the injectors' and producers' locations as the optimization variables. The final formulation is a dynamic and nonconvex mixed integer nonlinear model, and is solved by a modified outer approximation method.

Keywords: Simultaneous injector and producer well placement, mixed integer nonlinear programming, PDE constraint optimization.

1. Introduction

We are in the millennium of energy. As hydrocarbon prices climb higher and higher, the optimal recovery of new and marginal/mature oil fields becomes more important. The first step in exploiting a given hydrocarbon field is well drilling. Wells play two important roles: a group of them produces oil, while another group injects another fluid (such as water). This is both to maintain the pressure of the reservoir and to increase the sweep efficiency. Well placement is a critical step with a permanent impact, and hence, finding the best location to drill the wells will have high economic benefits. This work utilizes the previous study of Tavallali et al. (2011) as the base platform and improves their model. We consider both the injectors' and producers' locations as the optimization variables. This is a complex task as further important modifications to the model are required.

Although higher oil flow rate improves the revenue, higher water injection can play a twofold role. It can both increase and decrease the economic profit of the project. Hence, the different nature of producers and injectors necessitates introducing both new binaries and new logical constraints**.**

2. Previous works

In a pioneering study, Rosenwald and Green (1974) developed a mixed integer linear programming (MILP) model to select the optimal well locations from a limited set of potential sites to best satisfy the demand targets. Later, Ierapetritou et al. (1999) formulated a MILP model and utilized a decomposition approach through a series of

[1*] Corresponding author: Tel.: +65 6516-6359, Fax: +65 6779-1936, Email – cheiak@nus.edu.sg

quality cut-offs and feasibility tests to obtain the optimal selection of vertical wells in a 3D reservoir model. In another study, Cullick et al. (2004) introduced a two stage method for determining well locations in a 3D reservoir model. The first stage determined the completions for strictly vertical wells, while the second stage determined the configuration of the wells obtained in the first stage.

Although mathematical programming is the pioneer method in addressing optimal well placement problem, it could not become common in practice in comparison with evolutionary methods (Yeten et al., 2003 and Güyagüler et al., 2002). The main reason is due to the inaccuracy of the models used to represent the reservoir response. To overcome that, Tavallali et al., used a rigorous multiphase flow model in their MINLP model to determine the optimal producer locations. They employed two mutually exclusive sets of reservoir cells: (a) already existing wells, and (b) the rest of cells. The latter formed the potential producer set. They also modified the outer approximation with equality relaxation and augmented penalty method to solve this problem.

In the current paper, we use the method of Tavallali et al as the base platform and target simultaneous producer and injector placement to extend its applicability. We improve the model; however we use their solution algorithm directly. The algorithm consists of a decomposition of the MINLP model into an iterative nonlinear programming (NLP), a local search procedure and MILP.

In contrast to their study, each cell will now be a candidate for both producer and injector well site. To achieve that, the remaining parts of this paper are organized as follows. First, the oil drilling problem is described. Subsequently, the model is presented, and illustrated through a case study. Next is a discussion of the results, and finally, the paper is closed with a conclusion and acknowledgements.

3. Problem Definition

Given an oil reservoir with existing wells, the goal is to expand the production by infill drilling of new producers and injectors to meet a projected oil demand for a given time horizon. Necessary geological and PVT data of the reservoir and the fluids are assumed to be available through preliminary studies and lab tests. Furthermore, relevant economic data such as projected demand curve, drilling costs, injection costs, discount rate, oil revenue forecasts, etc, as well as operational data such as water-cut limits, maximum injection pressure, minimum production pressure, production and injection capacity expansion plan for surface facilities are also provided. Finally the minimum allowable well-to-well distance is also specified.

The objective of the mathematical programming model is to maximize the net present value (NPV) of oil production over a fixed planning horizon through the simultaneous determination of new producer and new injector well locations.

It is assumed that the reservoir is a horizontal 2D plane with only water and oil phases, capillary pressure in the reservoir is negligible and the main driving mechanism is water-drive injection.

4. Model

The oil production plan is subjected to mass balances for each phase and should ensure that it meets the oil demand while keeping within the various plant production and injection capacities and operational water cut limits. Moreover, the number of drilled wells should match the budget and decision of the management team.

We use set $l = 1,2,\ldots,\mathrm{L}$ to refer to the discrete cell location, and $t = 1,2,\ldots,\mathrm{T}$ to represent the discrete time steps. The main decision variables are the total fluid flow rate in or out of the well and oil flow rate. They are shown by q_l^t and $q_{o,l}^t$ respectively. As is usual in the reservoir modeling field, we use negative values for the well flow rate of injectors ($q_l^t \leq 0$) and positive value for producers ($q_l^t \geq 0$). Additionally, we define two binary variables: y_l and z_l to choose the well location and its functionality (producer/injector) respectively. y_l indicates the absence ($y_l = 0$) or presence ($y_l = 1$) of a well, while z_l reflects the functionality of the well, $z_l = 1$ for a producer, $z_l = 0$ for an injector.

It is evident that should there be no well present in the cell, there cannot possibly be any flow rate:

$$q_l^t \leq z_l\left(Q_{p0} + E^t\right) \tag{1}$$

$$-y_l|Q_{i0} + I^t| \leq q_l^t \tag{2}$$

where Q_{p0} and Q_{i0} refer to the initial production and injection capacities of the reservoir. E^t and I^t are the production and injection expansion capacities of the reservoir.

Furthermore, if there is no well, it should also be reflected that there is no producer, and hence:

$$z_l \leq y_l \tag{3}$$

For any producer well, the respective flow rates must be tuned to provide the minimum required tubing head pressure (THP_l^L) behind the production choke valves. It is to facilitate the required pressure for the surface operations and separation stages:

$$q_{o,l}^t \leq \psi_l M_{o,l}^t \left(P_l^t - \left[\gamma_1 {q_l^t}^2 + \gamma_2 {q_{o,l}^t}^2 + \gamma_3 q_l^t + \gamma_4 q_l^t + \gamma_5 \frac{q_{o,l}^t}{q_l^t} + \gamma_6\right] - THP_l^L\right) + (1 - z_l) q_l^U \tag{4}$$

where, ψ_l is connection transmissibility factor for wells, $M_{o,l}^t$ is the oil mobility that combines the pressure and saturation dependency of the multiphase fluid flow. q_l^U is an upperbound for production. The γ is the regression parameter and the associated regression terms in the middle bracket, capture the pressure drop inside the well string due to hydrostatic, frictional, and acceleration effects. The binary variables are introduced to ensure the equations will be reduced to their true form only for the appropriate functionality of the well (i.e. producer well), and become loose constraints in the other cases. Similarly, ignoring frictional, and acceleration pressure drops and considering maximum possible THP_l^U for an injector, we can have:

$$q_l^t \geq \psi_l M_{w,l}^U \left(P_l^t - \rho_{w,l} g L - THP_l^U\right) - (1 - y_l)|q_l^L| - z_l|q_l^L| \tag{5}$$

Here, $M_{w,l}^U$ is the maximum water mobility. With the same idea, the ratio of q_l^t and $q_{o,l}^t$ can be modeled in a general sense, using the proper mobility and binary terms.

We maximize NPV as the well placement objective. It comprises of the following parts: drilling, oil revenues and oil processing costs, water production costs, and water injection costs:

$$Min \sum_{l \notin \boldsymbol{IW} \cup \boldsymbol{IP}} \left(c_f y_l\right) - \sum_{t>1} \sum_l \left[c_o q_{o,l}^t - c_{pw} z_l \left(q_l^t - q_{o,l}^t\right) + c_{iw}(1 - z_l) q_l^t\right] \times \frac{\Delta h^t}{\frac{h^t}{(1+\alpha)^{365}}} \tag{6}$$

The fixed costs for drilling a well are reflected in the first summation term. The second summation term consists of the variable costs and profits. c_o, c_{pw}, c_{iw} refers to the oil

production profit, water production cost and water injection cost per unit volume respectively. The final group of terms outside the summation is to account for the time value of money of the cash flows.

5. Case Study

The computations are performed on a Dell Precision T7400 mini-work station with Intel(R) Xeon (R) CPU X5492 @ 3.40 GHz Processor, 64 GB of RAM. The model and algorithm are implemented in GAMS 23.7.3. The MILP models are solved by GUROBI 4.5.1 solver. Additionally the NLP problems are mainly solved by CONOPTD 0.1 and in (rare) case of failure IPOPT and SNOPT.

The reservoir is modeled into a 20 by 20 spatial grid, with each block having the dimensions of 94.1m x 79.6m x 5.56m. There are already 3 existing producers and 2 existing injectors. They are shown by the white stars and triangles respectively in the subsequent figures. The reservoir has been producing oil for the last 250 days with an initial production capacity of 1300m^3/day and injection production capacity of 1500m^3/day. It is suggested to drill 3 new producers and 2 new injectors to plan the next production horizon of 2150 days.

Before performing the case study, a set of 10 mono-producer well placement runs were carried out to gauge the solver's performance. The solver successfully managed to converge to the global optimal solution which was verified using a brute force search to identify the NPVs of drilling a well at every single possible location.

For the case study, different sets of initial guess of 3 additional producers and 2 additional injectors are provided to the solver to begin the run. Figure 1 represents the progress of the best solution through the course of optimization with the NPV shown above each stage . Notice that after major changes in the first two iterations the rest are location refinement through local search stage.

The final solution's NPV after 7 major iterations and 25 production simulations is $504 million with 3 new producers and no new injectors, which is an improvement over the NPV of $486 million for the base case which contained only the existing wells, and no additional producers or injectors drilled.

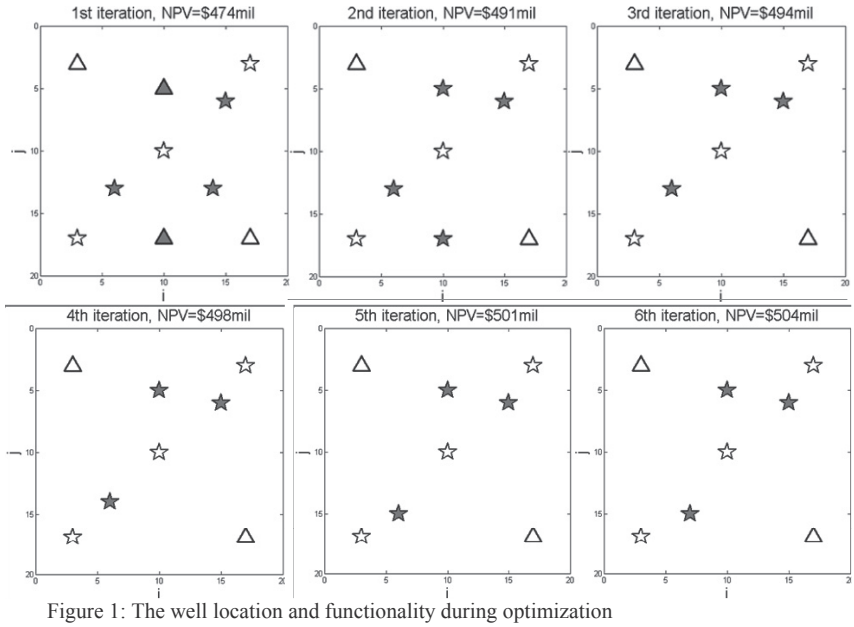

Figure 1: The well location and functionality during optimization
Stars represent producers, triangles represent injectors
Shaded shapes represent additional guesses, white shapes represent an already existing well

6. Discussion

It is notable that similar to Tavallali et al. (2011) we only used local search for the oil producer with the least production history. Owing to the non-convexity of the problem, the local search is extremely crucial in helping to find a better solution. We foresee even better results if we also include injector perturbation in the local search stage. However special care should be given to the screening criteria in the local search. Tavallali et al (2011) selected the well with the lowest level of oil production, as it is the lowest contributor to the NPV of the project, thus, possibly the best candidate to improve on. In contrast, injectors with the highest amount of water injection would have the highest injection costs. However, this may not necessarily mean that the injector has the greatest negative impact on the NPV. This injector could also be the one which provide the most effective water drive energy and sweep and drain the remaining oil zones. It is the actual role of injectors in the first place and hence contributes to the NPV positively in an indirect manner.

7. Conclusion

We have successfully improved on the previous work of Tavallali et al. (2011) by allowing each cell location to have an equal chance of becoming a producer or an injector. The remaining bottlenecks in place are a result of the large size of the problem. In addition there is a level of uncertainty regarding the well placement solutions as there is no definitive way to check whether the solutions are close to the global optimum, and hence this concern will need to be addressed through future additional testing of the model.

8. Acknowledgements

We would like to extend our gratitude to Schlumberger for the provision of the VFPi software to aid us in our work, and Maritime Industry Attachment Programme for their provision of the research grant.

Abstract

As a result of the expanding global LNG market, contracts are becoming more complex due to significant variations in price formulations, flexibility, duration, lead-time, quality, capacity, commitments, discounts and other terms and conditions. The existence of various uncertainties further complicates the contract selection process. We have presented a 2-stage mixed integer linear programming formalism to select LNG contracts with minimum total procurement cost under uncertain demand and LNG price over the planning horizon.

Keywords: LNG; contract, natural gas; vendor selection.

1. Introduction

Recent increases in energy prices, the rise in natural gas demand due to the concerns over CO_2 emissions and a possible carbon tax, the development of a low-cost and high-capacity liquefied natural gas (LNG) value chain, the emergence of new suppliers with large gas reserves, the flow of uncommitted LNG capacity to the market, and the disappearance of conventional contract clauses such as destination are stimulating global LNG trade. Moreover, natural gas market liberalization is resulting in the emergence of new buyers with variable demands, which is increasing the competitiveness and dynamicity of the market. The LNG contracts are thus diversifying in price formulations, flexibility, duration, quality, quantity, commitment, discount, and other terms and conditions. Finding a combination of contracts and suppliers, which trades off various cost factors in an optimal manner, is becoming more and more challenging, where systematic optimization-based approaches can be very useful.

Recently, Khalilpour and Karimi (2011) introduced a deterministic mixed-integer linear programming (MILP) formalism to help the LNG buyers select the best combination of suppliers and contracts in an integrated manner that addresses various aspects, such as contract timings and lengths, demands, price formulations, volume discounts, delivery terms, shipment costs, purchase commitments, etc. However, in reality contract selection is associated with numerous uncertainties (e.g. LNG demand and price). In this study, we have further extended the previous formulation to consider the uncertainties in order to improve robustness of decision making. This paper introduces the new formulation followed by an example.

2. Problem Statement

Consider a company that plans to procure LNG over a given planning horizon H comprising P multiple periods (p = 1, 2, ..., P) of a given fixed length (day, week, etc.). The LNG price in the market is defined as a function (linear, S-curve, etc.) of crude oil price. LNG need or demand is function of many parameters such as energy prices, economical development of the society, etc.

The company assumes I scenarios ($1 \leq i \leq I$) for oil price. Let OP_{pi} denote the oil price for scenario i during period p. For each oil price scenario, it assumes J scenarios ($1 \leq j \leq J$) for LNG demand. Let D_{pij} denote the total LNG demand in period p with a Wobbe Index, WI, (MJ/m^3) in the range of $[WI_p^L,\ WI_p^U]$. Let Pr_{ij} be the probability of oil price scenario i and demand scenario j. Then, P_{ij} = Pr[Demand scenario j for oil price scenario i] × Pr[Oil price scenario i].

The company has access to several potential globally distributed suppliers (or sellers) and a spot market. Thus, it can purchase LNG of varying grades and qualities and then blend these purchases to meet its WI specification. Following Bansal et al. (2007), we replace each supplier with the set of its offered contracts to make this a contract (versus supplier) selection problem. Let C denote the total number of all contracts (c = 1, 2, .., C) offered by the potential suppliers. Let L_c denote the stipulated length of contract c measured in the number of periods. Each contract is of a pre-specified type, either FOB (freight on board) or DES (delivered ex-ship). For an FOB contract, the buyer is responsible for the transport. The buyer may own or charter a fleet of LNG vessels or employ a 3PL (third party logistics provider) to transport its cargo. If it has a limited fleet or does not plan to charter vessels for all its cargo needs, then it may opt for a certain desired mix of DES and FOB contracts for reasons of flexibility.

The current Sales and Purchase Agreements (SPA) enforce a clause that "LNG shall be sold or purchased in full cargo lots" (GIIGNL, 2004). Thus, the company orders its purchases in terms of the number of vessels rather than the volume or mass of LNG. Let w_{cp} (tonnes of LNG) denote cargo size under contract c for purchases in period p. If it is an FOB contract, then the company determines w_{cp}, otherwise the SPA stipulates it. The amount of LNG purchased in a period under a contract may be limited by the seller's production capacity or its non-technical policies such as customer base diversification. On the other hand, the buyer's policies may advocate multi-sourcing and supplier or energy source diversity, and result in similar limits. Therefore, let q_{cp}^U denote the given maximum number of full cargo loads that the company can purchase in period p under contract c. It is also possible to have a constraint on the total purchase under a contract over the entire contract length. Thus, let Q_c^U denote the given maximum amount (tonnes) of LNG that the company can purchase under contract c.

The aim of this problem is, therefore, to determine: the contracts that the buyer should sign with respect to stochastic conditions; the contracts start times; the amount of LNG cargo that the buyer should order under each contract in each period; the spot market sales or procurement under any stochastic scenario; and the total minimum cost for LNG procurement.

3. Formulation

The primary decisions in this problem are to select contracts and their start times. Therefore, we define the following binary variable for each contract c as follows:

$$z_c = \begin{cases} 1 & if\ contract\ c\ is\ selected \\ 0 & otherwise \end{cases} \qquad 1 \leq c \leq C$$

$$ys_{cp} = \begin{cases} 1 & if\ contract\ c\ starts\ with\ period\ p \\ 0 & otherwise \end{cases} \qquad 1 \le p \le P,\ 1 \le c \le C$$

Since a contract can begin only once in the horizon, we get:

$$z_c = \sum_{p=1}^{P} ys_{cp} \qquad 1 \le c \le C \qquad (1)$$

Equation 1 allows us to treat z_c as a continuous variable. ya_{cp} allow us to determine if a contract is active during a period by using the following 0-1 continuous variable:

$$ya_{cp} = \begin{cases} 1 & if\ contract\ c\ is\ active\ during\ period\ p \\ 0 & otherwise \end{cases} \qquad 1 \le p \le P,\ 1 \le c \le C$$

$$ya_{cp} = \sum_{p'=\max[1,\ p-CL_c+1]}^{p} ys_{cp'} \qquad 1 \le p \le P,\ 1 \le c \le C \qquad (2)$$

Let q_{cp} denote the amount of LNG cargo that the company orders during period p under contract c. If contract c is inactive during period p, then this must be zero.

$$q_{cp} \le q_{cp}^{U} y_{cp} \qquad 1 \le p \le P,\ 1 \le c \le C \qquad (3)$$

Similarly, the total purchase over the entire contract length cannot exceed its upper bound.

$$\sum_{p=1}^{P} w_{cp} q_{cp} \le Q_c^{U} z_c \qquad 1 \le c \le C \qquad (4)$$

The cumulative procurement from all contracts during a period ($\sum_{c=1}^{C} w_{cp} q_{cp}$) might be less or more than the stochastic demand, D_{pij}. In case, that the contracted quantity for a period is less than the demand, the remainder will be procured from spot market (BS_{pij}), and if there is redundancy, it will be sold to spot market (SS_{pij}). In other words,

$$BS_{pij} - SS_{pij} + \sum_{c=1}^{C} w_{cp} q_{cp} = D_{pij} \qquad 1 \le p \le P,\ 1 \le i \le I,\ 1 \le j \le J \qquad (5)$$

We have to ensure that at any period p, at most one of the variables BS_{pij} or SS_{pij} have nonzero value. We define the following binary variable, yd_{pij}, as:

$$yd_{pij} = \begin{cases} 1 & if\ the\ contracted\ LNG\ for\ period\ p\ is\ less\ than\ demand \\ 0 & otherwise \end{cases}$$

Then,

$$BS_{pij} \le yd_{pij} D_{pij} \qquad 1 \le p \le P,\ 1 \le i \le I,\ 1 \le j \le J \qquad (6)$$

$$SS_{pij} \le (1 - yd_{pij}) D_{pij} \qquad 1 \le p \le P,\ 1 \le i \le I,\ 1 \le j \le J \qquad (7)$$

The company may desire the contracted LNG quantity for any period p ($\sum_{c=1}^{C} w_{cp} q_{cp}$) to be in certain range of any demand scenario, D_{pij}. Such policies are practiced to further reduce or control supply surplus/shortage risks. Let [fD^L, fD^U] denote the desired range for the fraction of fixed contracts in the company's procurement plan.

$$fD^L D_{pij} \le \sum_{c=1}^{C} w_{cp} q_{cp} \le fD^U D_{pij} \qquad (8)$$

In addition to meeting quantity needs, the purchases must also satisfy quality requirements. Assuming that the separate shipments over each period can be mixed over time to meet the desired quality, we can write this quality constraint as:

$$WI_p^L \sum_{c=1}^{C} \frac{w_{cp}\, q_{cp}}{SG_{cp}} \le \sum_{c=1}^{C} \frac{WI_{cp}\, w_{cp}\, q_{cp}}{SG_{cp}} \le WI_p^U \sum_{c=1}^{C} \frac{w_{cp}\, q_{cp}}{SG_{cp}} \qquad (9a\text{-}b)$$

where WI_{cp} is the Wobbe index for LNG purchased under contract c during period p and SG_{cp} is the specific gravity of LNG under contract c at period p.

As discussed before, FOB contracts offer some flexibility to the company in terms of destination and trade. Unless the company has decided to use only one specific type (FOB or DES) of contract, it may desire a certain percentage of FOB contracts in the contract mix. Let [f^L, f^U] denote the desired range for the fraction of FOB contracts in the company's procurement plan.

$$f^L \sum_{c=1}^{C} z_c \le \sum_{c=1, c \in FOB}^{C} z_c \le f^U \sum_{c=1}^{C} z_c \qquad (10a\text{-}b)$$

Let $STPC_{ij}$ denote the company's total cost of LNG procurements under oil price and demand scenarios (i, j). It includes the fixed costs of contracts, the cost of contracted

LNGs transport, procurement cost of LNG from spot market, and sales price of surplus LNG to spot market. Let v_{cpi} denote the price ($/tonne) of LNG under contract c during period p and at oil price scenario i. Similarly, PB_{ci} and PS_{pi} are procurement and selling price of spot market during period p under oil price scenario i, respectively. For DES contracts the transport cost is included in the LNG price, and we do not need to compute a separate transport cost. However, if a contract is FOB, then we compute its transport cost (TC_{cp} $ per round trip of cargo shipment during period p under contract c) by considering the ship's time-charter cost, its operating expenditure, boil-off losses and port and passage fees for the entire round trip. We set $TC_{cp} = 0$ for the DES contracts.

$$STPC_{ij} = \sum_{c=1}^{C} FC_c z_c + \sum_{p=1}^{P} \left[BS_{pij} PB_{ci} - SS_{pij} PS_{pi} + \sum_{c=1}^{C} q_{cp} \left(v_{cp} w_{cp} + TC_{cp} \right) \right] \quad (11)$$

where FC_c denotes the fixed cost of signing contract c. With this, the company's goal is to minimize the Expected Total Procurement Cost, $ETPC$, given by

$$ETPC = \sum_{i=1}^{I} \sum_{j=1}^{J} Pr_{ij} STPC_{ij} \quad (12)$$

The complete formulation for LNG procurement for a single-site buyer is given by Equations 1-10 and 11-12 where q_{cp} is an integer, ys_{cp} and yd_{cp} are binary, z_c and ya_{cp} are 0-1 continuous and the rest of the variables are continuous.

4. Example

A buyer plans its LNG purchases over 14 years (H = 14 years) or 56 quarterly periods (P = 56). The company has defined three stochastic values for current crude oil prices, i.e. $70 (probability=0.25), $100 (0.50) and $150 (0.25) with assumption of a constant escalation rate of 0.74% per period. For each crude oil scenario, they have defined three demand scenarios (with equal probabilities) over the planning horizon. Figure 1 illustrates the profiles of the nine different demand projections. The buyer's facilities need LNG with a WI of 51-53 MJ/m^3.

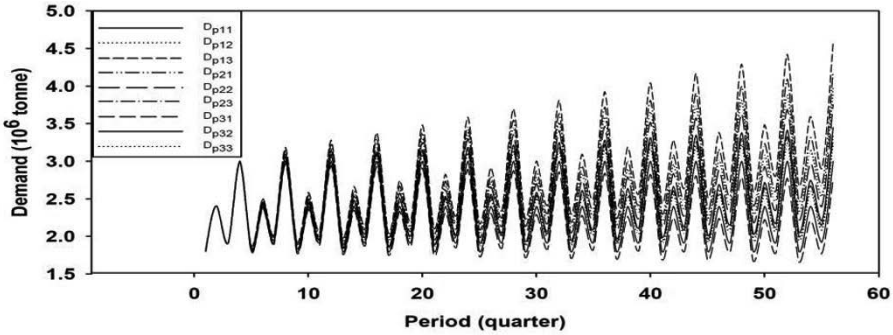

Fig. 1: The buyer's periodical LNG demand under various scenarios.

At present, it is considering C = 40 candidate contracts. Due to its internal policies, the buyer has some limits on total purchase quantities from a few contracts. Some contracts also have supply limits. Some contracts use S-curve price formulas with different price-breaks, while some others use linear formulations. Some contracts are FOB and others are DES. The detailed specifications of the contracts are elsewhere (Table 5 of Khalilpour and Karimi (2011)). The company has its own shipping fleet with the LNG carrier size of w_{cp}= 67,500 tonnes (about 150,000 m^3) for delivery of FOB LNGs.

The MILP model was solved using GAMS software with short execution time of 0.608 CPU s. Figure 2 presents the optimal purchase plan that has 11 of the 40 contracts of which seven contracts are FOB (c = 1, 11, 12, 21, 22, 31 and 32) and four contracts (c = 6, 9, 26 and 36) are DES.

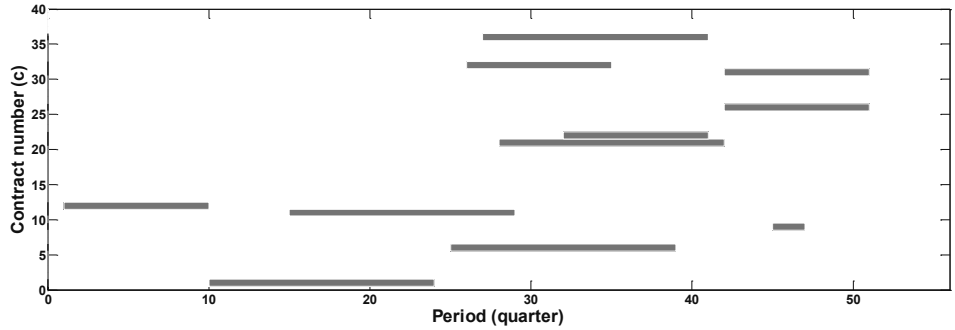

Fig. 2: Optimal contracts and their schedule.

Figure 3 presents the percentage of fixed contracts (taken as base 100%), demand under scenario (*i,j*), procured LNG from spot market and sales LNG to spot market over the entire planning horizon (14 years). The spot market procurement under the nine scenarios will vary in the range of 0.73% - 12.55% of contracted LNG quantity and the surplus LNG for selling to spot market will be in the range of 1.61-15.43 % of contracts.

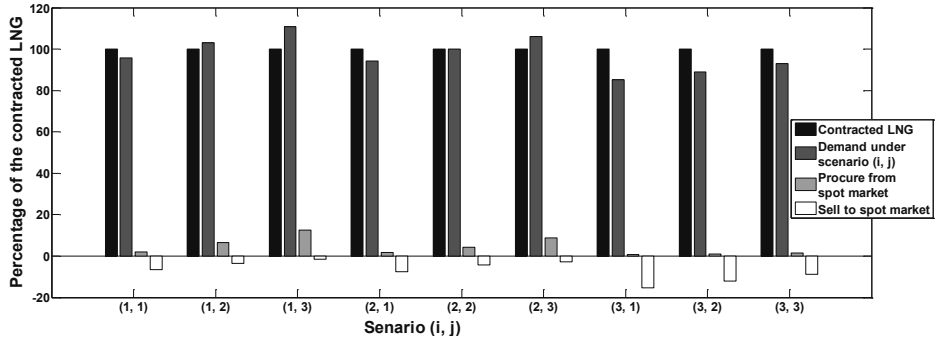

Fig. 3: Percentages of demand and spot market procumbent/sales for each scenario based on fixed contracts (taken as 100%).

5. Conclusion

In this paper, we presented a mixed integer linear programming formalism to select LNG contracts with minimum total procurement cost where the LNG demand and price are uncertain during the planning horizon. We introduced a scenario-based methodology and a 2-stage algorithm to select the here-and-now fixed contracts as first stage. The second stage involves the wait-and-see decisions. In the future if any of the stochastic demand or price scenarios happen, the company can then sell the surplus to spot market or procure if there is shortage.

Abstract

In this paper, we introduce a generalized multiperiod version of the pooling problem to represent time varying blending systems, and also propose novel approaches to solve these problems to global optimality. The primary difficulties in solving this optimization problem are the presence of bilinear terms inherent in blending operations, as well as binary decision variables required to impose the operational constraints over multiple time periods. A general nonconvex MINLP formulation is presented that is used to globally optimize small systems, but quickly becomes intractable as problem size increases. A novel approximation of specified precision for the nonconvex bilinear terms is developed (a radix-based discretization scheme), with which the problem can be reformulated as an MILP. Solving this new formulation requires much less computational time than when the MINLP model is solved directly with a global optimization solver such as BARON. This then allows for the global optimization of larger blending systems. A comparison of the two formulations is presented, along with detailed computational results of each approach.

Keywords: global optimization, pooling problem, MINLP, discretization, radix-based

1. Introduction

The efficient blending of liquid fuels to meet both technical and environmental specifications has been a growing research area in recent years as stricter regulations and smaller profit margins drive the need for the globally optimal blending scheme (Misener & Floudas, 2009). Specifically in refineries, the blending of different distilled fractions to meet specifications - without waste - is of great importance. Research up to this point has focused on what has become known as the pooling problem, posed by Haverly in 1978. In short, the problem is as follows: Multiple liquid streams with various properties (called qualities) are fed from supply tanks into blending tanks where they are assumed to be perfectly mixed in some proportion to meet a set of specifications, and are then fed into demand tanks. The goal is then to select the flows that minimize the overall cost of the blending process. The traditional pooling problem is assumed to operate at steady state, and thus inventory and other dynamics are neglected. In practice, however, supply and demand vary with time, and therefore the inventory in each tank varies as well. This gives rise to a multiperiod blending problem, which has received very little attention in the literature. Therefore, unlike the pooling

problem, the supply and demand flows in the multiperiod problem are specified as a function of time. Additionally, mass balances over each blending tank must allow for accumulation in the form of inventories, as flow into a tank need not equal the flow leaving the tank. Lastly, a special operational constraint is imposed: flow cannot both enter and exit a blending tank in the same time period. This avoids the dynamic change of concentration associated with filling and draining a tank at the same time. The multiperiod blending problem allows for a more accurate modeling of a blending system that varies over time, as is the case in gasoline and crude oil blending in refineries.

2. Multiperiod Blending Problem

2.1 Problem Description

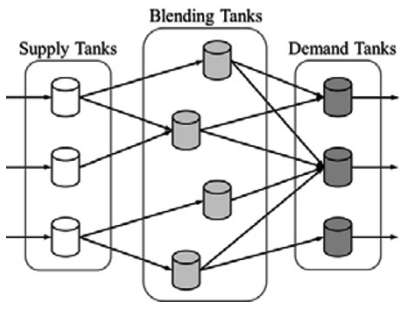

Figure 1: The pooling problem

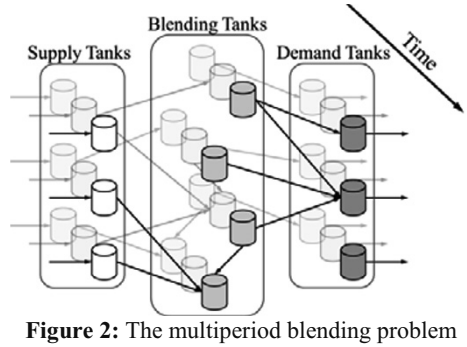

Figure 2: The multiperiod blending problem

The multiperiod blending problem can be stated as follows. A network of supply, blending, and demand tanks is given that operates over a time horizon defined by a set of time periods. At time $t = 0$, an initial inventory is specified for each tank, as well as initial values for the qualities. Given the specified network topology, the optimal flows between the tanks in each time period must be determined, as well as the corresponding inventory levels, which are carried over from one period to another. It is important to note that each time period is not independent of the others due to the coupling created by the inventories. For example, flow may be diverted to a tank for temporary storage to be used in a later period, or there may be no direct path from a source tank to a demand tank. Thus, the optimization must be performed simultaneously over all time periods.

In detailed terms, incoming supply flows ($F_{s,t}$) enter supply tanks each time period, and demand flows ($F_{d,t}$) are withdrawn from the demand tanks each time period. The supply flows to a given tank are assumed for simplicity to have the same composition over all time ($C_{q,s}$) but can vary in amount (hence the subscript t in $F_{s,t}$). Likewise, the concentration of flows leaving the demand tanks must be within specified bounds ($C^L_{q,d}$ and $C^U_{q,d}$), but the flows can also vary in amount (hence the subscript t in $F_{d,t}$). Bounds on inventories are also given for each tank (I^L_n and I^U_n) and for each flow between each tank ($F^L_{n\to n'}$, usually zero, and $F^U_{n\to n'}$). Lastly, costs for the supply flows (β_s), demand flows (β_d), and fixed and variable costs for flows within the network (α and β, respectively) are taken into account with the goal of maximizing the profit (or minimizing the costs) of the multiperiod network operation to most efficiently mix the fuels to meet demand specifications. Because of the operational constraint that flow cannot both enter and exit a blending tank in the same time period, as well as to represent the fixed costs, binary decision variables $y_{n\to n',t}$ must be introduced into the

problem such that $y_{n\to n',t}$ =1 when any flow exists between tank n and tank n' in time period t, and $y_{n\to n',t}$ = 0 otherwise.

2.2 MINLP Formulation

Given a network topology and all associated values described above, the schedule for blending the fuels is sought that maximizes total profit. As stated earlier, the multiperiod blending problem naturally involves binary variables $y_{n\to n',t}$ for all the streams in each time period, and bilinearities for the mass balance constraints involving mixing. This leads to the following nonconvex mixed-integer nonlinear programming (MINLP) model:

$$Max \sum_{t\in T}\left[\sum_{b\in B}\sum_{d\in D}\beta_d F_{b\to d,t} - \sum_{s\in S}\sum_{b\in B}\beta_s F_{s\to b,t} - \sum_{n\in N}\sum_{n'\in N}\left(\alpha_{n\to n'}y_{n\to n',t}+\beta_{n\to n'}F_{n\to n',t}\right)\right] \quad (1)$$

Subject To:

$$F_{n\to n',t} \le F^U_{n\to n'}y_{n\to n',t} \qquad \forall n,n'\in N; t\in T \quad (2a)$$

$$F_{n\to n',t} \ge F^L_{n\to n'}y_{n\to n',t} \qquad \forall n,n'\in N; t\in T \quad (2b)$$

$$C_{q,b,t} \le C^U_{q,d} + M(1-y_{b\to d,t-1}) \qquad \forall q\in Q; d\in D; t\in T \quad (3a)$$

$$C_{q,b,t} \ge C^L_{q,d} + M(1-y_{b\to d,t-1}) \qquad \forall q\in Q; d\in D; t\in T \quad (3b)$$

$$C_{q,b,t} \le C^U_{q,d} + M(1-y_{s\to d,t-1}) \qquad \forall q\in Q; s\in S; t\in T \quad (3c)$$

$$C_{q,b,t} \ge C^L_{q,d} + M(1-y_{s\to d,t-1}) \qquad \forall q\in Q; s\in S; t\in T \quad (3d)$$

$$I_{s,t} = I_{s,t-1} + F_{s,t} - \sum_{n\in N}F_{s\to n,t} \qquad \forall s\in S; t\in T \quad (4a)$$

$$I_{b,t} = I_{b,t-1} + \sum_{n\in N}F_{n\to b,t} - \sum_{n\in N}F_{b\to n,t} \qquad \forall b\in B; t\in T \quad (4b)$$

$$I_{d,t} = I_{d,t-1} + \sum_{n\in N}F_{n\to d,t} - F_{d,t} \qquad \forall d\in D; t\in T \quad (4c)$$

$$I_{b,t}C_{q,b,t} = I_{b,t-1}C_{q,b,t-1} + \sum_{s\in S}F_{s\to b,t}C_{q,s} + \sum_{b'\in B}F_{b'\to b,t}C_{q,b',t-1} - \sum_{n\in N}F_{b\to n,t}C_{q,b,t-1} \qquad \forall q\in Q; b\in B; t\in T \quad (5)$$

$$y_{n\to b,t} + y_{b\to n',t} \le 1 \qquad \forall b\in B; n,n'\in N \quad (6)$$

$$I^L_n \le I_{n,t} \le I^U_n \qquad \forall n\in N; t\in T$$

$$y_{n\to n',t}\in\{0,1\} \qquad \forall n,n'\in N; t\in T$$

$$F_{n\to n',t}\ge 0; \quad I_{n,t}\ge 0; \quad 0\le C_{q,b,t}\le 1 \qquad \forall b\in B; n,n'\in N; t\in T; q\in Q$$

To solve the multiperiod blending problem, the MINLP formulation must be solved to global optimality due to the bilinear constraints in (5).

3. Radix-based Discretization

Because the primary difficulty is the presence of bilinear terms and the difficulty in obtaining feasible solutions with MINLP algorithms, we propose an approximation for the bilinear term u = F·C by introducing a novel radix-based discretization (RBD) of C. This approach was proposed in the solution of water network problems by Teles, Castro, & Matos (2012). The approximation constraints, which can be derived using disjunctive programming and exact linearizations, replace the bilinear terms F·C in equation 5 of the MINLP formulation (I·C is treated similarly)This set of constraints essentially represents C as a discrete value based on a given radix (in this case 10) to arbitrary precision (determined by p, the smallest power of 10 allowed, and P, the

largest power of 10 allowed). Other radices (or bases) can also be used. The accuracy of the solution depends on the precision of this approximation.

$$u = \sum_{k=p}^{P} \sum_{j=0}^{9} 10^k \cdot j \cdot \hat{F}_{j,k} \tag{7}$$

$$C = \sum_{k=p}^{P} \sum_{j=0}^{9} 10^k \cdot j \cdot z_{j,k} \tag{8}$$

$$\hat{F}_{j,k} \leq F^U \cdot z_{j,k} \qquad \forall k \in \{p, \dots, P\}, j \in \{0, \dots, 9\} \tag{9}$$

$$\sum_{j=0}^{9} \hat{F}_{j,k} = F \qquad \forall k \in \{p, \dots, P\} \tag{10}$$

$$\sum_{j=0}^{9} z_{j,k} = 1 \qquad \forall k \in \{p, \dots, P\} \tag{11}$$

$$z_{j,k} \in \{0,1\}; \quad \hat{F}_{j,k} \geq 0 \qquad \forall k \in \{p, \dots, P\}, j \in \{0, \dots, 9\}$$

However, a global or near global solution can be found by fixing the binary variables to the values found by the approximation and resolving the problem with a global or local NLP solver. Also, we should note that to ensure feasible solutions, the tolerances for the satisfaction of constraints need to be adjusted accordingly.

While the proposed reformulation introduces significantly more constraints and variables, it changes the class of the problem from an MINLP to a mixed-integer linear programming problem (MILP). This class of optimization problem can generally be solved more efficiently, especially using highly refined commercial solvers such as IBM ILOG's CPLEX Optimizer (Int, 2009) and Gurobi Optimization's Gurobi Optimizer (Gur, 2011). These solvers can also take advantage of multiple computing threads, a further advantage over current MINLP solvers. It should also be noted that to avoid numerical instability, the range of powers ($P - p$) should be minimized, and robust LP solvers should be used to solve the relaxed LPs in the MILP solver.

4. Computational Results

The nonconvex MINLP model was implemented in the modeling language GAMS (Brook et al, 1988) and solved using BARON 9.3.1 (Sahinidis, 1996) to guarantee a global optimum. For comparison, the discretized MILP formulation was also implemented in GAMS and solved using Gurobi 4.5.1. Using this new radix-based discretization approach at a discretization of p = -3 and P = 0 (10^{-3} to 10^{0}), we can solve previously intractable problems (requiring BARON more than 6 hours of computational time to close the optimality gap to 0.1%) in minutes. The results of this approach and the MINLP formulation solved by BARON are shown in Table 1. All computations were performed on an Intel Core i7 processor at 2.93GHz. The Gurobi results used eight threads simultaneously, while BARON could only utilize one thread.For an 8 tank, 3 time period problem with 2 qualities selected from the test problems, the optimal schedule is shown in Figure 3 and detailed results in Table 2.

Table 1: Computational results of MINLP (BARON) and MILP (Gurobi) formulations for five test multiperiod blending problems

Tanks	6	8	8	8	8
Time Periods	3	3	3	4	4
MINLP CPU Time (s)	17.7	*>21600.0*	*>21600.0*	*>21600.0*	*>21600.0*
RBD CPU Time (s)	3.0	663.6	389.7	845.9	409.7
CPU Time Speedup	5.9x	>32.5x	>55.4x	>25.5x	>52.7x

Table 2: Computational results for 8 tank, 3 time period, 2 quality problem

	CPU Time (s)	Objective	Constraints	Cont. Vars.	Bin. Vars.
MINLP	>21600.0	*13.4517	628	136	87
RBD (MILP)	389.7	13.5268	7092	4632	855
NLP Post-Solve	0.2	13.5268	447	327	0

*Best lower bound

While the discretization approach greatly increases the problem size, the time required to solve the problem is decreased significantly. Additionally, after solving the discretized MILP, the binary variables present in the original problem were fixed and the problem was solved again with BARON acting as an NLP solver (see Table 2).

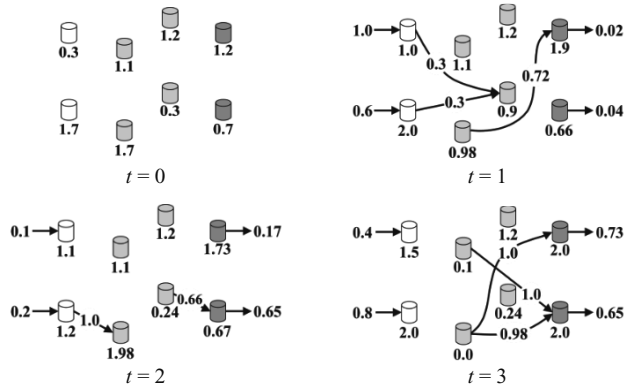

Figure 3: Optimal solution for 8 tank, 3 time period, 2 quality problem

5. Conclusion

We have addressed in this paper the multiperiod blending problem for which a nonconvex MINLP formulation was proposed. It was shown that the radix-based discretization approach has allowed the solution of larger multiperiod blending problems, with up to 8 tanks and 4 time periods, in a significantly shorter amount of time. However, as problem size increases, the discretized approach may become intractable. Thus, for future investigation, decomposition approaches will likely be required for the solution of very large systems.

Finding an optimized set of transformations for convexifying nonconvex MINLP problems

Andreas Lundell* Tapio Westerlund
Center of Excellence in Optimization and Systems Engineering
Åbo Akademi University, Turku, Finland

Abstract

In this paper we describe a method for obtaining sets of transformations for reformulating a mixed integer nonlinear programming (MINLP) problem containing nonconvex twice-differentiable (C^2) functions to a convex MINLP problem in an extended variable space. The method for obtaining the transformations is based on solving a mixed integer linear programming (MILP) problem given the structure of the nonconvex MINLP problem. The solution of the MILP problem renders a minimal set of transformations convexifying the nonconvex problem. This technique is implemented as an part of the α signomial global optimization algorithm (αSGO), a global optimization algorithm for nonconvex MINLP problems.

Keywords: global optimization, nonconvex MINLP problems, reformulation techniques, signomial functions

1. Introduction to the αSGO-algorithm

The αSGO-algorithm is a global optimization method for nonconvex MINLP problems (Lundell et al., 2012). An αBB-type underestimator is used for nonconvex C^2-functions. In the αBB-underestimator a quadratic function $\alpha(x-\overline{x})(x-\underline{x})$, where α is large enough to guarantee convexity, is added to a nonconvex function resulting in a convex underestimator on the interval $[\underline{x},\overline{x}]$ (Floudas, 2000). In the αSGO-algorithm, instead of using a branching tree for dividing the nonconvex problem into convex subproblems, a reformulation technique based on different transformation schemes is utilized for signomial functions and an αBB-type reformulation for C^2-functions. The reformulations convexify the problem and overestimates its feasible region in an extended variable-space. The solutions to the subproblems form a converging sequence towards the global optimum when the overestimations are iteratively reduced. However, a certain amount of freedom exists in how to choose the transformations. For signomial terms, different types of transformation schemes (for positive terms: the positive power transformation (PPT), exponential transformation (ET) and mixed power and exponential transformation (MPET); for negative terms: the power transformation (PT)) can be applied term-wise (Lundell et al., 2009) in addition to the αBB-reformulation (αR). Depending on what combinations of transformations are chosen, the number of discrete and continuous variables needed in the reformulations may vary, leading to reformulated problems of different complexities. Therefore, a method for automatically obtaining an optimized set of these transformations is described in this paper. It is based on solving a MILP problem, where the parameters of the problem are specified by the nonconvex signomial terms and C^2-functions in the MINLP problem. The method was previously described in, *e.g.,* Lundell and Westerlund

*andreas.lundell@abo.fi

(2009b) for the predecessor of the αSGO-algorithm, *i.e.,* the SGO-algorithm. Here, the method is extended to allow for nonconvex C^2-functions, as well as some modifications to the transformations available for nonconvex signomial functions.

2. The optimization method for transformations

In the MILP formulation, the following sets are used for the terms and functions: J_{S_+} and J_{S_-} are the set of nonconvex positive and negative signomial terms respectively, and J_{S} is the union of these two sets, *i.e.,* all nonconvex signomial terms; J_{G} is the set of nonconvex C^2-functions (excluding the signomials); J is the union of J_{S} and J_{G}. The set I correspond to all variables in the problem and I_j, $j \in J$, is the set of variables in the j-th signomial term or nonconvex function. The set K is all nonconvex constraints in the problem. Also, some binary variables are needed: B_i indicate if the variable x_i is transformed in the problem or not and B_i^{P}, B_i^{E}, B_{ki}^{α} what type of transformation is used; ${b_{ji}}^{\mathrm{P}}$, ${b_{ji}}^{\mathrm{E}}$ and ${b_{ji}}^{\alpha}$ indicate whether a power transformation $x = X^Q$, exponential transformation $x = \exp(X)$ or αR have been applied to the i-th variable in the j-th term or function; β_j^{PPT}, β_j^{MPET} and $\beta_j^{\alpha R}$ indicate which transformation is applied to the j-th term or function. The integer variables N^{P}, N^{E} and N^{A} represent the total number of distinct transformations needed. The real variables Δ are transformation dependent penalties used for selecting numerically better transformations. The powers Q in the power transformations are in the interval $[Q_{\min}, Q_{\varepsilon}]$ if negative and in the interval $[Q_{\varepsilon}, Q_{\max}]$ if positive. Finally, the power of the variable x_i in the j-th signomial term p_{ji} is a given parameter and can be any real value.

To find an optimized set of transformations convexifying the problem at hand while keeping the reformulated problem as simple as possible, the objective function will be

$$\begin{aligned}\text{minimize} \quad & \delta_B \sum_{i\in I} B_i + \delta_I \left(N^{\mathrm{P}} + N^{\mathrm{E}} + N^{\alpha}\right) + \delta_N \sum_{j\in J_{S_+},\, i\in I} \left({b_{ji}}^{\mathrm{P}} + {b_{ji}}^{\mathrm{E}} + {b_{ji}}^{\alpha}\right) \\ & + \delta_N \sum_{j\in J_{S_-}, i\in I} \left({b_{ji}}^{\mathrm{P}} + {b_{ji}}^{\alpha}\right) + \delta_\Delta \sum_{j\in J_{S_+}} \left(\Delta_j^{\mathrm{PPT}} + \Delta_j^{\mathrm{MPET}} + \Delta_j^{\alpha R}\right) + \delta_\Delta \sum_{j\in J_{S_-}} \left(\Delta_j^{\mathrm{PT}} + \Delta_j^{\alpha R}\right). \end{aligned} \tag{1}$$

The strategy parameters δ in the objective function are δ_B, δ_I, δ_N and δ_Δ and these are normally selected such that $\delta_B \gg \delta_I \gg \delta_N \gg \delta_\Delta$. To guarantee a convex reformulation, the constraints (2–22) are also included in the MILP problem.

Only one transformation is allowed per signomial term, so therefore

$$\forall j \in J_{S_+}: \quad \beta_j^{\mathrm{PPT}} + \beta_j^{\mathrm{MPET}} + \beta_j^{\alpha R} = 1 \qquad \text{and} \qquad \forall j \in J_{S_-}: \quad \beta_j^{\mathrm{PT}} + \beta_j^{\alpha R} = 1. \tag{2}$$

The following expressions are used to determine whether the i-th variable is transformed using a power or exponential transformation in some constraint

$$\forall i \in I: \quad B_i^{\mathrm{P}} \geq \tfrac{1}{\mathrm{card} J_{\mathrm{S}}} \textstyle\sum_{j\in J_{\mathrm{S}}} {b_{ji}}^{\mathrm{P}} \quad \text{and} \quad \forall i \in I: \quad B_i^{\mathrm{E}} \geq \tfrac{1}{\mathrm{card} J_{S_+}} \textstyle\sum_{j\in J_{S_+}} {b_{ji}}^{\mathrm{E}}. \tag{3}$$

For the αR, it is necessary to determine this per constraint, since a different transformation variable is needed for each constraint

$$\forall i \in I, k \in K: \quad B_{ki}^{\alpha} \geq \tfrac{1}{\mathrm{card} J_k} \textstyle\sum_{j\in J_k} {b_{ji}}^{\alpha}. \tag{4}$$

The binary variables corresponding to whether a variable is transformed at all in the problem is determined through the following constraint

$$\forall i \in I: \quad B_i \geq \tfrac{1}{\mathrm{card} J} \Big(\sum_{j\in J_{\mathrm{S}}} {b_{ji}}^{\mathrm{P}} + \sum_{j\in J_{S_+}} {b_{ji}}^{\mathrm{E}} + \sum_{j\in J} {b_{ji}}^{\alpha} \Big). \tag{5}$$

Since a transformation variable is needed for each power transformation with different powers Q for each variable, the binary variables $\gamma_{j_1 j_2 i}$, indicating whether the transformations of the i-th variable in the j_1-st and j_2-nd terms are different, are needed

$$\forall j_1, j_2 \in J_S, j_1 \neq j_2, i \in I_j: \quad \begin{cases} \gamma_{j_1 j_2 i} \geq \frac{1}{Q_{\max}+Q_{\min}} (Q_{j_1,i} - Q_{j_2 i}) - (2 - b^{\mathrm{P}}_{j_1 i} - b^{\mathrm{P}}_{j_2 i}) \\ \gamma_{j_1 j_2 i} = \gamma_{j_2 j_1 i}. \end{cases} \tag{6}$$

The integer variables N^{P}, N^{E} and N^{α} are used to count the number of transformation variables in the reformulated problem

$$N^{\mathrm{P}} = \sum_{i \in I_j} B^{\mathrm{P}}_i + \tfrac{1}{2} \sum_{j_1, j_2 \in J_S, j_1 \neq j_2,\ i \in I_j} \gamma_{j_1 j_2 i},\ N^{\mathrm{E}} = \sum_{i \in I_j} B^{\mathrm{E}}_i, \text{ and } N^{\alpha} = \sum_{k \in K,\ i \in I_j} B^{\alpha}_{ki}. \tag{7}$$

For C^2-functions, the αR is always used for nonconvex functions (*i.e.,* with an $\alpha \geq 0$), so

$$\forall j \in J_G, i \in I_j: \alpha_{ji} > 0: {b_{ji}}^{\alpha} = 1, \beta^{\alpha R}_j = 1, \text{ and } \forall j \in J_G, i \in I_j: \alpha_{ji} = 0:\ {b_{ji}}^{\alpha} = 0. \tag{8}$$

The αR may be used for signomial terms, and in this case it should be used on all variables with positive α-values in the term.

$$\forall j \in J_S, i \in I_j: \alpha_{ji} > 0:\ {b_{ji}}^{\alpha} = \beta^{\alpha R}_j, \quad \text{and} \quad \forall j \in J_S, i \in I_j: \alpha_{ji} = 0:\ {b_{ji}}^{\alpha} = 0. \tag{9}$$

The constraints in Eqs. (10–12) should be applied to all negative signomial terms, *i.e.,* $j \in J_{S_-}$. For variables with a negative power in negative terms, the transformation power Q should be larger than $-Q_{\min}$ (which is already given by the bounds of the variable Q) and less than the parameter value $-Q_{\varepsilon}$ if the PT is used. Also, the PT should be applied to all variables in the term if used on one variable:

$$\forall j \in J_{S_-}, i \in I_j: p_{ji} < 0: \quad Q_{ji} \leq -Q_{\varepsilon} \beta^{\mathrm{PT}}_j + Q_{\max}(1 - \beta^{\mathrm{PT}}_j) \quad \text{and} \quad {b_{ji}}^{\mathrm{P}} = \beta^{\mathrm{PT}}_j. \tag{10}$$

For variables with positive powers, the transformation power should be between $Q_{\min}$ and one if the PT is used on the term. However, not all variables need always to be transformed since if $Q = 1$ no transformation occurs and then b^{P} can be zero:

$$\forall j \in J_{S_-}, i \in I_j: p_{ji} > 0: \begin{cases} Q_{\varepsilon} \beta^{\mathrm{PT}}_j - Q_{\min}(1 - \beta^{\mathrm{PT}}_j) \leq Q_{ji} \leq \beta^{\mathrm{PT}}_j + Q_{\max}(1 - \beta^{\mathrm{PT}}_j) \\ \frac{1}{\max\{Q_{\max}, Q_{\min}\}} (1 - Q_{ji}) - (1 - \beta^{\mathrm{PT}}_j) \leq {b_{ji}}^{\mathrm{P}} \leq \beta^{\mathrm{PT}}_j. \end{cases} \tag{11}$$

If the PT is used, the sum of the powers should be less than or equal to one, so

$$\forall j \in J_{S_-}: \quad \sum_{i \in I_j} p_{ji} Q_{ji} \leq M + (1 - M) \beta^{\mathrm{PT}}_j, \quad \text{where} \quad M = Q_{\max} \cdot \max_i |p_{ji}|. \tag{12}$$

For the PPT, the constraints (13–15) should be applied to all positive signomial terms, *i.e.,* $j \in J_{S_+}$. Since we can choose between three transformation schemes for positive signomial terms (PPT, MPET or αR), the constraints are somewhat more complicated. If the PPT is used, the sum of the powers in the transformed term should be greater than or equal to one, otherwise the constraint should be relaxed. This can be expressed as:

$$\forall j \in J_{S_+}: \quad \sum_{i:\ p_{ji} > 0} p_{ji} Q_{ji} + \sum_{i:\ p_{ji} < 0} p_{ji} \geq 1 - M(1 - \beta^{\mathrm{PPT}}_j), \tag{13}$$

where the parameter M can be chosen as $M = Q_{\min} \cdot \sum_{i \in I_j : p_{ji} > 0} p_{ji} + \sum_{i \in I_j : p_{ji} < 0} |p_{ji}| + 1$.

No transformations are needed for the variables with negative powers when using the PPT. Since only one variable is allowed to have a positive transformation power in each term transformed using the PPT scheme, the following condition is needed

$$\forall j \in J_{S_+}: \quad \sum_{i:\ p_{ji}>0} {b_{ji}}^{+} = \beta_j^{\mathrm{PPT}}, \quad \text{where} \quad {b_{ji}}^{+} = 1 - {b_{ji}}^{-} - (1-\beta_j^{\mathrm{PPT}}). \tag{14}$$

The transformation powers when using the PPT should be between $-Q_{\min}$ and $-Q_\varepsilon$ in all except one transformation, where the power must be between one and $Q_{\max}$:

$$\forall j \in J_{S_+}, i \in I_j : p_{ji} > 0: \quad \begin{cases} Q_{ji} \geq -Q_{\min}{b_{ji}}^{-} + {b_{ji}}^{+} - (Q_{\min}+1)(1-\beta_j^{\mathrm{PPT}}) \\ Q_{ji} \leq Q_{\max}{b_{ji}}^{+} - Q_\varepsilon {b_{ji}}^{-} + (Q_{\max}+Q_\varepsilon)(1-\beta_j^{\mathrm{PPT}}) \\ {b_{ji}}^{\mathrm{P}} \geq \frac{1}{\max\{Q_{\max},Q_{\min}\}}(Q_{ji}-1) - (1-\beta_j^{\mathrm{PPT}}) \\ {b_{ji}}^{\mathrm{P}} \geq {b_{ji}}^{-} - (1-\beta_j^{\mathrm{PPT}}). \end{cases} \tag{15}$$

For the MPET, the constraints (16) and (17) are applied to all positive signomial terms, *i.e.,* $j \in J_{S_+}$. For any variable with positive power in a positive signomial term, to which the MPET is applied, either the exponential or a power transformation, with transformation powers between $-Q_{\min}$ and $-Q_\varepsilon$, should be used. This is enforced using:

$$\forall j \in J_{S_+}, i \in I_j : p_{ji} > 0: \ {b_{ji}}^{\mathrm{E}} + {b_{ji}}^{\mathrm{P}} \geq \beta_j^{\mathrm{MPET}} \text{ and } Q_{ji} \leq -Q_\varepsilon {b_{ji}}^{\mathrm{P}} + Q_{\max}(1-\beta_j^{\mathrm{MPET}}). \tag{16}$$

The following condition assure that the correct transformation is selected

$$\forall j \in J_{S_+}: \quad \beta_j^{\mathrm{PPT}} + \beta_j^{\mathrm{MPET}} \geq \tfrac{1}{\mathrm{card} I_j} \sum_{i \in I_j : p_{ji}>0} {b_{ji}}^{\mathrm{P}} + {b_{ji}}^{\mathrm{E}}. \tag{17}$$

If only the objective function (1) and the constraints (2–17) are used in the MILP formulation, the solution would not take into consideration that different types of transformations (including power transformations with different powers Q) lead to transformations with different underestimation errors. Thus, if alternate solutions exists that lead to transformed problems with the same number of additional variables used in the transformations we are also interested in finding the transformations with better numerical properties. Results regarding the tightness of the power and exponential transformations can be found in, *e.g.,* Lundell and Westerlund (2009a). For example, it has been shown that a single-variable power transformation with positive power gives a tighter underestimator than a single-variable exponential transformation applied to the same power function x^p. The same is true for the single-variable exponential transformation with respect to a single-variable power transformation with negative powers. These facts could be used to favor the PPT over the ET and the ET over the NPT. The problem is then how to penalize the αR, since no general theoretical results are known regarding the tightness of the αBB-underestimator in comparison to the signomial transformations.

The numerical penalties can be included in the MILP formulation by adding variables Δ_j^{PT}, Δ_j^{PPT}, Δ_j^{MPET}, $\Delta_j^{\alpha R}$ to the objective function (1), corresponding to a penalty if the transformation in question is applied to the i-th variable in the j-th term or function group. The exponential transformation is selected to have a numerical penalty zero, and the power transformations are penalized as follows: a transformation with a negative power $-Q_{\min} \leq Q \leq -Q_\varepsilon$ (Eqs. (18) and (22)) has a penalty which is zero at $-Q_{\min}$ and one at $-Q_\varepsilon$; a power transformation with a positive power $1 \leq Q \leq Q_{\max}$ (Eq. (20)) has a penalty of one at one and zero at $Q_{\max}$; a power transformation with a positive power

$Q_\varepsilon \leq Q \leq 1$ (Eq. (21)) has a penalty which is one at Q_ε and zero at one; the αR has a fixed penalty of one for each variable in a term, *i.e.,* $\Delta_j^{\alpha R} = 1$:

$$\forall j \in J_{S_-}, \forall i \in I_j : p_{ji} < 0 : \ \Delta_{ji}{}^{\mathrm{PT}} \geq \tfrac{1}{Q_{\min} - Q_\varepsilon} (Q_{ji} + Q_{\min}) - (1 + Q_{\min})(1 - \beta_j^{\mathrm{PT}}) \quad (18)$$

$$\forall j \in J_{S_+}, \forall i \in I_j : p_{ji} > 0 : \ \Delta_{ji}{}^{\mathrm{PT}} \geq \tfrac{1}{Q_\varepsilon - 1} (Q_{ji} - 1) - (1 - \beta_j^{\mathrm{PT}}) \quad (19)$$

$$\forall j \in J_{S_+}, \forall i \in I_j : p_{ji} > 0 : \ \Delta_{ji}{}^{\mathrm{PPT}} \geq \tfrac{1}{1 - Q_{\max}} (Q_{ji} - Q_{\max}) - b_{ji}{}^{-} - (1 - \beta_j^{\mathrm{PPT}}) \quad (20)$$

$$\forall j \in J_{S_+}, \forall i \in I_j : p_{ji} > 0 : \ \Delta_{ji}{}^{\mathrm{PPT}} \geq \tfrac{1}{Q_\varepsilon + Q_{\min}} (Q_{ji} + Q_{\min}) - b_{ji}{}^{+} - (1 - \beta_j^{\mathrm{PPT}}) \quad (21)$$

$$\forall j \in J_{S_+}, i \in I_j : p_{ji} > 0 : \ \Delta_{ji}{}^{\mathrm{MPET}} \geq \tfrac{1}{Q_\varepsilon - Q_{\min}} (Q_{ji} - Q_{\min}) - b_{ji}{}^{\mathrm{E}} - 2(1 - \beta_j^{\mathrm{MPET}}). \quad (22)$$

3. An example

If the MILP method is applied to the nonconvex function $x_1^2 x_2 - x_2^{-1} + x_2 x_3 + 5 \sin x_2 \cos x_3$ in a MINLP problem, the total number of additional transformation variables needed in the reformulated convex MINLP problem is four. Two of the variables (x_2 and x_3) are involved in transformations so in addition two binary variable or SOS2-sets are needed. If a rigid transformation scheme is used without optimizing the transformations, the worst-case scenario is instead seven transformation variables and three binary variable or SOS2-sets. As the number of variables in the binary variable sets are increased iteratively in the αSGO-algorithm, this small decrease in initial variables will have a large direct impact on the solution process and the number of iterations required in the algorithm.

4. Results and discussion

In this paper it was shown how the MILP method from Lundell and Westerlund (2009b) could be extended to handle all the transformations schemes in the αSGO-algorithm. By including also the αBB convex reformulation technique, it is possible to obtain the set of transformations for obtaining a convex reformulation of any MINLP problem containing nonconvex twice-differentiable functions.

Abstract

Global convergence and fast performance of barrier nonlinear programming (NLP) solvers are frequently challenged by linearly dependent constraints. Such constraints arise in many process optimization models, and they often preclude finding successful NLP solutions. To deal with this problem we present a structured regularization strategy for barrier methods that identifies and excludes dependent constraints in the KKT system while leaving independent constraints unchanged. As a result, more accurate Newton directions can be obtained and much faster convergence can be expected for the KKT system over the conventional regularization approach. Numerical experiments with examples derived from the CUTE and COPS test sets as well as two refinery blending problems demonstrate the effectiveness of the proposed method and significantly better performance of the NLP solver.
Keywords: Barrier NLP Methods, Dependent Constraints, KKT Regularization, Newton's Method

1. Introduction

Practical nonlinear programming (NLP) algorithms are required to solve challenging optimization problems derived from chemical engineering applications. One of the most important challenges is the presence of dependent constraints. Regardless if this dependency is local or structural, many NLP algorithms that are based on Newton's method experience convergence difficulties. When this happens, NLP iterations produce very little progress, calculation of Lagrange multipliers is ill-conditioned, and penalty parameters for the line search become very large.

Dependent constraints are not completely avoidable in nonlinear programming, as they can arise through local linearization of nonlinear constraints. Moreover, reformulation of complementarity constraints, which may be used to describe switching behavior, can lead to linearly dependent active constraint normals at any feasible point (Fletcher et al., 2006). Also, discretized dynamic problems with path constraints can violate the linear independence constraint qualification (LICQ), as the finite element mesh is refined (Kameswaran and Biegler, 2008). Finally, poor model formulations, such as redundant or inconsistent model descriptions, induce failure of the NLP solver.

It is important for a practical NLP solver to consider the case when LICQ does not hold. This problem was considered in the framework of reduced space barrier NLP methods by taking advantage of variable decompositions to detect and remove dependent constraints (Wang et al., 2011). Here we consider a related approach for full space barrier methods, where decomposition is avoided in order to maintain sparsity. Instead, we develop a new, structured regularization method that implicitly detects and handles constraint dependency in the KKT system and leads to fast performance.

2. Barrier Method Background

Consider the NLP problem of the form

$$\min_{x\in R^n} f(x) \quad s.t.\ c(x)=0,\ x\geq 0 \tag{1}$$

where the objective function and equality constraints, $f(x): R^n \to R$ and $c(x): R^n \to R^m$ with $m \leq n$, are assumed to be twice continuously differentiable. We use the simpler form (1) for more efficient derivation, although our approach is directly applicable to double bounded problems as well. The primal-dual interior point method solves problem (1) through a sequence of barrier problems (Wächter and Biegler, 2006):

$$\min_{x\in R^n} \phi_\mu(x) = f(x) - \mu\sum_{i=1}^{n} \ln x^{(i)}, \quad s.t.\ c(x)=0 \tag{2}$$

with decreasing values of barrier parameter $\mu > 0$. Problem (2) is solved through the primal-dual equations

$$\begin{aligned} \nabla f(x) + A\lambda - v &= 0 \\ c(x) &= 0 \\ XVe - \mu e &= 0 \end{aligned} \tag{3}$$

where $A = \nabla c(x)$, $\lambda \in R^m$ is the vector of Lagrange multipliers for the equality constraints, the dual variable is $v = \mu X^{-1} e$, X and V are diagonal matrices generated from vectors x and v respectively and $e^T = [1,...,1]$. Note when $\mu = 0$ and $x, v \geq 0$, the equations (3) are the first order KKT conditions of problem (1). The Newton step to solve (3) at iteration k is calculated from the simplified linear system:

$$\begin{bmatrix} \nabla^2_{xx} L_k + \Sigma_k & A_k \\ A_k^T & 0 \end{bmatrix} \begin{pmatrix} d_k^x \\ \lambda_{k+1} \end{pmatrix} = -\begin{pmatrix} \nabla \varphi_\mu(x_k) \\ c(x_k) \end{pmatrix}. \tag{4}$$

where $\nabla^2_{xx} L_k$ is the Hessian of Lagrange function $L(x,\lambda,v) = f(x) + c(x)^T\lambda - v$, $\Sigma_k = X_k^{-1} V_k$ is a barrier term added to the Hessian, and the search direction for v is obtained from $d_k^v = \mu X_k^{-1} e - v_k - \Sigma_k d_k^x$. When Jacobian A_k^T is not full rank, the KKT matrix in (4) is singular and Newton step cannot be taken. A popular regularization approach for barrier solvers, e.g., IPOPT, is to modify the KKT matrix as:

$$\begin{bmatrix} \nabla^2_{xx} L_k + \Sigma_k + \delta_H I & A_k \\ A_k^T & -\delta_c I \end{bmatrix}. \tag{5}$$

where $\delta_H > 0$ is adjusted and $\delta_c > 0$ is a small constant. In particular, the latter correction handles rank deficient Jacobians in (5), but may greatly distort the Newton step, and can lead to much slower convergence, especially for large-scale problems.

3. Constraint regularization and inertia correction

3.1. Structured constraint regularization method

We omit subscript k in (4) and (5) and partition A to $[A_I \mid A_D]$ with dependent columns in A_D. These columns can be found through an LU factorization of A^T, i.e.

$$LA^T = \begin{bmatrix} U_1 & U_2 \\ 0 & 0 \end{bmatrix}. \tag{6}$$

Through multiplying (4) with matrix $diag(I, L)$ and defining $\lambda = L^T[\lambda_I^T \quad \lambda_D^T]^T$ and $Lc = [(Lc)_I^T \quad (Lc)_D^T]^T$, we can obtain a linear system equivalent to (4) but with its

constraint related parts organized according to their dependency. To solve the resulting system we add a regularization term corresponding to the dependent constraints to get:

$$\begin{bmatrix} \nabla^2_{xx}L+\Sigma & \begin{bmatrix} U_1^T & 0 \\ U_2^T & 0 \end{bmatrix} \\ \begin{bmatrix} U_1 & U_2 \\ 0 & 0 \end{bmatrix} & \begin{bmatrix} 0 & 0 \\ 0 & -\delta_D I \end{bmatrix} \end{bmatrix} \begin{pmatrix} d^x \\ \lambda_I \\ \lambda_D \end{pmatrix} = -\begin{pmatrix} \nabla\varphi_\mu \\ (Lc)_I \\ (Lc)_D \end{pmatrix}. \tag{7}$$

which leads to $-\delta_D\lambda_D + (Lc)_D = 0$. By choosing δ_D very large relative to $(Lc)_D$, this leads to negligible values for λ_D, which has the same effect as solving (7) with its last equation removed. Moreover, this is equivalent to

$$\begin{bmatrix} \nabla^2_{xx}L+\Sigma & A_I \\ A_I^T & 0 \end{bmatrix} \begin{pmatrix} d^x \\ \bar{\lambda} \end{pmatrix} = -\begin{pmatrix} \nabla\varphi_\mu \\ c_I \end{pmatrix} \tag{8}$$

where $\bar{\lambda} = L^{-T}\lambda_I$, and the factorization in (6) is not needed. Therefore, the regularization in (7) promotes progress toward feasibility of the independent constraints without distorting their Newton directions, but removes the dependent constraints from the current iteration. This approach works well if the dependent constraints are consistent at the optimum solution. On the other hand, inconsistent constraints are eliminated, though they remain infeasible at convergence and can be presented to the user for correction. The inconsistent case has also been discussed in Fletcher et al. (2002) and Gill et al. (2005).

3.2. Inertia correction

In addition to the structured regularization in (7), the Hessian may also need to be regularized to guarantee a descent direction and maintain positive curvature in constrained directions. Therefore, system (4) is modified to

$$\begin{bmatrix} \nabla^2_{xx}L+\Sigma+\delta_H I & A \\ A^T & -M \end{bmatrix} \begin{pmatrix} d^x \\ \lambda \end{pmatrix} = -\begin{pmatrix} \nabla\varphi_\mu \\ c \end{pmatrix} \tag{9}$$

where $\delta_H > 0$ and M is a diagonal matrix with δ_D on the columns corresponding to dependent columns of A. Both regularization terms are important for global convergence of barrier NLP algorithms. Moreover, appropriate corrections δ_H and δ_D are found when the KKT matrix in (9) has an inertia (*n, m, 0*) with *n* positive, *m* negative, and no zero eigenvalues. As modified from Wächter and Biegler (2006), the following algorithm achieves the correct inertia for (9).

Inertia Correction Logic:

Set initial values for $M := 0, \delta_{\min} > 0, \delta_H := 0, \kappa_\delta < 1$, and $\delta_H^{last} := 0$.

1. Factorize the KKT matrix in (9):
- If its inertia is $(n, m, 0)$, save the current value of regularization parameter $\delta_H^{last} \leftarrow \delta_H$ provided that $\delta_H > 0$. Continue to solve linear system (9).
- Otherwise go to step 2.
2. If the factorization has fewer than *m* negative eigenvalues or is singular, correct the lower-right corner of the KKT matrix in (9) as follows:
- Corresponding to each dependent column of A, add a large element $-\delta_D$ (say, $\delta_D = 10^{30}$) to the diagonal of M and go to step 1.
3. Determine the value of δ_H:
- If $\delta_H = 0$ and $\delta_H^{last} = 0$, set δ_H to an initial tentative value; go to step 1.

- If $\delta_H = 0$ and $\delta_H^{last} > 0$, set δ_H to $\min\{\delta_{\min}, \kappa_\delta \delta_H^{last}\}$, where $\kappa_\delta < 1$; go to step 1.
- Otherwise increase the value of δ_H. If δ_H is too large, inertia correction fails and turn to the feasibility restoration phase; otherwise go to step 1.

In this last step, the feasibility restoration phase (Fletcher et al., 2002) is designed for filter methods, as in IPOPT, to reduced infeasibility and promote successful steps.

4. Numerical results

We implemented the structured regularization strategy within the FORTRAN version of full-space IPOPT (Wächter and Biegler, 2006), and we use the MUMPS sparse solver (Amestoy et al., 2001) for the linear system (9). Also, the filter line search option in IPOPT is selected for global convergence. We demonstrate this approach on 47 examples derived from CUTE and COPS test sets as well as two large-scale refinery blending examples. These examples were designed with dependent constraints and present difficulties for current NLP solvers.

4.1. Examples from CUTE and COPS test sets

We first consider the 47 test examples from the CUTE and COPS test set, which were used with reduced-space IPOPT in our previous work (Wang et al., 2011). Curtis et al. (2009) modified these examples by making the first equality constraint $c_1(x) = 0$ dependent with an additional constraint $c_1(x) - c_1^2(x) = 0$ (consistent case) or $c_1(x) - c_1^2(x) = 1$ (inconsistent case).

We compare both regularizations (5) and (9) for these cases. First, all inconsistent examples are expected to converge to stationary points that minimize infeasibility. For the inconsistent case, both regularizations behave similarly because feasibility restoration is eventually triggered and this step dominates the calculation.

On the other hand, for the examples with consistent constraints, we see a significant improvement with the structured regularization. Using the default options in IPOPT, the conventional regularization (5) solves only 29 out of 47 problems. Failures usually occur at infeasible points with no improvement possible. The new, structured regularization solves 45% more problems and fails on only five problems. These failures occur at points of minimum infeasibility in the restoration step. Performance profiles (Dolan and Moré, 2001) are shown in Figure 1, and indicate that the structured regularization strategy is much more efficient than its conventional counterpart.

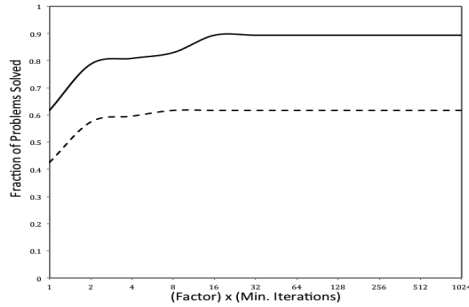

Figure 1. Performance plot for examples with consistent dependent constraints using Structured (solid line) vs. Conventional Regularization (dashed line). The plot (*fraction vs. factor*) shows the *fraction* of problems solved within a *factor* of minimum number of iterations for each example.

4.2. Refinery blending examples

The original refinery blending models have many nonconvex terms and several complementarity constraints. Reformulation of these constraints leads to linearly

dependent constraints, which were detected during solution. IPOPT with conventional regularization solves neither problem under default options. On the other hand, with the structured regularization and default options, IPOPT easily solves both examples. Problem characteristics and numerical results are presented in Table 1. In particular, #depcon represents the largest number of dependent constraints encountered by MUMPS at a given iteration; #iter is the number of iterations taken to solve the problem. It is clear that structured regularization leads to more efficient convergence for IPOPT.

Table 1. Numerical results for two refinery blending examples

	#var	#con	#depcon	conventional	structured
Blend1	833	772	5	failed with singular matrix	optimum found #iter = 75
Blend2	5176	4702	83	failed with ≥ 3000 iter.	optimum found #iter = 399

5. Conclusions

We present a new, structured regularization method to improve convergence of NLP algorithms when dependent constraints are present. Different from the conventional regularization method, which distorts Newton iterations, the structured regularization excludes dependent constraints from the current iteration. We incorporate this strategy into the inertia correction of KKT matrix and implement it within the solver IPOPT. Numerical results on degenerate examples indicate that the structured regularization method is more efficient than its conventional counterpart in handling dependent constraints, and shows significantly better performance within IPOPT.

Abstract

We consider the problem of estimating transmission parameters in a model of childhood disease transmission. We show the structural equivalence between parameter estimation and two-stage stochastic programming, and use the Progressive Hedging decomposition strategy to efficiently compute parameter values on large-scale, real-world observations.

Keywords: Parameter estimation, Stochastic programming, Progressive Hedging.

1. Introduction

Nonlinear programming continues to be an effective tool for parameter estimation in models of chemical engineering processes. The size of these estimation problems can become computationally prohibitive when rigorous dynamic models and many observations are considered, outstripping desktop computing capabilities. As well, we are no longer seeing continued increases in CPU clock speed. Computer chip manufacturers are focusing instead on the development of hyper-threaded and multi-core architectures to provide performance improvements via parallelism (Schenk et al., 2009). Given this paradigm shift in computer architecture, continued performance improvements on challenging nonlinear programming problems demands that we develop algorithms that can effectively utilize parallel computing architectures.

Classical parameter estimation problems are structurally equivalent to two-stage stochastic programming problems. There is a suite of decomposition strategies for solving stochastic programming problems and, in this paper, we make use of the Progressive Hedging algorithm to provide a parallel solution strategy for a large-scale dynamic parameter estimation problem. A general form of a parameter estimation problem can be written as follows:

$$\begin{aligned} \min \quad & \textstyle\sum_{s\in S} P_s f(w_s, \varepsilon_s) \\ \text{s.t.} \quad & g(x_s, y_s, w_s, \theta) = 0 \quad \forall\, s \in S, \\ & h(y_s, y_s^*, \varepsilon_s) = 0 \quad \forall\, s \in S. \end{aligned} \tag{1}$$

Here, S denotes the set of all observations. The vectors x_s are unmeasured state variables, the y_s correspond to model outputs (measured variables), and the w_s represent unknown model noise. Model parameters are denoted by θ and are to be estimated by fitting the model outputs y_s to the known measurements y_s^*. The constraints g represent the system model, and h defines the measurement errors between the calculated and

measured outputs. In the objective, P_s, where $\sum_{s\in S} P_s = 1$, is a weight for each observation, and $f(w_s,\varepsilon_s)$ represents some goodness-of-fit function given the estimated model and measurement noise.

A general formulation for the extensive form (also known as the deterministic equivalent) of a two-stage stochastic programming problem is given as follows:

$$\begin{aligned} &\min \quad \sum_{s\in S} P_s f(v_s, u_s) \\ &\text{s.t.} \quad q(v_s, u_s) = 0, \qquad u_s = \bar{u}\,, \qquad \forall\, s \in S. \end{aligned} \tag{2}$$

Here, the goal is to determine optimal values for the first-stage variables (given by $\bar{u}$) while considering uncertainty through a number of possible realizations in S. The variables v_s represent second-stage, scenario-specific decision vectors (also called recourse variables). The objective function usually computes an expected value across all possible scenarios, where P_s is the probability associated with a particular scenario.

The parameter estimation problem in Eq. (1) is structurally equivalent to the two-stage stochastic programming problem given in Eq. (2). The parameters θ are equivalent to first-stage variables, while the remaining variables can be considered second-stage variables. In parameter estimation, the goal is to determine parameter values that are common across all observations, while the measurement and model errors can be considered recourse variables that provide a mechanism for matching with the measurements from each individual observation.

This equivalency is important because a number of stochastic programming decomposition techniques have been developed to handle multi-scenario problems with a very large number of scenarios and decision variables. Progressive Hedging (PH) is one such algorithm, and decomposes a stochastic program by scenarios (Rockafellar and Wets, 1991). As discussed below, PH is also particularly amenable to parallelization.

In this work, we demonstrate the potential of PH for the efficient solution of large-scale nonlinear parameter estimation problems. Specifically, we estimate transmission parameters in an SIR disease model using pre-vaccination measles data from 60 cities in England and Wales (Grenfell, 2011). The estimation problem is formulated as a multi-scenario problem with a scenario for each city and transmission parameters as common variables. City size is used to weight the likelihood of each scenario, so larger cities receive greater weight. The following sections describe in detail the problem formulation and estimation approach, along with the resulting solutions.

2. Model Formulation

As early as 1929, researchers proposed that measles transmission is correlated with school terms (Soper, 1929). Measles data from England and Wales is used to estimate the seasonal pattern of the transmission parameter across all 60 cities. The SIR model used in this work is shown below in Eq. (3). The corresponding dynamic optimization problem is converted to a large-scale nonlinear programming problem (through the simultaneous discretization approach) using a three-point Radau collocation on finite elements (Zavala, 2008). The number of finite elements was chosen to yield one finite element per reporting interval of the data giving 26 finite elements per year.

The optimization model for a single city is as follows:

$$\min \quad \sum_{t\in T}\left(\omega_M(\varepsilon_{Mt})^2 + \omega_\phi\left(\varepsilon_{\phi t}\right)^2\right)$$

$$\text{s.t.} \quad \frac{dS}{dt} = -\left(\frac{\beta(y(t))S(t)I(t)}{N} + \varepsilon_M(t)\right) + B(t), \qquad \frac{dI}{dt} = \frac{\beta(y(t))S(t)I(t)}{N} + \varepsilon_M(t) - \gamma I(t)$$

$$\frac{d\phi}{dt} = \frac{\beta(y(t))S(t)I(t)}{N} + \varepsilon_M(t), \qquad R_i^* = \eta_i(\phi_i - \phi_{i-1}) + \varepsilon_{\phi i} \tag{3}$$

$$\bar{\beta} = \frac{\sum_{i\in\tau}\beta_i}{|\tau|} = 2.05, \qquad 0.05 \le \beta(y(t)) \le 5.0$$

$$0 \le I(t), S(t) \le N, \qquad 0 \le \phi(t)$$

Here, *S* denotes individuals with no immunity to the disease, *I* denotes individuals that are infected with the disease and are infectious, *N* denotes the total population, and *β(t)* denotes the time-varying transmission parameter. The function *y(t)* maps the overall time horizon into the elapsed time within the year, making *β(y(t))* a seasonal transmission parameter with a periodicity of one year. *B* denotes the reported births, and the recovery rate $(Y = 1/14)$ is given as a known scalar input. ε_M represents the dynamic model noise, which is assumed to be normally distributed. The index *i* denotes a point in time within the set of data reporting intervals *T*, η denotes a reporting factor accounting for under-reporting, and R_t^* denotes the actual reported incidence over a given time interval. The cumulative new incidence is ϕ, and $\varepsilon_{\phi t}$ represents the measurement noise. ω_M and ω_ϕ represent weights for the model and measurement noise terms, respectively. These weights are set to be proportional to the inverse of the assumed variance of the error terms. The $\bar{\beta}$ term denotes the average β across the yearly set of discretizations τ and is constrained here due to difficulties in simultaneously estimating *S* and β. $|\tau|$ is the cardinality of the set τ.

The England and Wales measles data contains biweekly reported measles case counts by city for the years 1944 through 1963. The number of births per year is also reported by city. We assume births are uniform throughout the year. For all cities, population is assumed to be constant throughout the time horizon. The reporting fraction was estimated for London using a susceptible reconstruction technique that is similar to those described elsewhere (Bobashev et al., 2000; Finkenstädt et al., 2000), with the exception that we restrict the reporting factor to vary linearly with time.

3. Estimation Approach

The problem shown in Eq. (3) was formulated in the algebraic modeling language Pyomo (Hart et al., 2011; Hart et al., 2012). This model is for a single city and data set. Prior to estimation, we specify a scenario tree and use PySP (Watson et al., 2011) to automatically convert this problem into the multi-city problem. PySP and Pyomo are both part of the open-source Coopr software package released by Sandia National Laboratories. PySP allows for convenient formulation and solution of multi-scenario problems. PySP takes a model formulated for a single scenario, data for multiple scenarios, constructs the multi-scenario problem, and then uses one of two approaches to solve the problem. The first approach considers the extensive form of the multi-scenario problem. This has the form of Eq. (2) and is solved using the interior-point solver IPOPT (Wächter, A. and Biegler, 2006). The other approach utilizes Rockafellar and Wets' Progressive Hedging (PH) algorithm, with IPOPT as the subproblem solver. Problem sizes and solution times for both approaches are shown in Table 1.

The PH algorithm is outlined below, where *P* is the weight placed on each observation, *C* is the set of all observations, and ρ is a tuning parameter:
For the base model Eq. (3):

1. Initialize the iterate $k \leftarrow 0$ and let $\omega_c^k = 0$
2. For all scenarios $c \in C$: $\beta_c^0 \leftarrow argmin\ f_c(\varepsilon)$
3. Update the iterate, $k \leftarrow k + 1$, and update $\bar{\bar{\beta}}$:
   $\bar{\bar{\beta}}^{k-1} \leftarrow \sum_{c \in C} P_c \beta_c^{k-1}$ where $\sum_{c \in C} P_c = 1$
4. For all scenarios $c \in C$, update ω and β: $\omega_c^k \leftarrow \omega_c^{k-1} + \rho(\beta_c^{k-1} - \bar{\bar{\beta}}_c^{k-1})$
   $$\beta_c^k \leftarrow argmin\ f_c(\varepsilon) + \omega_c^k \beta_c + \frac{\rho}{2} \left\| \beta_c - \bar{\bar{\beta}}^{k-1} \right\|^2$$
5. If termination criterion not met, go back to step 3.

Steps 2 and 4 are computationally expensive, but these steps can be solved in parallel - allowing for significant performance improvements.

4. Results & Conclusions

Figure 1 shows the estimated values of the seasonal transmission parameter. The extensive form and the PH approach yield nearly identical solutions that are consistent with published values (Finkenstädt and Grenfell, 2000). PH was terminated once the sum of differences between the first stage variables and their average reached a value less than 1×10^{-4}, indicating logical convergence.

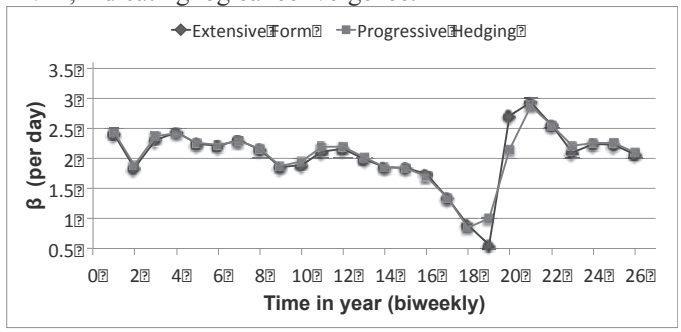

Figure 1: Estimated transmission parameters for extensive form and PH solutions.

Table 1 shows that the extensive form solution requires a total of 5.5GB of RAM. We wish to solve problems with 100s of observations, and problems of this size will not only require very long solution times but also more memory than would be available on a single computer. Using Progressive Hedging in serial requires more time but less memory. The parallel solution of this problem using PH shows good speed-up, and memory requirements remain low for each compute node.

Eqs. 1 and 2 demonstrate that two-stage stochastic programming problems are structurally equivalent to nonlinear programming parameter estimation problems. This similarity allows large-scale nonlinear parameter estimation problems to be solved using stochastic programming decomposition techniques. Our results demonstrate that Progressive Hedging can be used to solve very large parameter estimation problems in parallel with significant reductions in solution times and memory requirements.

Further improvements will allow greater speed-up for parallel PH. Currently, if even one scenario requires significantly longer to converge than the rest of the scenarios, many computing nodes remain idle for extended periods of time. Asynchronous

approaches being studied will reduce the number of idle processors by allowing the majority of computing nodes to continue with the next iteration of PH using an altered update formula. Improved strategies for the selection of the algorithm parameter ρ could also further reduce solution times.

Table 1. Timing and Memory Results

	Extensive Form	PH (serial)	PH (60 processors)
Jacobian Nonzeros	2594522	43184	43184
Variables	625948	10430	10430
Constraints	594721	9883	9883
Solver Time (min)	27.9	93.3	5.1
PySP Time (min)	6.6	8.9	2.1
Solver RAM (GB)	2.2	<0.050	<0.050
PySP RAM (GB)	3.3	3.6	<0.45

Performance Analysis of Shooting Algorithms in Chance-Constrained Optimization

S. Werk, * T. Barz, H. Arellano-Garcia, G. Wozny
Chair of Process Dynamics and Operation, Berlin University of Technology, Sekr. KWT 9, 10623 Berlin, Germany

Abstract

An important aspect for model-based design and development as well as for process monitoring and control is the consideration of uncertain process parameters. One approach for the explicit consideration of such uncertainties is the formulation of *Chance-Constrained* optimization problems. Within the last years, several different methods for the efficient solution of these problems have been presented. In this work, chance constraints are evaluated following the idea of the *variable mapping approach*.

Because the efficiency of the original approach deteriorates with an increasing number of uncertain parameters, the probability integration has been extended recently to the exploitation of sparse grids. In this work, additional techniques for improving the efficiency of the variable mapping approach are presented. Firstly, the solution of a subproblem, the so called *shooting task* is analyzed in detail and enhanced through an idea called here *result recycling*. Secondly, possible extensions are presented which make use of second order derivative information. The new methods are verified by application to an industrially validated process model of a vacuum distillation column for the separation of multicomponent fatty acids.

Keywords: Chance Constrained Optimization, uncertainty, stochastic optimization, higher order derivatives, result recycling

1. Introduction

For industrial process models it is often not possible to assign exact values to all model parameters. In model-based process optimization, different approaches for the explicit consideration of those uncertain parameters have been proposed, under these Approximated Polyhedral Dynamic Programming (Björnberg and Diehl, 2006), Robust Stochastic Programming (Nagy and Braatz, 2003) or Chance-Constrained Optimization based on the *variable mapping approach* (Arellano-Garcia and Wozny, 2009).

The latter, which is discussed here, consists mainly in two parts, the solving of a *shooting task* and the multivariate integration over a known probability distribution function. Recently, significant performance advancements have been reported through the use of sparse grids in the integration task (Geletu et al., 2011). This work focuses on enhancements of the first task, the solution of the *shooting problem*. Moreover, special attention is given to the exploitation of second order derivative information, which is getting more and more popular through solvers like IPOPT (Wächter and Biegler, 2006).

2. Chance Constraint Optimization

To include a Chance Constraint in an optimization problem, Eq. (1) is used, where u represents the decision variables of the optimization problem, ξ the vector of uncertain parameters and the scalar y^{max} a constraint limit. The scalar α stands for the probability, with which the term $f(u,\xi) \leq y^{max}$ has to be fulfilled. ξ is assumed to be multivariate normally distributed with the mean vector μ and the covariance matrix Σ, although a normal distribution is not presupposed.

$$\Pr\{f(u,\xi) \leq y^{max}\} \geq \alpha \tag{1}$$

In the mapping approach (see Wendt et al., 2002), the calculation of a probability $Pr\{\cdot\}$ is performed solving the integral (2), where φ represents the multivariate normal distribution density function. The integration limits are chosen as depicted in Eq. (3).

$$\Pr\{f(u,\xi) \leq y^{max}\} = \int_{-\infty}^{\infty} \dots \int_{-\infty}^{\infty} \int_{-\infty}^{\bar{\xi}_n : f\left(u,\xi_1,\dots,\xi_{n-1},\bar{\xi}_n\right)=0} \varphi(\xi_1,\dots,\xi_n) d\xi_n d\xi_{n-1} \dots d\xi_1 \tag{2}$$

$$\approx \int_{\mu_1-3\sigma_1}^{\mu_1+3\sigma_1} \dots \int_{\mu_{n-1}-3\sigma_{n-1}}^{\mu_{n-1}+3\sigma_{n-1}} \int_{\mu_n-3\sigma_n}^{\bar{\xi}_n : f\left(u,\xi_1,\dots,\xi_{n-1},\bar{\xi}_n\right)=0} \varphi(\xi_1,\dots,\xi_n) d\xi_n \dots d\xi_1 \tag{3}$$

Since the anti-derivative of the density function is not analytically available, a numerical integration is required. Therefore, the outer $n-1$ integrals are used to provide a grid of integration points. Accordingly, for each tuple $(\xi_1,\dots,\xi_{n-1})$ the upper integration limit $\bar{\xi}_n$ of the most inner integral has to be determined, such that $f(u,\xi_1,\dots,\xi_{n-1},\bar{\xi}_n) = 0$ holds. This subproblem, called *shooting task*, is a classic root-finding problem. For general nonlinear process models, the calculation of f implies the solving of a system of differential algebraic equations. This calculation can be considered as the computational time determining step, consequently a reduction of evaluations has a strong impact on the total performance. In the next two chapters, we present two different techniques to improve this part of the calculation.

3. Result recycling for initial estimations

One way to reduce the number of evaluations of f is to improve the initial estimations of the starting points for the root-finding. For the very first u, the best estimations should be μ_n, since no other information is available. For further sets of decision variables $\bar{u}$, the previous results can be reused for starting points. The circumstance that the grid of integration points is independent of u allows for good estimations. Below ξ_n is the vector of the solutions of $\xi_n : f(u,\xi) = 0$ for the whole grid.

For the following approaches the already evaluated u's are considered to be in the set U, while the current one is called $\bar{u}$. For all approaches a metric d is needed, to determine the distance of two different u's. A $\hat{u} \in U$ is called the closest $\hat{u} \in U$, if $d(\hat{u},\bar{u}) \leq d(u,\bar{u})$ for all $u \in U$.

3.1. Nearest neighbour approach

This approach determines the closest $\hat{u} \in U$ and takes its $\hat{\xi}_n$ as initial estimations. In spite of the simplicity, the initial estimations might be much better than μ_n.

3.2. Affine hull approach

For this approach, the closest subset $\{\hat{u}_1, \ldots, \hat{u}_K\} \subseteq U$ has to be determined, whose affine hull includes $\bar{u}$. Then, the linear equation system on the left side of Eq. (4) needs to be solved to obtain the different α_k as weight factors.

$$\sum_{k=1}^{K} \alpha_k \hat{u}_k = \bar{u}, \quad \sum_{k=1}^{K} \alpha_k = 1 \qquad \Rightarrow \qquad \bar{\xi}_n \approx \sum_{k=1}^{K} \alpha_k \hat{\xi}_k \tag{4}$$

Having determined them, $\bar{\xi}_n$ can be calculated according to the right side of Eq. (4).

3.3. Derivative approach

The last approach presented here is the derivative approach. It can only be used, if the derivatives $\frac{\partial f}{\partial \hat{u}}$ and $\frac{\partial f}{\partial \hat{\xi}_n}$ are available. Since $f(\hat{u}, \hat{\xi}) = 0$ holds, with the use of the implicit function theorem the derivative $\frac{\partial \hat{\xi}_n}{\partial \hat{u}}$ can be calculated. Therefore, a first order Taylor Polynomial can be formulated so as to provide an initial estimation.

$$\bar{\xi}_n \approx \hat{\xi}_n + \frac{\partial \hat{\xi}_n}{\partial \hat{u}} \cdot (\bar{u} - \hat{u}) \tag{5}$$

If the second derivatives $\frac{\partial^2 f}{\partial \hat{u}^2}$, $\frac{\partial^2 f}{\partial \hat{u} \hat{\xi}_n}$ and $\frac{\partial^2 f}{\partial \hat{\xi}_n^2}$ are also available, with the same approach $\frac{d^2 \hat{\xi}_n}{d \hat{u}^2}$ can be calculated and a second order Taylor polynomial can be constructed:

$$\bar{\xi}_n \approx \hat{\xi}_n + \frac{\partial \hat{\xi}_n}{\partial \hat{u}} \cdot (\bar{u} - \hat{u}) + \frac{1}{2} (\bar{u} - \hat{u})^T \cdot \frac{\partial^2 \hat{\xi}_n}{\partial \hat{u}^2} \cdot (\bar{u} - \hat{u}) \tag{6}$$

4. Enhanced root-finding using Halley's method

In case second order derivatives are available, the Newton-step in the root finding for the solution of the shooting task can be extended. To do so, a second order Taylor polynomial is constructed for each ξ_n, used in the root-finding process. The root of this polynomial is calculated using Eq. (7). This method is also known as Parabolic Halley's method.

$$\begin{aligned} & f(x_1) \approx f(x_0) + f'(x_0)(x_1 - x_0) + \frac{1}{2} f''(x_0)(x_1 - x_0)^2 \stackrel{!}{=} 0 \\ & \Rightarrow x_1 = x_0 - \frac{f'(x_0) - \operatorname{sgn}(f'(x_0)) \cdot \sqrt{f'(x_0)^2 - 2 f(x_0) f''(x_0)}}{f''(x_0)} \end{aligned} \tag{7}$$

The convergence of this method is cubic, while Newton's method's is only quadratic, even though, with good initial estimations or linear relation between ξ and f its effect on computational time might be low, since only one Newton-step is usually needed then.

5. Numerical tests

In the following, the different techniques presented in the preceding sections are compared by their efficiency for the evaluation of chance constraints in a practical application. To do so, an industrial packed distillation column for the separation of fatty acids is considered (Figure 1). The process model consists in a system of differential algebraic equations (179 implicit defined differential and 232 algebraic equations).

The Murphree tray efficiencies η_1 and η_2 for the rectification and stripping section are assumed to be uncertain model parameters with uncorrelated normal distributions of $\eta_1 \sim \mathcal{N}(0.55, 0.08^2)$ and $\eta_2 \sim \mathcal{N}(0.6, 0.1^2)$. The C10 stream of the bottom section is very sensitive towards the Murphree efficiencies. For the dynamic optimization problem it is assumed, that its mass concentration $f(u, \eta_1, \eta_2)$ at the end of the time horizon may not exceed 1.5 percent with a probability of 90 percent. Therefrom the Chance Constraint Eq. (8) is formulated. The objective function minimizes the reboiler duty, which is defined as decision variable u with a starting value of 610.70 MW. The reflux ratio is fixed to 1.0.

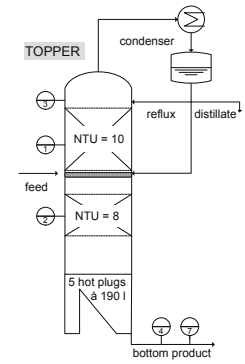

Fig. 1. Packed vacuum distillation column for the distillation of fatty acids (Barz et al., 2011).

$$\Pr\{f(u, \eta_1, \eta_2) \leq 1.5\} \geq 0.90 \tag{8}$$

All different result recycling approaches are evaluated with the classical Newton's method as well as with the Halley's method by using the Sequential Least Squares Programming solver of SciPy 0.9.0 on a Intel Core i7-2700K, running Ubuntu Server 11.10 64bit. All dynamic simulations as well as first and second order derivative generation have been realized using the numeric solver sDACl (Barz et al., 2011). To guarantee a consistent comparison, the same number of evaluations of the probability function was ensured. The results are presented in table 1.

initial estimation approach	Newton's method	Halley's method
none	548 (0.0%)	542 (1.1%)
nearest neighbour	406 (25.9%)	406 (25.9%)
affine hull	402 (26.6%)	402 (26.6%)
1st order derivative	404 (26.3%)	404 (26.3%)
2nd order derivative	404 (26.3%)	404 (26.3%)

Table 1. Number of function evaluations $f(u, \xi)$ (improvement in percent).

All of the different approaches for better initial estimations have shown significant speed improvement from 25.9 to 26.6 percent. The affine hull approach did show the highest speed improvement while the derivative approaches and the nearest neighbour approach did perform slightly slower. The use of Halley's method for the root-finding problem did not show a significant improvement over Newton's method in this case study.

To evaluate the efficiency of the initial estimation approaches in scenarios with multiple Chance Constraints, the previous example is extended as follows: The reboiler duty can be varied over time, and the C10 stream has different constraints over time. Figure 2 shows the result of an optimization with ten equally spaced time steps. The mass concentration of the C10 stream decreases from 1.95 at the end of the first time step to 1.5 at the end of the time horizon. All limits have to hold with a probability of 90 percent. The optimized reboiler duty over time is shown in the bottom diagram. To obtain the optimal solution without record recycling, the simulation had to be performed 17046 times, while the use of the 1st order derivative approach reduced this number to 9655, a performance increase of over 43 percent.

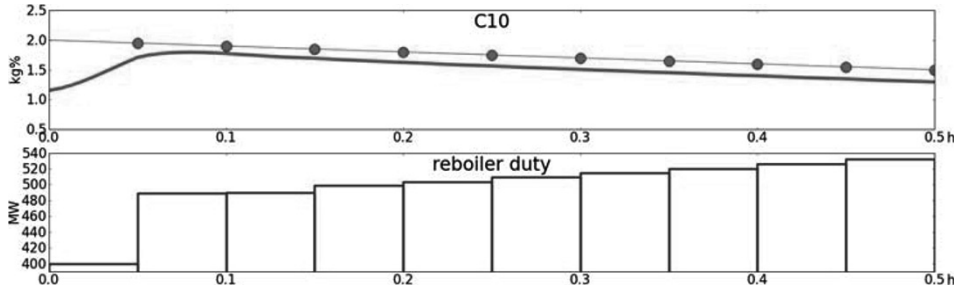

Fig. 2. Extended case study. Top: expected value of mass concentration of C10 bottom stream (bold line) and its restrictions (dots). Bottom: reboiler duty over time.

6. Conclusion

In this paper, we discussed various algorithmic improvements of a method for the evaluation of probabilities of Chance-Constraints in general optimization problems. The new approaches considered in this work aim at the reduction of the number of necessary solutions of a shooting problem, which arises when following the mapping approach.

For our industrial case study, we have shown, that recycling of previous results within the optimization can reduce the computation time up to 43 percent. A second approach based on the exploitation of available second order derivative information using Halley's root finding method did not show clear improvements. Anyhow, preliminary results indicate that problems exist for which this approach performs much better. This and further improvements of the presented strategies for a result recycling are currently under investigation. All approaches are implemented in a software framework to be easily applicable to other optimization models.

Abstract

Investigating the root causes of abnormal events is a crucial task for an industrial process. When process faults are detected, isolating the faulty variables provides additional information for investigating the root causes of the faults. Numerous data-driven approaches require the datasets of known faults, which may not exist for some industrial processes, to isolate the faulty variables. The contribution plot is a popular tool to isolate faulty variables without a priori knowledge. However, it is well known that this approach suffers from the smearing effect, which may mislead the faulty variables of the detected faults. In the presented work, a contribution plot without the smearing effect to non-faulty variables was derived. A continuous stirred tank reactor (CSTR) example was provided to demonstrate that the proposed approach is not only capable of isolating faulty variables of a simple fault but also a complex fault.

Keywords: fault detection and isolation, principal component analysis, contribution plots, missing data analysis.

1. Introduction

In modern chemical processes, the operating data are collected and stored in a historical database. However, information about process operations is hidden under the historical data. Therefore, it is more practical to develop methods that detect and investigate the root causes of process faults based on data-driven approaches, rather than to use other methods based on rigorous process models or knowledge-based approaches. Since the measured variables are correlated for a chemical process, principal component analysis (PCA) is a popular tool to extract the features of the process data that are applied to monitor the process variations. After a fault is detected, the faulty variables need to be isolated in order to diagnose the root causes of the fault. Contribution plots are the most popular tool for identifying which variables are pushing the statistics out of their control limits. Kourti and MacGregor, 1996 remarked that the contribution plots may not reveal the assignable causes of abnormal events; however, the group of variables contributed to the detected events will be unveiled for further investigation. Westerhuis et al., 2000 introduced the confidence limits of the contribution plots to enhance the capability of identifying the behaviors of faulty variables departing from the normal operating condition (NOC). They reported that there must be a careful interpretation of the contribution plots, since the residuals of the PCA are smeared out over the other variables. Yoon and MacGregor, 2000 comprehensively compared model-based and

data-driven approaches for fault detection and isolation, and summarized that the contribution plots provide for the easy isolation of simple faults, but that additional information about operating the process is needed to isolate complex faults.
The remainder of this paper is organized as follows. The proposed approach of the contribution plots without smearing effect to non-faulty variables is detailed in section 2. In section 3, a CSTR example is provided to demonstrate the effectiveness of the proposed approach. Finally, conclusions are given.

2. Proposed Approach

Yue and Qin, 2001 combined the statistics Q and T^2 of PCA to develop an index that is minimized when isolating the faulty variables, i.e., $\varphi = \mathbf{x}^{\mathrm{T}}\boldsymbol{\Phi}\mathbf{x}$ where $\mathbf{x}$ is a normalized measured vector with zero means and unit variances, and $\boldsymbol{\Phi} \equiv \tilde{\mathbf{P}}\tilde{\mathbf{P}}^{\mathrm{T}}/Q_\alpha + \mathbf{P}\boldsymbol{\Lambda}^{-1}\mathbf{P}^{\mathrm{T}}/T_\alpha^2$ in which $\boldsymbol{\Lambda}$ and $\mathbf{P}$ respectively are a diagonal matrix with first K terms of the significant eigenvalues and the respective eigenvectors and $\tilde{\mathbf{P}}$ contains the residual eigenvectors; Q_α and T_α^2 respectively are the (1-α) confidence limits of the statistic Q and T^2. For a multiple sensor fault, the reconstructed variables can be written according to the combined index: $\boldsymbol{\xi}^{\mathrm{T}}\boldsymbol{\Phi}\mathbf{x} = \mathbf{0}$ where $\boldsymbol{\xi} \equiv \begin{bmatrix} \boldsymbol{\xi}_1 & \boldsymbol{\xi}_2 & \cdots & \boldsymbol{\xi}_{nf} \end{bmatrix}$, in which nf is the number of faulty variables and $\boldsymbol{\xi}_i$ is a column vector in which the i^{th} element is one and the others are zero. The monitored variables can be decomposed as $\mathbf{x} = \boldsymbol{\Gamma}\mathbf{x} + (\mathbf{I} - \boldsymbol{\Gamma})\mathbf{x}$, where $\boldsymbol{\Gamma}$ is a diagonal matrix, in which the values of the diagonal elements are one for the faulty variables and zero for the non-faulty ones. Therefore, minimizing the combined index can be rewritten as: $\boldsymbol{\xi}^{\mathrm{T}}\boldsymbol{\Phi}\boldsymbol{\Gamma}\mathbf{x} = -\boldsymbol{\xi}^{\mathrm{T}}\boldsymbol{\Phi}(\mathbf{I} - \boldsymbol{\Gamma})\mathbf{x}$. The left-hand side of the above equation contains the data to be reconstructed by the normal data in the right-hand term. The data that to be reconstructed can be expressed as: $\boldsymbol{\Gamma}\mathbf{x} = \boldsymbol{\xi}\mathbf{x}_{nf}$ in which $\mathbf{x}_{nf}$ is the collection of the faulty variables. The reconstruction of the faulty variables can be obtained by the following equation:

$$\mathbf{x}_{nf}^{*} = -\left(\boldsymbol{\xi}^{\mathrm{T}}\boldsymbol{\Phi}\boldsymbol{\xi}\right)^{-1}\boldsymbol{\xi}^{\mathrm{T}}\boldsymbol{\Phi}(\mathbf{I} - \boldsymbol{\Gamma})\mathbf{x} \tag{1}$$

Since $\boldsymbol{\Phi}$ is a full-rank matrix, $\left(\boldsymbol{\xi}^{\mathrm{T}}\boldsymbol{\Phi}\boldsymbol{\xi}\right)$ is invertible. The reduction of the combined index (RCI) after reconstructing the faulty data can be written as follows:

$$\varphi - \varphi_{nf}^{*} = \left(\mathbf{x}_{nf} - \mathbf{x}_{nf}^{*}\right)^{\mathrm{T}}\left(\boldsymbol{\xi}^{\mathrm{T}}\boldsymbol{\Phi}\boldsymbol{\xi}\right)\left(\mathbf{x}_{nf} - \mathbf{x}_{nf}^{*}\right) \tag{2}$$

Therefore, the fault isolation task is to find subset $\mathbf{x}_{nf}$ from $\mathbf{x}$ to maximize the RCI, until the statistics Q and T^2 are under the corresponding control limits, without the information from faulty variables. The contribution of the i^{th} faulty variable to RCI can be defined as:

$$c_i^{RCI} = \left[\left(\mathbf{x}_{nf} - \mathbf{x}_{nf}^{*}\right)^{\mathrm{T}}\left(\boldsymbol{\xi}^{\mathrm{T}}\boldsymbol{\Phi}\boldsymbol{\xi}\right)^{0.5}\boldsymbol{\xi}_i\right]^2 \tag{3}$$

The proposed approach first evaluates each RCI with a reconstructed variable and inserts the variable with the maximum RCI into $\mathbf{x}_{nf}$ in the first step. Next, the RCIs are evaluated using the reconstructed data of a non-faulty variable and the selected faulty variables in $\mathbf{x}_{nf}$. The non-faulty variable with the maximum RCI is inserted into $\mathbf{x}_{nf}$. The

steps of adding a new faulty variable into $\mathbf{x}_{nf}$ is repeated until both statistics Q and T^2 are under the corresponding control limits. The algorithm is summarized as follows:

1. Set $nf = 0$ and $\mathbf{x}_{nf} = \varnothing$.
2. For $i = 1 \ldots N\text{-}nf$, which N is the number of variables,
   Reconstruct the data of $\mathbf{x}_{nf} \cup \mathbf{x}_i \notin \mathbf{x}_{nf}$ using *(1)* and evaluate the RCI using *(2)*.
3. Add the variable with the maximum RCI into $\mathbf{x}_{nf}$ and set $nf = nf + 1$.
4. If the statistics Q and T^2, without the information of the selected faulty variables, are still over their control limits, go back to step 2.
5. Decreasingly sort the selected faulty variables according to the contributions of RCI using *(3)* and retain the variables in $\mathbf{x}_{nf}$ that sufficiently reduce the statistics Q and T^2 under the corresponding control limits.

Steps 2-4 of the algorithm guarantee *(2)* to be a monotonically increasing function with the number of selected faulty variables; therefore, the statistics Q and T^2 monotonically decrease during iterations. The non-faulty variables, which may be selected in the early stage of the iterations under insufficient information about the faulty variables, are removed from $\mathbf{x}_{nf}$ in step 5. When diagnosing the root causes of process faults, the selected faulty variables do not equally contribute to the faults. The contribution plots for the reduction of statistics can be used to find the faulty variables with the most contributions, as the contributions have been confined within the selected faulty variables and the fault magnitude will not smear over to the non-faulty variables.

3. Continuous Stirred Tank Reactor Example

A nonisothermal continuous stirred tank reactor (CSTR) with feedback control systems was simulated; the schematic diagram of the CSTR and feedback control system is shown in Fig. 1 and the details of the simulated CSTR can be found in Singhal and Seborg, 2002. Data from the monitored variables (listed in Table 1) were collected every minute. PCA was applied to the dataset with a 1-day window size, and four PCs were retained using cross-validation. The PCA model captured about 81% of the total variance. Two sensor faults were considered, based on the work of Yoon and MacGregor, 2001. The simple fault data were generated by introducing a bias of 1 K to the measurement of the feed temperature (T_F) after the first day. After the simple fault was triggered, the smearing effect of the contribution plots could be observed, as shown in Fig. 2(a) where the Q contributions were normalized with the corresponding 99% confidence limits. The result was similar with what Yoon and MacGregor, 2001 reported. Figure 2(b) shows that the contributions of RCI, normalized with the sum of RCIs, indicate the third variable (the feed temperature) was over 80% responsible for this simple fault.

Table 1. Monitored Variables for the CSTR Example

ID	Variable Description	ID	Variable Description
1	Reactor temperature (T)	6	Reactor exit flow rate (Q)
2	Coolant exit temperature (T_C)	7	Coolant flow rate (Q_C)
3	Feed temperature (T_F)	8	Reactor feed flow rate (Q_F)
4	Coolant feed temperature (T_{CF})	9	Reactant concentration (C_A)
5	Reactor level (h)		

The complex fault data were generated by adding a bias of 1 K to the measurement of the reactor temperature (T) after the first day. Since the reactor temperature was regulated by the coolant flow rate (Q_C), the measured temperature would be brought back to its set point after a short period of time, as shown in Fig. 3(a). However, the actual reactor temperature was lower than its set point; therefore, the reactant

concentration (C_A) would be higher than the normal operating data due to the lower reaction rate, as Fig. 3(b) shows. The coolant flow rate reached a new steady-state condition after the fault had been compensated, as shown in Fig. 3(c), which induced the coolant exit temperature (T_C) to be lower than its normal operating values due to the excess of the coolant flow rate, as Fig. 3(d) shows. The other monitored variables were not affected by this complex fault. Figure 4(a) shows that the faulty variables were identified as variable 2, 5, 6, and 9, according to the normalized Q contribution plots. It misidentified the reactor level and the reactor exit flow rate as faulty variables and lost the faulty variable Q_C. The proposed approach repeatedly selected the variables with the maximum RCI as the faulty variable candidates until both statistic Q and T^2 were under the corresponding control limits. The normalized contributions, based on RCI in the faulty variable candidate, were then plotted. Figure 4(b) shows the correct faulty variables, T_C, Q_C, and C_A, were identified.

4. Conclusions

The presented work developed a contribution plot without the smearing effect to non-faulty variables. The proposed approach was shown to have the capability of isolating multiple sensor faults without predefined faulty datasets. In the CSTR example, the fault isolation results using the contribution plots of RCI were more precise than the solutions found using the traditional contribution plots. The results show that the predefined faulty datasets are not necessary for the proposed approach; in addition, the smearing effect of the traditional contribution plots is also eliminated.

Integrated Sensor Network Design

Nabil M, Sridharakumar Narasimhan*
Department of Chemical Engineering; Indian Institute of Technology Madras; India

Abstract

Selection of sensors is an important structural decision for the safe and optimal operation of a chemical plant. Recently, we have proposed a mixed integer cone formulation for selecting sensors for linear data reconciliation with the aim of minimizing the operational loss caused due to measurement noise. In this work, we extend our formulation to select a redundant sensor network such that the system is observable in case of sensor failures. Finally, the proposed approach is illustrated using an evaporation process.

Keywords: data reconciliation, sensor faults, convex optimization

1. Introduction

Efficient process monitoring, control and fault diagnosis are vital for optimal and safe operation of a chemical process. The success of each of the above activities depends critically on the choice of the sensor network. Although sensor network design problems have been discussed extensively in literature, they are tailored for each activity independently (Chmielewski et al., 2002; Bhushan and Rengaswamy, 2000). Since the individual design problems are incommensurable, the integration of sensor network design is difficult to account for the multi-faceted elements (observability, controllability, redundancy, accuracy, reliability, etc.,). To this end, there is an increasing interest to define performance metrics based on process economics. Despite this, a sensor network is chosen to cater to a specific objective rather than considering all objectives simultaneously. Thus, the current objective is to determine an economically optimal sensor network that considers both data reconciliation and sensor failure case.

In this work, we extend our optimization framework that was addressed for data reconciliation to account for sensor faults as well. In particular, we address the problem for the case of single sensor failure situation by defining a set of convex constraints. Hence preserving convexity of our earlier formulation and guaranteeing globally optimal solutions. The proposed approach is exemplified using an evaporator system.

2. Problem Formulation

In this section, we present a systematic approach of reformulating the sensor network selection problem based on process economics. First, we present the data reconciliation problem followed by which sensor network design formulation for data reconciliation is presented. Next, we define the set of constraints that accounts for sensor failure situation.

2.1. Data reconciliation

Data reconciliation is a method to improve the accuracy of the measurements corrupted by random noise, given the process model and description of noise. Chmielewski et al. (2002) have proposed a formulation by defining the measurement vector by incorporating

*sridharkrn@iitm.ac.in

the process model as: $y = Cz_p + v$, $v \in \mathcal{N}(0, \Sigma_v)$; where C is a process matrix and z_p denotes primary variables (defined as any set of variables that form a minimum observable network). It is important to note that the vector y denotes the set of all variables of interest which contains both measured and unmeasured variables. Also note that fixing z_p fixes the process matrix C which is independent of the sensor network to be chosen. For more details, the reader is referred to Chmielewski et al. (2002). Thus, the reformulated reconciliation problem is unconstrained and is stated as:

$$\min_{\hat{z}_p} (y - C\hat{z}_p)^T \Sigma_v^{-1} (y - C\hat{z}_p) \tag{1}$$

where $\Sigma_v^{-1} = diag\{\frac{q_i}{\sigma_i^2}\}$ and q_i is a binary variable (0 or 1) denoting that the particular variable is unmeasured or measured respectively. Unmeasured variable ($q_i = 0$) can also be inferred statistically as the sensor with infinite variance. Reconciled estimate of primary variables, $\hat{z}_p = (C^T \Sigma_v^{-1} C)^{-1} C^T \Sigma_v^{-1} y$ and hence the reconciled estimate of all variables of interest, $\hat{z} = C\hat{z}_p$. The covariance matrix of estimation error is given by

$$\Sigma_z = C(C^T \Sigma_v^{-1} C)^{-1} C^T \tag{2}$$

It is important to recall that data reconciliation adjusts the given measurement data such that the residual is minimized. However, sensor network design objective is to select those variables that result in least residual for the assumed measurement noise characteristics. Hence the formulation (1) is of direct use for sensor network design where q_i is the decision variable.

2.2. Sensor network design

Sensor network plays a significant role in the optimal and safe operation of a chemical plant. The typical objective of the sensor network design problem based on reconciliation framework is to minimize average error i.e., $Tr(\Sigma_z)$ (Narasimhan and Jordache, 2000) where $Tr(.)$ denotes the trace operator. Recalling $\Sigma_v^{-1} = diag\{\frac{q_i}{\sigma_i^2}\}$, the sensor network design problem can be mathematically stated using expression (2) as:

$$\min_{q_i} \quad Tr(C(C^T \Sigma_v^{-1} C)^{-1} C^T) \tag{3}$$

where the invertibility of $C^T \Sigma_v^{-1} C$ signifies that the system is observable. However for the average error to be minimum, $C^T \Sigma_v^{-1} C$ has to be positive definite. As discussed in section 1, to quantify in terms of process economics we have recently proposed a formulation that minimizes the weighted error variances i.e., $Tr(W\Sigma_z)$ (Nabil and Narasimhan, 2012). The sum of weighted error variances is called "average loss" as it represents the operational loss in profit caused due to measurement error. Thus, economically optimal sensor network is obtained by solving

$$\min_{\hat{q}_i} \quad \tfrac{1}{2} Tr(WC(C^T \Sigma_v^{-1} C)^{-1} C^T) \tag{4}$$

where the weighting matrix $W = RR^T$ is a function of the economic objective function J. The formulation is a non linear integer programming problem. However, it could be transformed into easily solvable Linear Matrix Inequalities (LMIs) using convex optimization

theory (Boyd and Vandenberghe, 2004). For the purpose of brevity, only the final form of the optimization formulation which is a mixed integer cone problem is presented here:

$$\min_{t,q_i,Y} \quad \overline{L} = \tfrac{1}{2}t \tag{5a}$$

$$s.t. \quad Tr(Y) \leq t \tag{5b}$$

$$Y \succ 0 \tag{5c}$$

$$\begin{bmatrix} Y & R^T C \\ (R^T C)^T & (C^T \Sigma_v^{-1} C) \end{bmatrix} \succ 0 \tag{5d}$$

$$\textstyle\sum_{i=1}^{n_z} c_i q_i \leq c^* \tag{5e}$$

where the scalar t and matrix Y are the internal variables created during convexification of the constraints. Additionally, the last constraint (5e) is imposed to restrict the number of sensors being chosen based on the maximum allowable capital cost (c^*) where c_i denotes the cost of selecting the ith sensor.

Sensor Failure Case: The primary requirement of any fault diagnostic approach is detecting and identifying the origin of faults. Hence, the selection of a suitable sensor network plays a key role in the detection of faults. Sensors should be selected such that the system is observable in case of any process faults and sensor faults. Typical fault diagnostic sensor network designs are based on digraph or signed digraph approach. Later, to handle sensor faults, the term reliability was defined based on the sensor failure probability information to quantify the unobservability value of the variables. Thus, a sensor network that maximizes the least reliability is typically chosen. However, this reliability is showed to be dual to the error variance problem (Kotecha et al., 2008). Therefore, maximizing reliability is equivalent to minimizing error variances. However, this metric is not readily deciphered by the operators as discussed earlier. Hence, our current focus is to design an economically optimal sensor network that can handle sensor failure situations in addition to data reconciliation.

To this end, we use redundant measurements which are not only useful in improving the accuracy of measurements but also helps us to observe the system when some sensor fails. Without loss of generality, it is assumed here that only one sensor can fail at a time. Although the formulation (5) could result in redundant measurements, it might not be observable in case of sensor failures. Thus, a new set of observability conditions have to be imposed that would yield a redundant sensor network of degree one (i.e., if any one of the sensor fails, the system is still observable). For the system to be observable, it is mentioned earlier that $C^T \Sigma_v^{-1} C$ has to be positive definite. Hence, with our weighted variance formulation, to account for a single sensor failure situation, the following 'n' (number of potential variables available for measurement) additional constraints have to be imposed such that all $C^T \Sigma_v^{-1} C$ is positive definite:

$$C^T \begin{bmatrix} 0 & 0 & 0 & 0 & 0 \\ 0 & \frac{q_2}{\sigma_2^2} & 0 & 0 & 0 \\ 0 & 0 & \frac{q_3}{\sigma_3^2} & 0 & 0 \\ 0 & 0 & 0 & \ddots & 0 \\ 0 & 0 & 0 & 0 & \frac{q_n}{\sigma_n^2} \end{bmatrix} C \succ 0, \text{ if first sensor fails}$$

$$C^T \begin{bmatrix} \frac{q_1}{\sigma_1^2} & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & \frac{q_3}{\sigma_3^2} & 0 & 0 \\ 0 & 0 & 0 & \ddots & 0 \\ 0 & 0 & 0 & 0 & \frac{q_n}{\sigma_n^2} \end{bmatrix} C \succ 0, \text{ if second sensor fails and so on.}$$

The above defined matrix inequality constraints ensures that the system is observable if that sensor fails. In other words, the formulation finds a sensor network with one degree of redundancy.

For the case of multiple sensor failures, ${}_nC^r$ additional constraints have to be imposed where 'r' denotes the number of sensors that can fail at a time. In such a case, the formulation (5) along with the suitable set of constraints would yield a degree 'r' redundant sensor network. However, multiple sensors failing at a time is less common in practice and hence not discussed further.

As the above constraints are convex in relaxed form, the mixed integer cone programming formulation of problem (5) is preserved and hence solved using a branch and bound technique to obtain a globally optimal sensor network. In this work, the problem is solved using YALMIP, a freely available software for solving convex optimization problems (Löfberg, 2004).

3. Case study: Evaporator system

Consider the forced circulation evaporation process. The details of the system including the mathematical model, operational constraints, objective function and nominal optimal values are given in Nabil and Narasimhan (2012). The process model has five degrees of freedom assuming the active constraints are enforced. Therefore, at least five variables have to be measured for the system to be observable for data reconciliation. However, if any of the sensor fails then the system is always unobservable. Hence, the redundant sensor network of at least degree one is required to handle single sensor failing at a time.

In the proposed formulation (5), redundant measurements are chosen based on the available capital cost (c^*). In this case study, the cost of flow, temperature and pressure sensors are assumed to be 100 \$, 150 \$ and 200 \$ respectively to show the effect of available monetary resource. Here we present the results of formulation (5) for two case: without and with sensor failure conditions. The corresponding economically optimal sensor networks obtained are tabulated in Table 1 and Table 2 respectively. Up to the available resource of 600 \$, only five sensors could be selected as shown in Table 1 and hence there is no feasible sensor network available to account for sensor faults. With 650 \$ of available resource, the economically optimal network obtained for both the cases are the same. However, for the available resource of 700 \$, the optimal network is different for the two cases considered. This implies that, although the sensor network $\{F_2, F_3, F_5, F_{100}, F_{200}, P_2\}$ result in a lower average loss than the network $\{F_2, F_3, F_5, F_{100}, F_{200}, T_{201}\}$, the latter can handle sensor failure situation while the former cannot. From the result obtained for the available resource of 750 \$, it can be inferred that the available resource is utilized to exploit redundancy by selecting more sensors for sensor failure situation than the one solved for reconciliation only. Indeed, the average loss is the same for both cases. It is also important to observe that increasing the number of measurements show a decrease in operational loss (due to measurement noise) which is because redundancy improves the data.

Table 1. Optimal sensor network for data reconciliation only

Available resource, c^* ($)	Sensor Network	Sensor cost ($)	Average loss ($/h)
500	$F_2, F_3, F_5, F_{100}, F_{200}$	500	12.2
550	$F_2, F_3, F_{100}, F_{200}, T_{201}$	550	10.28
600	$F_2, F_3, F_{100}, F_{200}, T_{201}$	550	10.28
650	$F_2, F_3, F_5, F_{100}, F_{200}, T_{201}$	650	9.57
700	$F_2, F_3, F_5, F_{100}, F_{200}, P_2$	700	9.48
750	$F_2, F_3, F_5, F_{100}, F_{200}, P_2$	700	9.48
800	$F_2, F_3, F_5, F_{100}, F_{200}, T_2, T_{201}$	800	9.10

Table 2. Optimal sensor network for both data reconciliation and sensor failure situations

Available resources, c^* ($)	Sensor Network	Sensor cost ($)	Average loss ($/h)
upto 600	Infeasible	-	-
650	$F_2, F_3, F_5, F_{100}, F_{200}, T_{201}$	650	9.57
700	$F_2, F_3, F_5, F_{100}, F_{200}, T_{201}$	650	9.57
750	$F_1, F_2, F_3, F_5, F_{100}, F_{200}, T_{201}$	750	9.48
800	$F_2, F_3, F_5, F_{100}, F_{200}, T_2, T_{201}$	800	9.10

4. Conclusion

Sensor network design procedure that can handle both data reconciliation and sensor failure simultaneously based on process economics was presented. The relaxed formulation is convex and thus yielding globally optimal solution. In summary, the redundant sensor network that is observable even if some sensor fail could be found using the proposed framework. The approach was successfully demonstrated using the evaporator system.

Reallocation Index Based Sensor Network Design for Efficient Fault Diagnosis

Suryanarayana Kolluri, Mani Bhushan *

Department of Chemical Engineering, Indian Institute of Technology Bombay, Mumbai-400076, India

Abstract

A novel concept of reallocation index is proposed and incorporated in the base case design of sensor networks from a fault diagnostic perspective. Reallocation index indicates the possibilities of future reallocations of sensors. Maximization of reallocation index is added as an objective during sensor network design. The resulting design is then optimal not only for the base case, but also ensures that any future upgrade and reallocation can be carried out effectively with less cost. The proposed sensor network design approach is illustrated on the Tennessee Eastman challenge problem. It is shown that the design obtained after consideration of reallocation index performs much better than the design obtained without reallocation index.

Keywords: Sensor Locations, Reallocation Index, Fault Diagnosis, Optimization

1. Introduction

The problem of sensor network design is to choose the variables to be measured to optimize some criteria while satisfying various technical and economic constraints. Several approaches have been proposed in literature for designing sensor networks for various criteria such as those related to estimation-reliability, estimation-precision, gross error detection, data reconciliation and fault diagnostic relevant information, etc. (Bagajewicz, 2002). Most of the work in the area of sensor network design is for base case scenarios when the process does not have any existing sensors. However, over a period of time, the process usually goes through significant changes since the operating conditions of the process may change. Additionally new equipments can be added or deleted from the process. Due to these changes a design, which was optimal to begin with, may no longer be optimal or even adequate for meeting the requirements for the existing process. Hence, for existing processes a relevant problem is of sensor network retrofit, i.e. modifying an existing sensor network to meet specific requirements or improving the quality of information available about the process. Recognizing this need, Bagajewicz and Sanchez (2000) proposed a reallocation and upgrade formulation which allows optimal modification of an existing network while maximizing performance related to precision. In their formulation, new sensors can be added (termed upgrade) or existing sensors can be transferred to other variables (termed reallocation). Bhushan et al. (2003) used the upgrade and reallocation idea of Bagajewicz and Sanchez (2000) for retrofitting an existing sensor network from a fault diagnostic perspective. There are few other approaches that directly incorporate possibilities of process change during base case design. Bo and Bing-Zhen (2002) considered the notion of sensor network flexibility (ability to observe variables when new streams are added) in the base case sensor network design for linear processes.

*mbhushan@iitb.ac.in

Bhushan et al. (2008) proposed maximizing network distribution (number of measured variables) during base case design so that the resulting design is robust to future changes in the process.

In this paper, we propose a novel reallocation index based approach to integrate sensor network retrofit with the design problem. The objective is to maximize possibilities of reallocation of sensors in future without compromising on the optimality of base case design. This is possible since often there are multiple solutions for the base case design problem. So, our approach is to select, amongst those multiple solutions, the solution which enables maximum number of reallocations in future. The idea being that in case of significant variations in the process/operating conditions, it will be easy (for example, cost-wise) to retrofit the existing network while achieving the desired performance objectives. We apply our approach to the problem of sensor network design from a fault diagnostic perspective where the process is modeled as a signed digraph. However, the proposed idea of reallocation index can be easily incorporated with problem of sensor network design for other objectives and model types as well. This paper is structured as follows: in section 2 we briefly summarize the previous relevant work in the area of sensor network design and retrofit for fault diagnosis while in section 3 we propose the reallocation index based design formulation. In section 4 we apply our design idea to the well known Tennessee Eastman challenge process and compare the resulting sensor network to the network obtained from literature, before concluding in section 5.

2. Previous Related Work

The optimization formulations proposed for sensor network design for fault diagnosis are based on the concept of “unreliability of fault" which is defined as the probability of a fault occurring and remaining undetected due to simultaneous failure of sensors affected by that fault. For i^{th} fault, the unreliability is (Bhushan et al., 2008):

$$U_i = f_i \prod_{j=1}^{n} (s_j)^{(B_{ij}x_j)} \tag{1}$$

where f_i is the probability of occurrence of fault i, s_j is the failure probability of sensor placed on variable j, n is the number of variables in the process and matrix B is the fault-variable bipartite matrix such that $B_{ij} = 1$ if fault i affects variable j and is 0 otherwise. For various scenarios, such as single fault observability and resolution, the matrix B can be obtained from the cause-effect matrix A which in turn is obtained by analyzing the effect of faults on variables such as that obtained from the process signed digraph (Bhushan and Rengaswamy, 2002).

2.1. Base Case Design of Sensor Networks for Fault Diagnosis

Bhushan and Rengaswamy (2002) proposed the following optimization formulation for base case sensor network design for minimizing system unreliability:

$$\textbf{Formulation I:} \quad \min_{x_j, U, x_s} [U - \alpha x_s] \tag{2}$$

subject to:

$$U \geq \log U_i, \;\; i = 1, ...m; \;\; \sum_{j=1}^{n} c_j x_j + x_s = C^* \tag{3}$$

$$x_j \in \mathbb{Z}^+, \;\; j = 1, ...n; \;\; x_s \in \mathbb{R}^+; \;\; U \in \mathbb{R}^- \tag{4}$$

In the above formulation, the objective function U is the system unreliability defined as the maximum unreliability of detection amongst all faults (m in number). c_j is the cost of the sensor for measuring j^{th} variable, C^* is the available cost for selecting sensors, x_j is the main decision variable which indicates the number of sensors placed at j^{th} variable and variable x_s indicates the cost unused for the given C^*. Variable x_s becomes relevant since for the same optimal U different sensor networks with different costs can be obtained (multiple optimal solutions). The positive constant α in the objective function ensures that the least cost solution is chosen amongst these multiple solutions.

2.2. Reallocation and Upgrade of Sensor Networks for Fault Diagnosis

Bagajewicz and Sanchez (2000) proposed optimization formulations for reallocation and upgrade of sensor networks for improving precision of the estimated parameters. This idea was implemented by Bhushan et al. (2003) for retrofitting sensors from a fault diagnostic perspective as:

$$\textbf{Formulation II:} \quad \min_{x_j, q_j, u_{t,r}, x_s, U} [U - \alpha x_s] \tag{5}$$

subject to:

$$U \geq \log U_i, \;\; i = 1, ...m; \quad \sum_{j=1}^{n} c_j q_j + \sum_{t \in M_t} \sum_{r \in M_r} h_{t,r} u_{t,r} + x_s = C^* \tag{6}$$

$$x_j = q_j + x_j^* - \sum_{r \in M_r} u_{j,r}, j \in M_t, \notin M_r; \;\; x_j = q_j + x_j^* + \sum_{t \in M_t} u_{t,j}, j \in M_r, \notin M_t \tag{7}$$

$$x_j = q_j + x_j^* + \sum_{t \in M_t} u_{t,j} - \sum_{r \in M_r} u_{j,r}, j \in M_r \cap M_t; \;\; x_j = q_j + x_j^*, j \notin M_r \cup M_t \tag{8}$$

$$\sum_{r \in M_r} u_{j,r} \leq x_j^*, j \in M_t; \quad x_j, q_j, u_{t,r} \in \mathbb{Z}^+; \quad U_i \in \mathbb{R}^- \tag{9}$$

In the above formulation, x_j is the total number of sensors placed at j^{th} variable which is a sum of: new sensors (q_j), existing sensors (x_j^*), sensors reallocated to variable j ($u_{t,j}$) or away from variable j ($u_{j,r}$). $h_{t,r}$ is the cost for reallocating a sensor from variable t to r, M_t is the set of variables whose sensors can be reallocated to other variables and M_r is the set of variables which can receive sensors from other variables. Other constraints are as in Formulation I.

3. Reallocation Index Based Sensor Network

In the current work, we propose incorporation of reallocation index in the design of sensor networks. For a given sensor network, reallocation index (R_I) is defined as the total number of variables to which sensors can be transferred for a given sensor network:

$$R_I = \sum_{j=1}^{n} n_j \left(\sum_{k=1}^{n} M_{jk} \right) \tag{10}$$

where M_{jk} is the $(j,k)^{th}$ element of the reallocation compatibility matrix M, such that $M_{jk} = 1$ if sensor can be transferred from variable j to variable k and is 0 otherwise. The matrix M is assumed to be available during the design stage. n_j is a decision variable computed such that $n_j = 1$ if j^{th} variable is measured (irrespective of the number of

sensors placed on variable j) and is 0 if j^{th} variable is not measured. Our proposed base case design formulation is:

$$\textbf{Formulation III:} \quad \min_{x_j,U,x_s,n_j} [\lambda_1 U - \lambda_2 R_I - x_s] \tag{11}$$

subject to:

$$U \geq \log U_i, \;\; i = 1,....m; \quad \sum_{j=1}^{n} c_j x_j + x_s = C^* \tag{12}$$

$$n_j \leq x_j; \quad n_j \in \{0,1\}; \quad x_j \in \mathbb{Z}^+, j = 1,...n; \quad x_s \in \mathbb{R}^+; \quad U \in \mathbb{R}^- \tag{13}$$

with R_I as given in equation 10. In the above formulation, similar to the idea in Formulation I presented earlier, R_I is optimized while ensuring that U achieves its optimal value. The third objective x_s will minimize the cost used if the problem still has multiple solutions. The procedure for calculating weighting factors λ_1 and λ_2 to ensure this lexicographic optimization is given in Bhushan et al. (2008). The resulting optimization formulation is mixed integer linear programming (MILP) problem.

4. Case Study: Tennessee Eastman Process

The proposed optimization formulation incorporating reallocation index is applied to the Tennessee Eastman process (Downs and Vogel, 1993). The major unit operations in the process are: an exothermic two phase reactor, product condenser, flash separator, reboiled stripper and a recycle compressor. There are 50 measurable variables and 33 faults in the process (Bhushan et al., 2008). The data for sensor failure probabilities, fault occurrence probabilities, sensor costs and matrix B (bipartite matrix) which gives the information of fault affecting variables is taken from Bhushan et al. (2008). Sensor networks resulting from the proposed formulation (Formulation III) are tabulated in Table-1. These were obtained by solving the MILP optimization problems in CPLEX®. Corresponding to a given available cost C^*, the table lists the U, R_I and x_s values alongwith the sensors selected by formulation III. In the last column in the table, the number in bracket indicates the number of sensors selected. For example, 45(2) indicates 2 sensors are placed on variable 45. As expected, as the available cost C^* increases, the system unreliability of detection decreases or remains the same.

Comparison of Sensor Network Designs Obtained with and without Reallocation Index:
To demonstrate the utility of the resulting sensor networks the following numerical experiment is conducted for results obtained with $C^* = 6000$. Let S_1 be the sensor network obtained using proposed formulation for this case as listed in Table 1. Base case sensor network design without considering reallocation index (formulation I) is also obtained for $C^* = 6000$ as listed in Bhushan et al. (2008). Let this sensor network be labeled S_2. The two networks then are:

$S_1 = [1,2,3,4,5,6,8,9,13,42,43,45(2),46,47(2),48,49(2),50]$
$S_2 = [3,4,5,8,9,13,42,43,45(2),46,47(2),48,49(2),50]$

To evaluate the performance of the two networks after retrofit (using formulation II), the cause-effect matrix (A) which contains affect of original faults on variables as +1 (positive effect), -1 (negative effect), 2 (effect with unknown sign) and 0 (no effect) is randomly perturbed. This perturbation simulates unknown changes in the process. In particular,

randomly chosen +1 entries are changed to -1 or 2 and similarly randomly chosen -1 entries are changed to +1 or 2. The new fault-variable bipartite matrix B is generated again using single fault resolution procedure (Bhushan and Rengaswamy, 2002). With this bipartite matrix, reallocation and upgrade of the base case sensor networks is performed using formulation-II (with $C^* = 6000$) for two cases: first with S_1 and then with S_2 as the existing sensor network. This process is carried out for 1000 realizations. It was found that for about 73% of the cases, lower cost was used to retrofit network S_1 compared to the cost used for retrofitting S_2 while at the same time obtaining same or lower system unreliability. This demonstrates that incorporating R_I in the design stage has enabled efficient retrofit.

C^*	x_s	U	R_I	Sensors selected
1000	100	-2	8	1,2,3,4,13
4000	700	-2	11	1,2,3,4,6,7,13,22
6000	300	-5	12	1,2,3,4,5,6,8,9,13,42,43,45(2),46,47(2),48,49(2),50
10000	50	-8	12	1,2,3(2),4(2),5(2),6,8(2),9(2),13(2),42(2),43(2),45(3),46(2),47(3),48(2),49(3),50(2)

Table 1. Results for base case design with reallocation index

5. Conclusions

In this work, a novel concept of reallocation index is proposed for sensor network design. Incorporation of reallocation index during base case design ensures effective retrofit in future by creating possibilities for reallocation of sensors. The resulting optimization formulation is a mixed integer linear programming (MILP) problem. The utility of the approach is demonstrated on the Tennessee Eastman process for obtaining sensor networks that maximize fault diagnosis related criteria. Application of the proposed ideas for sensor network design for other objectives can also be investigated.

Abstract

Process monitoring is extremely important for producing high quality product and at the same time ensuring safe working environment in chemical process industry. Recently, it has been shown that selection of an appropriate subset of variables can improve the monitoring performance. The main contribution of this work is the development of a parallel version of the Genetic Algorithm-Principal Component Analysis algorithm which was proposed by Ghosh et al. [2] for variable selection. The developed algorithm has been implemented using NVIDIA's Compute Unified Device Architecture, CUDA parallel computing platform. Experimental results show that the proposed parallel approach is 12 times faster than the original serial code when applied to the Tennessee Eastman challenge problem.

Keywords: Genetic Algorithm, Compute Unified Device Architecture (CUDA), Graphics Processing Unit (GPU) parallel computing, Variable Selection.

1. Introduction

Process monitoring involves quick detection of process abnormal behavior as soon as the fault occurs, so that the corrective action can be taken promptly and losses can be minimized. Recently, it has been shown [1] that selection of an appropriate subset of variables can improve the monitoring performance. As the genetic algorithm-principal component analysis (GA-PCA) algorithm proposed in [2], the variable selection problem can be solved as a multi-objective optimization problem in which two objectives are (i) maximization of monitoring performance, and (ii) minimization of number of variables. This work was inspired by the successful deployment and acceleration of a wide variety of data mining and optimization problem through graphics processing unit computing. The objective of this work is to develop and evaluate the GPU version of a variable selection algorithm. Accelerated variable selection is desirable especially when large training dataset is involved. Furthermore, variable selection is required whenever process dynamics change is required. Since the variable selection problem is structured as a simulation optimization problem, the proposed parallelization approach with the use of GPU computing could be generalized and applied to a variety of simulation optimization techniques. Simulation optimization techniques are important tools in optimizing complex systems such as the supply chain management (SCM) system and decision support system (DSS), where expensive computational cost is known to be the major challenge for their practical applications. Hence, a computational efficiency improvement is highly desirable.

2. Graphics Processing Unit (GPU) Computing

GPU was originally designed for graphics rendering applications. Due to the massive parallelism of GPU by having many cores, GPU has evolved into General Purpose GPU (GPGPU) as a solution for tackling data explosion issues. Further development of GPGPU into GPU computing is done by introducing the general purpose programming interface as a replacement of the graphical programming API. Compute Unified Device Architecture (CUDA), developed by NVIDIA, is an architecture that attempts to harness the computing power of GPGPU. GPUs work as co-processors for CPU and this is done through incorporating CUDA kernels into the serial CPU program, from which computational acceleration can be achieved. A CUDA kernel is a function written in CUDA language, that when called, are executed N times in parallel by the N different CUDA threads.

Successful implementation of GPU computing include the parallel k-nearest neighbor algorithm developed in [3] which has achieved a 15 times speedup; [4] proposed the implementation of PCA on GPGPU with the use CUDA Basic Linear Algebraic Subroutines (cuBLAS) and 12 times acceleration was reported; [5] worked on an island model of GA which results in 7000 times speedup; and [6] reported the parallel GA algorithm was up to 400 times faster than the serial code. On the other hand, it has also been noticed that the application of GPU computing has been restricted to rather simple problems. The objective of this work is to study the performance of GPU computing on real life problem in the process monitoring perspective. This is done by developing and applying the parallel GA-PCA on the Tennessee Eastman challenge problem.

3. GPU implementation of GA-PCA

A PCA model for process monitoring can be constructed with all the measured process variables or a subset of these measured variables. In this work, we are interested to identify the subset of variables which is sensitive to faults; therefore a PCA model constructed using this subset is expected to have improved monitoring performance. To identify these variables, Ghosh et al. [2] proposed a multi objective GA-based stochastic optimization technique which minimizes the cumulative error rate, defined as sum of miss detection and false alarm rates, while at the same time minimizing the number of selected variables.

The main contribution of this work is the development of the parallel version of the GA-PCA algorithm which mainly involves the design of the CUDA kernel functions. Here, we propose to parallelize and include the most time consuming tasks of the serial GA-PCA code including PCA modeling and validation, in the CUDA kernels. Since the variable selection process is performed in MATLAB, the CUDA kernels are integrated into the MATLAB program through the use of MATLAB's MEX function.

The achieved computational efficiency improvement is closely related to a number of interrelated factors involved in the kernel design, and a series of experiments need to be carried so as to attain an optimal design. There are four important design factors to be discussed here in respect to GA-PCA algorithm. The first one is the execution configuration which includes both the grid size and block size. In evolutionary algorithm, it is intuitive to assume each chromosome as a block except for cases where the calculations for fitness value are extremely simple. In other words, the number of block in a grid is equal to the population size. As for the block size, as numerical methods like Jacobi transformation used for constructing PCA model are iterative

processes, it is more appropriate to have small thread block size. This is because large thread block will result in long waiting time at the point of barrier synchronization. Such waiting time becomes enormous as iteration increases. On the contrary, fitness evaluation in GA requires large thread block for optimal performance. This is because testing dataset is usually extremely large and the validation calculation on them tends to result in high computational intensity; besides the validation of testing sample is independent of each other, hence more threads are likely to provide higher parallelism without causing long waiting time. It should be noted that tasks require distinguished block size should be put into different kernels. The second design factor is the algorithmic level of parallelism. In PCA modeling step, a thread can be assigned a row or a column or a matrix element, in the case of fitness evaluation step, except for such element-level parallelism, a thread can also be assigned to a testing sample.

Memory type is another critical design factor need to be considered. In CUDA architecture, there are five memory types including global memory, texture memory, constant memory, shared memory and register. The different types of memory are characterized by memory bandwidth, lifetime, writability and the storage space. In the GA-PCA algorithm, data that is being modified repeatedly through thread cooperation such as covariance matrix, eigenvalues and eigenvectors should be stored in the shared memory if the size of data is sufficiently small. On the other hand, both training data and testing data may be too large to be stored in shared memory. In this case, global memory, texture memory or constant memory may be used since the data is for read only purpose. It should be noted that unique access patterns are required for texture and constant memory; otherwise global memory would be preferred. The last design factor to be covered here is the memory accessing pattern. Program developers should be aware that data transposition can sometime be used to take advantage of the coalesced memory access pattern of the global memory. Moreover, padding technique [7] which adds an extra column and/or row on matrix/vector may also help to reduce the occurrence of bank conflicts on shared memory. The objective of such techniques is to improve the memory transferring speed within GPU or between GPU and CPU. By considering these factors, a proposed parallel GA-PCA algorithm (in Matlab) is given in Fig. 1.

4. Application to Tennessee Eastman Challenge Process

The performance of the proposed parallel GA-PCA algorithm is evaluated by applying the algorithm to the benchmark Tennessee Eastman (TE) process. The TE process was designed for evaluating the performance of process control and monitoring, details can be found in [8]. TE process contains 52 process variables and 21 programmed faults. We have focused on 32 pre-selected variables. In this case study, the GA-PCA algorithm is used to identify the most informative variables that are affected significantly by the 21 programmed faults. The selected subset of variables is used to construct a reduced-PCA model [2] that has better monitoring performance as compared to a full PCA model with all the variables. The system used in this work is 32-bit Intel Core 2 Quad at 3.00GHz and 4.00GB of RAM, and an Nvidia Quadro2000 card.

Experimental results has shown that at the end of 1000 generations, the two objective values obtained from serial and parallel algorithm are equivalent for population size up to 1000. For instance, at population size of 100, both serial code and parallel code resulted in maximum 14 variables and the corresponding reduced-PCA models were reported to have comparable false detection rate, which is 0.26. On the other hand, the improvement in computation efficiency achieved by this parallel GA-PCA algorithm

was studied at various population sizes, as shown in Fig. 2. The optimal performance speedup was found at population size in the range of [40 80] which is about 12.4 times faster than the serial version; where the actual times are reduced from 10.3 min and 21.5 min to 0.8 min and 1.7 min at population size 40 and 80, respectively. Population size that is below this range, for instance 20 chromosomes in a population, results in only up to 10 times speedup. This is because the device resources like stream processors are not fully utilized. On the other hand, as population size increases beyond the point of 80, the computational speedup starts to decrease. There is only 3.47 times acceleration can be expected for population size equal to 1000. Such declining performance is due to the non-dominated sorting step which executes in serial fashion. This serial sorting step consumes significant amount of time when population size is large.

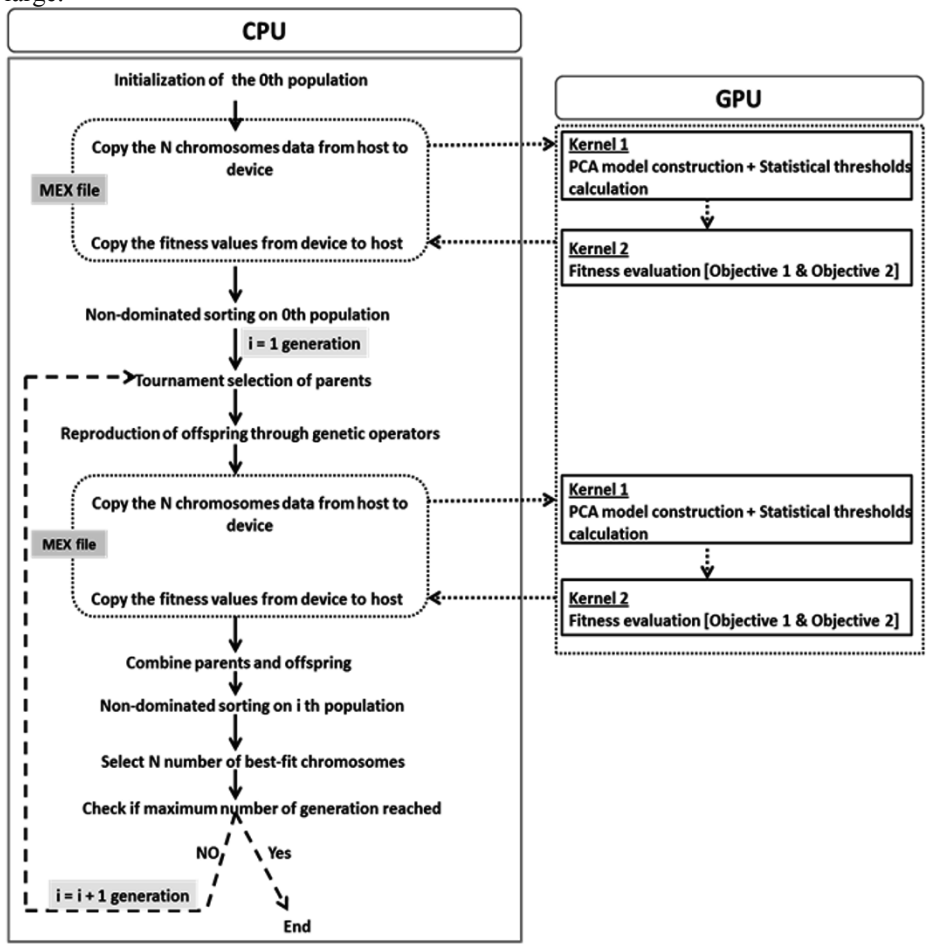

Figure 1: Heterogeneous/ parallel GA-PCA algorithm

5. Conclusions

The parallel GA-PCA algorithm proposed in this work has been shown to improve the computation efficiency of the serial program up to 12 times, when implemented on the Tennessee Eastman challenge problem which is considered as a real life process

monitoring problem. In order to identify the best computational acceleration possible with the proposed parallel GA-PCA algorithm, the effect of reducing the number of generation while keeping the same total amount of computation (by increasing population size) has to be studied and will be the subject of our future work. Future work should also extend to include applications where the size of data is too large to fit in the device memory space.

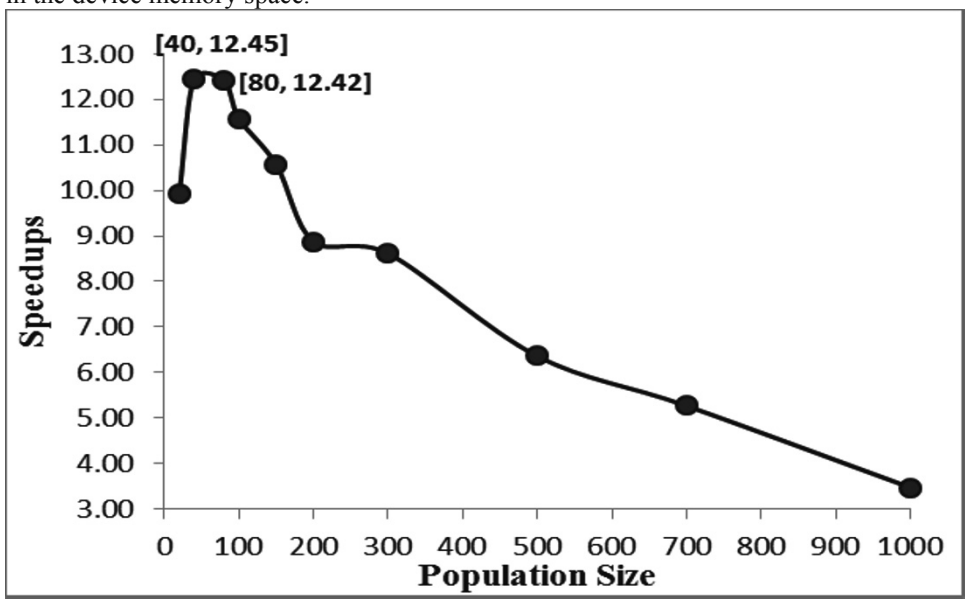

Figure 2: Speedups achieved by the parallel GA-PCA algorithm with respect to the serial algorithm. Experiments were conducted based on 1000 generations and 10 replicates of run. The relative standard deviations of the 10 runs are less than 5%.

Abstract

Chemical plants are now built to have large number of integrated and interlinked process units so as to optimize production and reduce waste. When an abnormal situation occurs, the automation systems alert the operators through alarms and help orient them to the new state. However, as most processes are highly-coupled, many simultaneous alarms can occur resulting in a flood of alarms. This can create confusion among operators, who must diagnose and rectify the fault before the condition escalates. Sometimes when the abnormal situation cannot be properly diagnosed, the operator will then activate the emergency shut-down, resulting in loss of productivity. In this work, we propose a novel alarm management framework, called *proactive alarms monitoring scheme* that provides operators with anticipatory information on incipient alarms that could happen within a certain time-window. This anticipatory information, which is built around a predictive algorithm, seeks to improve the sense-making facilities offered by the alarm system. As such, it allows plant operators to adopt a more proactive approach in managing alarm floods during various abnormal situations.

Keywords: Alarm Management; Hybrid Modeling; Process Monitoring

1. Introduction

Modern chemical plants are complex systems consisting of large number of process units. To optimize production of these plants, process operators and engineers depend on automation systems to extract information (e.g. through the thousands of sensors throughout the plant) and to assist them in the management of operations (e.g. through built-in controllers). When an abnormal situation occurs, there will be alarms which are presented on the operator monitoring screens to alert the operators. As modern chemical plants are highly interlinked and integrated (both up-stream and downstream), this may lead to many alarms occurring at the same time, causing a deluge of alarms, often called alarm flood (Liu et al., 2003, Liu et al. 2004). For inexperienced/novice operators, who rely primarily on alarms to diagnose faults, alarm flooding may lead to more confusion in the control room, resulting in information overload on the part of the operator. This causes the operators to become disoriented and when the problem cannot be promptly diagnosed, emergency shutdown would be triggered, resulting in loss of production, which is undesirable. On the other hand, experienced/expert operators, who have a more complete understanding of the process, tend to utilize trend displays to diagnose faults and predict future process states. This mental prediction helps them diagnose and rectify the abnormal situation early and prevent plant shut downs. While training novice operators to become experts can take years, one way to mitigate this performance gap is to use tools to aid young operators so that they perform just as well as experts. Expert

operators benefit from years of operational experience, which allows them to quickly understand and anticipate situations, as well as proactively initiate appropriate responses. Although younger operators may lack these knowledge and experience, technological intervention can help support and improve this manual decision-making process. One such example can be a predictive display, which provides the operator with information about the process' future state, so as to improve the operator's situation awareness and provide a longer lead time for action. In this paper, we explored a viable concept of developing a predictive alarm monitoring display to facilitate the performance of process control operators.

2. Proactive Alarms Monitoring Scheme

The utilization of predictive aids that help users anticipate future system states already exist in various other domains. For example, The Cockpit Display of Traffic Information found in modern jet airliners presents other aircrafts in the proximity and their trajectories, and alerts the pilots of any potential conflicts, thereby improving pilots' ability to anticipate and reducing their workload (Morphew & Wickens, 1998). Similar applications and benefits were also found in maritime (van Breda, 1990). A more familiar example is in hurricane forecasts, in which powerful simulations extrapolate where oncoming hurricanes will and will not strike. All these examples reflect the common technology of integrating available information in the system / environment to calculate a prediction, and present this result to the user during decision-making.

While predictive displays have been widely used in a variety of areas, it is still not practiced, particularly in the area of alarm management in chemical industries. In this work, a *proactive alarms monitoring scheme* with predictive capabilities is being developed such that control-room operators are provided with anticipatory information on incipient alarms that could happen within a certain time window. By providing this information, operators, both novice and expert, can obtain a complete sense of the true state of the process which would help them, localize and rectify the problem early before the plant reaches a dangerous operating state. Furthermore, the availability of this anticipatory information on alarms in advance of their actual occurrence reduces the confusion in the control room caused by alarm floods and allows efficient handling of abnormal situations.

The proactive alarms monitoring scheme is built around a predictive algorithm, which utilizes dynamic models of the process to anticipate the alarms. Developing dynamic models that are suitable for abnormal situations is particularly a challenge since it must take into account the structural and parametric changes to the nominal model of the process. As a result, these models do not get less and less reliable during abnormal situations when the process deviates further from the nominal operating point, something that existing models used in advanced process control systems (APC) faced. To develop these dynamic models, we proposed a new hybrid modeling strategy that utilizes both first-principles and data-driven modeling techniques. The predictive algorithm will then utilized this hybrid process model to offer an accurate short-term prediction of the rate-of-change of process variables which are then translated into predictions of time horizons for the occurrence of various alarms.

3. Case Study: A Depropanizer Unit

The development of the proactive alarms monitoring scheme is described using a simulation case study of a depropanizer unit. A schematic diagram of the unit is shown in Fig 1. The primary objective of the unit is to separate a feed mixture consisting primarily of C_3 and C_4 hydrocarbons, into two product streams. The lighter product consists primarily of C_{3s} and the heavier product consists of both C_{4s} and heavier hydrocarbons. The depropanizer unit has 24 measured process variables and each of them has its own alarm high and low limits. However, from the point of view of the operator, not all process variables have equal importance. For example, *FI16*, the flow indicator for hot oil to the reboiler, is not as important as compared to *TC11*, that control and highlight any temperature abnormalities for the 34th-tray which also dictates the temperature profile of the column. In this study, 9 process variables were selected for proactive alarms monitoring.

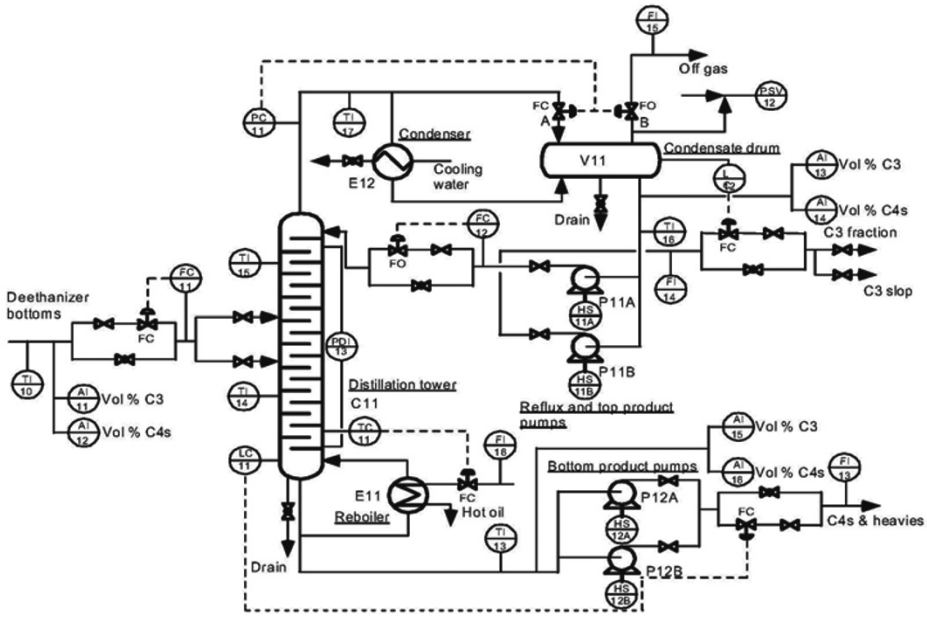

Figure 1.: Schematic diagram of a depropanizer unit

3.1. Predictive Algorithm

The predictive algorithm is built around a hybrid modeling framework that is used to predict the rate-of-change of process variables. In this case study, individual hybrid model for each process variable is developed. However, due to space constraints, only the steps for modeling of the tray temperature will be presented in this paper.

The temperature for *i*-th tray can be described by the following energy balance:

$$m_i \frac{d\Delta H_i^L}{dt} = L_{i-1}\Delta H_{i-1}^L + V_{i+1}\Delta H_{i+1}^V - L_i\Delta H_i^L - V_i\Delta H_i^V \quad (1)$$

where m, L, V, ΔH, represent the moles hold-up on the tray, liquid and vapor flowrates and the change in specific enthalpy (between a reference temperature, T_{ref} and its tray temperature) respectively. The subscript index denotes the tray number while the superscript index represents the type of flow. To facilitate the modeling development,

the following assumptions are made to Eq (1). One, it is assumed that the moles hold-up on each tray stay relatively constant and two, equimolar liquid and vapor flowrates are assumed. The terms ΔH_i^L and ΔH_i^V can be further expanded to $\Delta H_i^L = A_i^L(T_i - T_{ref}) + B_i^L(\frac{T_i^2 - T_{ref}^2}{2})$ and $H_i^V = \widetilde{V_i}\Delta P_i + A_i^V(T_i - T_{ref}) + B_i^V(\frac{T_i^2 - T_{ref}^2}{2})$, where T_i represent the temperature of *i*-th tray, ΔP_i represent the difference between the pressure of *i*-th tray (P_i) and a reference pressure (P_{ref}) and $A^L{}_i$, $B^L{}_i$, $A^V{}_i$, $B^V{}_i$ are constants describing the heat capacities of the liquid and vapour flow leaving the *i*-th tray. The above representations can be similarly used to describe ΔH_{i-1}^L and ΔH_{i+1}^V, respectively. The derivative of ΔH_i^L can be represented as $(A_i^L + B_i^L T_i)\frac{dT_i}{dt}$. The term $\widetilde{V_i}$ represent the molar volume of vapor flow which can be defined by the following equation $\widetilde{V_i} = \left(\frac{RT_i}{P_i} + \gamma_i RT_i\right)$, where γ_i is a constant that is used to account for any non-idealities in the vapour flow. It is further assumed that the heat capacities and gas properties are constant (e.g., $A^L{}_i = A^L{}_{i-1} = A$) since their variations between neighbouring trays (e.g. *i*+1, *i*-1 and *i*) are not strong. Rewriting Eq (1) based on the above assumptions, we have

$$\begin{aligned}\frac{dT_i}{dt} = & -\frac{B^L}{A^L}\left[T_i\frac{dT_i}{dt}\right] + \frac{1}{m_i}[L(T_{i-1} - T_i)] + \frac{B^L}{m_i A^L}\left[L\left(\frac{T_{i-1}^2 - T_i^2}{2}\right)\right] \\ & + \frac{1}{M_i A^L}\left[V\left(\frac{RT_{i+1}}{P_{i+1}}\right)\Delta P_{i+1} - V\left(\frac{RT_i}{P_i}\right)\Delta P_i\right] + \frac{\gamma_{i+1}}{M_i A^L}[VRT_{i+1}\Delta P_{i+1}] \\ & + \frac{A^V}{m_i A^L}[V(T_{i+1} - T_i)] + \frac{B^L}{m_i A^L}\left[V\left(\frac{T_{i+1}^2 - T_i^2}{2}\right)\right] - \frac{\gamma_i}{m_i A^L}[VRT_i\Delta P_i] \end{aligned} \quad (2)$$

Equation (2) is arranged in a way such that the terms on the left-hand side of the equation and in the square brackets are *known* while the rest of the terms are *unknown* constants. In this form, data-driven modeling techniques, such as linear regression can be performed using simulated plant data sets obtained during different abnormal situations to determine the unknown constants. Note that the training of Eq (2) using different set of plant data will generate different sets of constants, as such it is important to select the right set of plant data for training so that the set of constants that are determined offers good prediction capabilities even during abnormal situations whose plant data are not used for training. To aid us in this selection, a metric that compares the actual with the predicted times of a process variable that is about to hit its alarm limits is developed and is given as: $Metric = \frac{\left(\sum_{i=j}^{N}|\hat{t_i} - t_i|\right)}{(N-i+1)}$, where *j* represent the *j*th time instant when the prediction starts and *N* represents the time instant just before the alarm is triggered. Times $\hat{t_i}$ and t_i represent the predicted and actual times of the process variable at the *i*th time instant respectively. By using such a metric system, we can then select the set of constants with the lowest metric value to be used in Eq (2). Similar steps are used in developing the hybrid models for other process variables. Once the hybrid models for the process variables are developed, they can be used to predict a time horizon for the occurrence of each individual alarms. This information is then passed on to the operators through a proactive alarms monitoring display. A prototype of the display is shown in Fig. 2. In this display, the alarms of the depropanizer unit are grouped into various regions e.g., the level alarm for reflux drum (LC12) is placed under the "REFLUX DRUM" region while the bottom temperature (TI13) is placed under the "REBOILER" region. This helps reduce the complexity of

the display and allows operator to identify and understand the alarms in a systematic manner. The alarm display shows the temporal trends of the alarms in two panes, one showing alarms that have occurred in the recent past (e.g. 5 min) and the other showing incipient alarms as per the model prediction. An alarm summary containing the "Area of Interest" helps operators to focus on the region where the fault may originate. This will save the operators' time in identifying the problem and allow them to focus in bringing the plant back to safe operation.

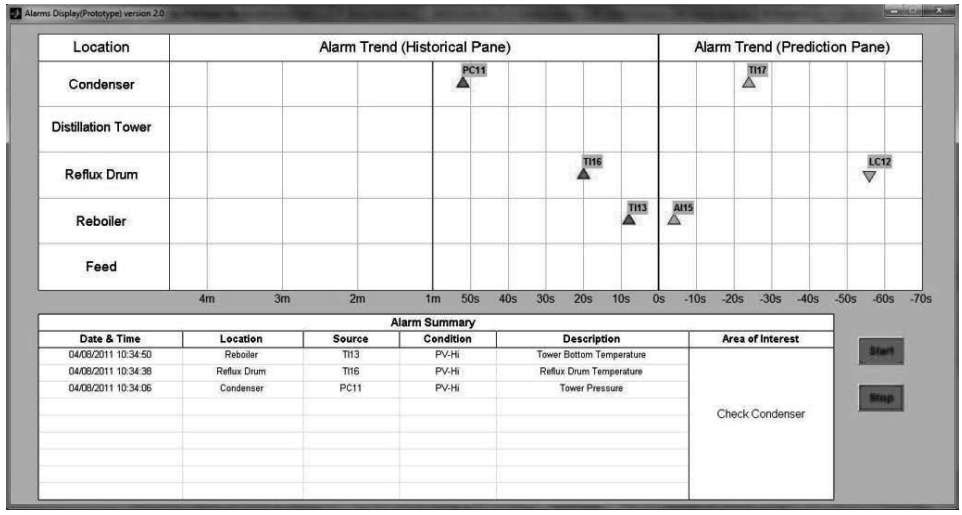

Figure 2: Prototype of proactive alarms monitoring display

4. Conclusion

In this paper, an alarm management framework, known as proactive alarms monitoring scheme is developed. This scheme has two primary objectives: (1) to provide operators with anticipatory information on incipient alarms that could happen within certain time-window and the likely abnormal situation that has occurred, and (2) to allow the operators to identify and rectify the problem early before the plant reaches a dangerous operating state. The scheme is built around a predictive mechanism that utilizes hybrid modeling techniques to predict the rate-of-change of process variables within the plant. The predicted rate-of-change of process variables are then translated into predictions of occurrence of various alarms. The historical record of alarms together with the predicted ones can be displayed to the operator to enable effective sense making. A case study of a depropanizer unit is used to illustrate the development of the proposed alarm monitoring scheme.

Synthesis of Large-scale Multi-stream Heat Exchanger Network Based on Pseudo-temperature Enthalpy Diagram Method Combined with Superstructure Method

Jilong Li, Jian Du*, Zongchang Zhao, Qingwei Meng, Pingjing Yao

Institute of Process Systems Engineering, Dalian University of Technology, Dalian, 116012, Liaoning, China

Abstract

This paper introduces a new approach for optimizing heat exchanger networks (HEN), which combines pseudo-temperature enthalpy diagram method and superstructure method. The approach focusing on the minimization of total annual cost, uses a simplified superstructure to solve the sub-networks which obtained by a pseudo-temperature enthalpy diagram, and also involves multi-stream heat exchangers as exchange units. An example taken from literature is studied here. The result of the study indicates the effectiveness and advantages of this methodology.
Keywords: pseudo-temperature enthalpy diagram; superstructure; heat exchanger network; multi-stream heat exchanger

1. Introduction

Traditional methods of heat exchanger network optimization can be generally divided into mathematical programming methods and heuristic ones. Although many studies have been done on these areas during last several decades, there are still flaws in each kind of methods. For example, the complexity of superstructure which grows with the scale of the problem exponentially limits the applicability of this method. Also a pseudo-temperature enthalpy diagram method[6] based on the pinch program can get a network that has the minimum thermodynamic area by the division of enthalpy interval with low complexity, it can rarely get the optimal solution due to the deficiency of various networks. As these are considered, a combined method is presented. Taking advantages of both methods mentioned, this method uses a pseudo-temperature enthalpy diagram to get a series of sub-networks and solve them by superstructure.

On the other hand, a multi-stream heat exchanger is used more widely in process industry thanks to the development of technology. Compared with a two-stream heat changer, a multi-stream one has higher efficiency, more compact and lower cost. There are mainly two categories of multi-stream heat exchanger, multi-channel heat exchanger and plate-fin heat exchanger. The former one can handle one cold stream and two or more hot streams or vice versa, called as one vs. more multi-stream heat exchanger, while the later one can handle both more than two cold streams and hot streams, called more vs. more multi-stream heat exchanger here. In this study, only one vs. more multi-stream heat exchanger is used because of the industry situation of the case and the convenience of program editing. A more vs. more multi-stream heat exchanger can be obtained by a further reorganization.[1,2]

2. Method representation

The method is illustrated in Sections 2.1 and 2.2. The fundamental stages are represented in Section 2.1. The practical calculation procedures are showed in Section 2.2.

2.1. Fundamental stage

Stage 1: Get a initial network by pseudo-temperature enthalpy diagram.

Get a set of ΔT_C^i as initial values according to the correlation equation (Xiao, 2005)[5]:

$$\Delta T_C^i = \sqrt{\frac{a_i h_r}{a_r h_i}} \cdot \frac{T_i^2}{T_r^2} \cdot \Delta T_C^r \tag{1}$$

This equation gives a relationship between each stream's ΔT_C^i. The best ΔT_C^i that can offer a minimum heat transfer area per heat load has been proved to relate to a_i and h_i.[3] Moreover, a later research found it also relating to the stream's temperature. To get a set of ΔT_C^i, a reference stream is needed, which is chosen by experience. However, this group of ΔT_C^i is just used as a group of initial values for the pseudo-temperature enthalpy diagram, and it still need to be optimzed by an intelligent algorithm.

Stage 2: Merge adjacent enthalpy intervals and construct sub-network.

The merging only occurs in ordinary enthalpy intervals which excluding hot/cold utility streams. First, a **Merge Array**, consisting of some Boolean variates, is defined to judge whether to merge the corresponding enthalpy intervals. The size of the merge array is one less than the number of ordinary enthalpy intervals. Each member of the array represents the judgment of merger: True means merging, while False means not.

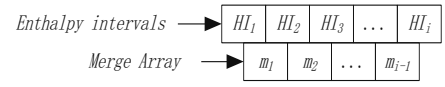

Fig. 1. Illustration for Merge Array

The merging begins with simply adding streams together. Any stream in the chosen intervals will exist in the new interval with its original property. After obtaining the new intervals, several possibilities exist:

Case 1. The number of streams is less enough (4 for cold/hot streams respectively in this study). All streams in the new intervals compose a sub-network directly.

Case 2. The number of streams is more than that. The following methods are proposed to simplified the sub-network:

Find out common streams existing in every original interval among cold and hot streams respectively. Merge these common streams according to the similarity of their heat transfer coefficient, until the number of streams becomes lower than the threshold value. A **Pseudo-stream** is named to describe the merged common stream, and its inlet and outlet temperatures are set as the lowest one if it is a hot stream, while the highest one if it is a cold stream to satisfy feasibility of heat transference. All pseudo-streams and other unmerged streams compose a sub-network. After synthesizing the network, pseudo-streams are split into real streams to match other streams if needed. All these treats are realistic thanks to the feature of multi-stream heat exchanger.

Stage 3: Optimize sub-networks by superstructure.

An improved two-stage non-isothermal mixed superstructure model (Fig. 2.) is used here. The features are illustrated as follows:

(i) There is no utility involved in this model. Obviously, the sub-network consists of several enthalpy intervals which have already attain heat equilibrium.

(ii) The outlet temperature of each branch needs not to be coincident. This extends the flexibility of candidate for structure.

(iii) One more branch without match is added in this model. This alteration covers the solution space more intuitively, and is beneficial for program editing.

Stage 4: Synthesize the finial network

Joint the results of each sub-network obtained in **Stage 3** and initial results of the intervals without merged in **Stage 1** together. Then total annual cost can be calculated, and is used as the object for optimizing.

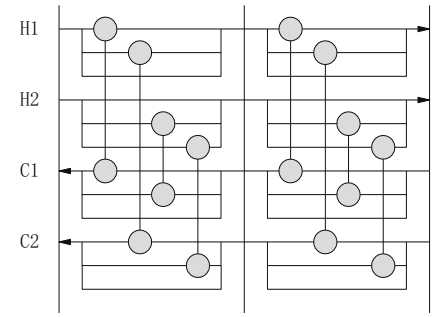

Fig. 2. A two-stage non-isothermal mixed superstructure

2.2. Practical calculation procedure

The stages above are realized in a program. Procedures are detailed as following:

(i) Generate a set of ΔT_C^i by heuristic method;
(ii) Use pseudo-temperature enthalpy diagram method to get a group of enthalpy intervals and synthesize an initial network;
(iii) Generate a merge array and initialize it randomly;
(iv) Merge certain enthalpy intervals according merge array and obtain sub-networks by the rules given above;
(v) Optimize sub-networks by superstructure method;
(vi) Optimize the merge array and repeat step iv and v until reach the convergence condition;
(vii) Optimize the set of ΔT_C^i and repeat step ii to vi until reach the convergence condition.

The optimization uses a simulated annealing and genetic algorithm (SA/GA). The convergence condition is set as: no evolution in 30 generations.

3. Case Study

An 11-stream problem (9 hot streams and 2 cold streams) is used to give an illustration of the new method. This case is taken from a reorganization project of the oil refinery system in a Chinese plant. It has been used in Wei's paper (2004)[4] and Xiao's paper (2006)[6]. The details of the process data are shown in Table 1. There is only one kind of cold/hot utility respectively. The cost of all heat exchangers (including coolers and heaters) in this case is calculated by the model: $1000A^{0.6}$\$/a, and heat transfer coefficient is calculated by $U=1/(1/h_h+1/h_c)$ kW• m^{-2}• K^{-1}.

In this study, as C2 has the largest enthalpy rate, it is selected as a reference stream. The ratios of other streams' temperature difference contribution value can be calculated by eq.(1). It can be found that C1 has the least one, so ΔT_C^i of C1 is set as 5℃, a temperature difference coefficient, and then other streams' ΔT_C^i can be obtained, as shown in Table 2. This group of ΔT_C^i is used as initial values in the calculation program. After 304 seconds' computation, an optimal solution can be obtained. It is compared with other results from literatures in Table 3, and the optimal network is shown in Fig. 3.

Details of the optimal solution gained are illustrated as following:

First, an initial network is obtained by pseudo-temperature enthalpy diagram method, and there are 12 enthalpy intervals and 19 heat exchangers. The total cost is 7,532,314\$• a^{-1}. Then the 2nd, 3rd, 4th, 5th, 6th and 7th enthalpy intervals are chosen to be merged into one and a simplified sub-network can be gained by our strategies, so as the 8th and 9th ones, and the 10th and 11th ones. (This chosen pattern is just a result due to the SA/GA.) After solving these three sub-networks by superstructure method respectively, and taking the results back to the initial network, the final result is obtained. In the final result, the number of heat exchangers decreases to 16, which mainly reduces the cost.

The total annual cost obtained by our method has a decrease by 12.49% compared with HEXTRAN's result, a decrease by 5.38% with that obtained using superstructure method by Wei[4] and a decrease by 4.91% with that obtained using pseudo-temperature enthalpy diagram method by Xiao[6]. The total area in this study is a little more than that by Wei, but quite more than that by Xiao. However, the utility cost decreases a lot. The reason is that a superstructure is used to search an optimal structure, but this disobeys the vertical match rules and leads to an increase in total area. However, a superstructure method is just a sub-optimization, and after the global optimization, the utility cost must be set to a low level to complete the optimal mission. This result also indicates the efficiency of our method for a large scale network.

4. Conclusion

This paper has presented a combined method jointing pseudo-temperature enthalpy diagram and superstructure together. Some strategies of merging enthalpy intervals and constructing sub-networks are proposed to realize the combined method such as introducing a Merge Array and rules for simplifying sub-network. A large scale problem is turn into several small scale problems in order to decrease the complexity of calculation. Besides, some improvements are brought to the model of superstructure to make it more suitable for editing program and calculating to improve the flexibility of structures. An example has been studied in this work to show the application of the proposed methodology. A relatively better result is obtained. Because of the division,

complexity is quasi-linear with scale instead of explosive. This makes our methodology suitable for a large scale problem. Further work could aim towards the improvement of the strategies. Some heuristic rules should be proposed to synthesis a sub-network directly instead of using superstructure. Though it may lose the optimal solution, it can simplify calculation extremely.

A New Tool For Simultaneous Targeting And Design Of Heat Exchanger Networks

Sharifah Rafidah Wan Alwi,[a] Zainuddin Abdul Manan[a], Misrawati Misman[a]

[a]*Process Systems Engineering Centre (PROSPECT), Faculty of Chemical Engineering, Universiti Teknologi Malaysia, 81310 Skudai, Johor, Malaysia.*

Abstract

Pinch analysis is a well-established methodology for the design of processes to achieve the minimum utility requirements. The Composite Curves (CCs) is a popular pinch analysis tool to determine the minimum energy targets. An efficient alternative to CCs is a numerical technique known as Problem Table Algorithm (PTA). However, the PTA does not fully show individual hot and cold streams heat cascade profile and cannot be used for Heat Exchanger Network (HEN) design. This paper introduces the Segregated Problem Table Algorithm (SePTA) as a new and versatile numerical tool for simultaneous targeting and design of a HEN. SePTA shows profiles of heat cascade across temperature intervals for individual hot and cold streams, and can be used to simultaneously locate pinch points, calculate utility targets and perform SePTA Heat Allocation (*SHA*). The *SHA* can be represented on a new SePTA Network Diagram (SND) that graphically shows a heat exchanger network together with the amount of heat exchange on a temperature interval scale. The new method is illustrated using a case study.

Keywords: Segregated Problem Table Algorithm (SePTA); heat allocation; network diagram; numerical; heat exchanger network.

1. Introduction

Heat pinch analysis is a popular and effective technique which allows utility targets to be determined using a graphical technique such as Composite Curves (CC) [1, 2] or a numerical technique such as Problem Table Algorithm (PTA) [2]. Other latest numerical techniques include the Simple Problem Table Algorithm (SPTA) [3], geometry-based approach [4], enthalpy flowrate and temperature technique [5], PTA with multiple utilities [6], Unified Targeting Algoritm (UTA) for diverse process integration problems [7] and Grid Diagram Table (GDT) that combines numerical and visualization tools [8]. All these methods require targeting and design to be done separately. Simultaneous targeting and design using a graphical method called Segregated Temperature vs. Enthalpy Plot (STEP) has recently been proposed [9]. The key advantage of STEP is its ability to clearly show the allocation of heat sources to demands since it is constructed based on individual streams as opposed to composite streams.

This paper presents the Segregated Problem Table Algorithm (SePTA) as a new numerical tool for simultaneous targeting and design of a maximum energy recovery network. SePTA is an extension to STEP (Streams Temperature vs. Enthalpy Plot) [15] which shows the profiles of heat cascade across temperature intervals for continuous individual hot and cold streams. SePTA can be used to simultaneously locate the pinch points, calculate the utility targets and conveniently perform network

design that overcomes the limitations of PTA. Though SePTA yields the same results as STEP, it can vitally complement the STEP technique in terms of accuracy as well as speed, and in terms of its amenability to computer programming. Table 1 represents the stream data for an illustrative case study that will demonstrate the application of SePTA.

Table 1: Example 1 stream data (ΔT_{min} = 10°C).

Stream	Supply temperature, T_s (^{0}C)	Target temperature, T_t (^{0}C)	Flowrate heat capacity, FCp (MW/^{0}C)	Entalphy, ΔH (MW)	Shifted supply temperature, T_s' (^{0}C)	Shifted supply temperature, T_t' (^{0}C)
H1	170	126	9	-396	165	121
H2	270	93	7	-1239	265	88
C1	60	160	5	500	65	165
C2	116	260	8	1152	121	265

2. SePTA for simultaneous targeting and design

2.1. SePTA for targeting

The targeting procedure using SePTA is described as follows:

1. The first step is to change the original hot temperature (T_h) and cold temperature (T_c) data into shifted temperatures (T_h' and T_c'). Using shifted temperatures effectively builds ΔT_{min} into heat exchange process and allows hot and cold streams to touch during stream matching and facilitates pinch point search. Assuming a minimum temperature approach (ΔT_{min}) of 10°C, the last two columns of Table 1 show the streams' shifted temperatures for the illustrative case study.
2. These temperatures are then sorted in descending order into temperature intervals, leaving out the temperatures which are common to both hot and cold streams.
3. Draw the arrow that shows the supply and target temperatures for all the hot and cold streams.
4. Begin by choosing the largest FCp hot stream for each temperature interval to determine the set of streams that will form Hot STEP 1. For example, Table 2 shows that between temperature intervals of 244°C to 165°C, there is only H2. Hence, H2 is chosen. Between 165°C and 155°C, both H1 and H2 exist. Since H2 (FCp = 5 kW/^{0}C) has a bigger FCp as compared to H1 (FCp = 3 kW/^{0}C), H2 is chosen. This procedure is repeated for all intervals.
5. Repeat step 4 to determine the set of streams to form the next hot STEP by extracting the remaining hot streams from the intervals with multiple streams. Referring to Table 2, for example, the set of streams to form Hot STEP 2 are determined from the remaining hot streams after Hot STEP 1 has been constructed. Between the temperature intervals of 165^{0}C and 121^{0}C, the remaining hot stream is H1.
6. Repeat steps 4 and 5 to determine the streams to form the continuous cold STEPs.
7. For each hot STEP and cold STEP, calculate the net heat capacity flowrate by deducting the heat capacity flowrates of the cold stream from the hot stream (see columns 11 and 12, Table 3).
8. FCp_{net} for each STEP is then multiplied with the temperature interval to get the net heat surplus (positive value) or deficit (negative value) for a given interval (see columns 13 and 14, Table 2.

9. Starting with a zero heat input at the highest temperature, cumulatively add the net enthalpy (surpluses or deficits) down the temperature intervals, to get an overall net enthalpy cascade (see columns 15 and 16, Table 2).
10. The cascade in step 9 normally contains negative heat flows and is thermodynamically infeasible. In order to have a feasible heat cascade, take the absolute value of the largest negative heat flow from this "infeasible heat cascade" and add this amount of heat as hot utility to the highest temperature interval in the cascade shown in the next column (Columns 17 and 18). All the net heat flows in the cascade now increase by this amount, and the minimum value becomes zero. Note that if all the values in step 9 are nonnegative, then step 10 is not required and the result remain as in step 9.
11. The heat added to the first available interval is the hot utility requirement (target) $QH_{STEP\ i}$. On the other hand, the summation of the heat removed from the final interval is the cold utility target $QC_{STEP\ j}$. The pinch point is the point(s) at which there is zero net heat flow in the cascade. From Table 2, the minimum hot and cold utilities are the total from the two STEPs. Hence, the minimum hot utility is 643.5kW and the minimum cold utility is 34.5kW. The shifted pinch temperature for this problem is 88^0C.

2.2. SePTA Heat allocation

The heat allocation can be determined by constructing SePTA Heat Allocation (SHA) as follows:

1. Rewrite all the stream selected for hot and cold STEP 1 from Table 2 with enthalpy for each temperature interval as shown in columns 7, 8, 10,11 and 12, 13, 15, 16 in Table 3.

2. Starting from the top of the column, cascade available heat from hot STEP 1 down the interval temperatures (columns 7 and 8) to cold STEP 1 (columns 10 and 11) (normally, hot utility will be the first match from hot STEP). Considering the minimum driving force for heat exchange (ΔT_{min}) that is built in the heat cascade, the hot streams interval temperature can be higher than or equal to cold streams interval temperature for feasible heat transfer.
3. In order to achieve minimum utility requirement, there should be no heat transfer across the pinch.
4. Repeat all steps to construct heat allocation for STEP 2.

Table 3: SePTA Heat Allocation.

2.3. SePTA Network Diagram

For better visualisation of the overall heat exchanger network (HEN), the SePTA heat allocation (*SHA*) can be converted into SePTA network diagram (SND) as shown in Figure 1. SND shows the heat exchanger locations for each hot and cold stream. It also shows the temperature supply and target for each heat exchanger according to scale as well as the corresponding heat load. Note that the exact stream mapping as well as the quantity of heat exchange is extracted from SePTA heat allocation (SHA) performed in the previous section.

3.Conclusion

A new numerical tool for simultaneous utility targeting and design of maximum energy recovery (MER) network known as the SePTA has been introduced as an extension for

STEP [15]. SePTA are profiles of heat cascade across temperature intervals for individual hot and cold streams, and can be used to simultaneously locate pinch points, calculate utility targets and perform SePTA Heat Allocation (*SHA*). The *SHA* can be represented on a new SePTA Network Diagram (SND) that graphically shows a heat exchanger network together with the amount of heat exchange on a temperature interval scale.

Abstract

The existing hyperstructure for the simultaneous heat exchanger network synthesis (HENS) have embedded the alternative structures excluded by a stagewise superstructure. However, the existing hyperstructure-based approaches employs pinch-based transshipment model and do not simultaneously allow cyclic matching. In this work, we propose a simultaneous mixed-integer nonlinear programming formulation based on a hyperstructure of multistage stream superstructures. We include cyclic matching, avoid the pinch-based transshipment model and allow exchangers for utilities in each stage. Using several examples, we demonstrate the significant advantages of our approach compared to those from the literature.

Keywords: heat exchanger network synthesis (HENS); hyperstructure; mixed-integer nonlinear programming (MINLP); optimization; superstructure

1. Introduction

Energy is the essence of life. Without access to affordable alternative energy, how to utilize limited fossil energy efficiently will remain a key issue for the foreseeable future. The chemical process industry consumes extensive energy to produce utilities for heating and cooling process streams. Because of its holistic and optimal integration between the hot and cold process streams and utilities to reduce energy usage, heat exchanger network synthesis (HENS) has gained intense and significant attentions in both practice and research for several decades.

In general, the HENS problem is to derive a network of 2-stream heat exchangers (HEs) with minimum total annualized cost (TAC), which integrates given sets of hot and cold process streams and utilities with known flow rates, heat contents, and inlet and outlet temperatures. There are two main approaches for HENS, sequential and simultaneous. The simultaneous approach is considered as more attractive as it does not rely on the concept of pinch and holistically trade-offs the various factors (utility usage, number and areas of HEs) that impact TAC. The simultaneous approach, as a result, can increase the possibility of obtaining better networks. Most of the simultaneous synthesis methods employ a stagewise superstructure (Yee and Grossmann, 1990) of possible 2-stream matches of HEs and assume isothermal mixing to eliminate the nonlinear energy balance for substream mixing at each stage. The limitations of this multistage superstructure and isothermal mixing assumption are well established in the literature by Huang et al. (2012). Floudas and Ciric (1989) developed a hyperstructure allowing non-isothermal mixing and cross flow. Subsequently, Ciric and Floudas (1991) combined this hyperstructure with the pinch-based transshipment model of Papoulias

and Grossmann (1983) to simultaneously select optimal heat exchanger network (HEN) for a variable heat recovery approach temperature. However, unless in advance dividing those streams into two substreams based on the pinch temperature, the hyperstructure-based model does not allow cyclic matching, which may help to decrease the requirement of HE area at the expense of using more numbers of units in some cases and give superior HENs with less TAC. Furthermore, the limited attention on the hyperstructure-based approach may be attributed to the fact that applying the pinch-based transshipment model needs to partition the temperature interval, which depends on a predetermined temperature interval approach temperature (TIAT). Whenever, a poor choice of TIAT may lead to a suboptimal network. The challenge, therefore, is to establish a generalized superstructure-based model that accounts for all the possible HEN configurations.

In this work, we propose a simultaneous model based on a hyperstructure of stagewise stream superstructures to address HENS. Specially, we focus on including the certain alternatives in the HEN configurations which the stagewise superstructure neglects. We present examples in which cross flows not accounted by the existing literature eliminate superior HENs. We propose an MINLP model that avoids the pinch-based transshipment model and allows exchangers of process streams with utilities in each stage. We then solve several examples to demonstrate the significant advantage of our approach and compare the results with those from the literature.

2. MINLP Formulation

Consider the well-known HENS problem with two types of streams, process and utility, we use i for hot streams, j for cold streams, and s for any stream. Thus, we need to decide the inlet and outlet temperatures along with the flow rates for each HE in the final network with minimum TAC. We base our formulation on a hyperstructure of multistage stream superstructures shown in Figure 1. This is a combination of the one used by Huang et al. (2012) and the one proposed by Floudas and Ciric (1989). It comprises K stages $(k = 1, 2, \dots, K)$ with $I \cdot J$ potential 2-stream exchangers in each stage. Furthermore, in each stage, splitters are located at the inlet of the stream to the network and at the exits of each HE; mixers are located at the inlets of each HE, and at the exit of the stage. We let $K \geq 2$ allow possible cyclic matches between a hot and a cold process stream. Then let hot (cold) utility streams i (j) enter stage k, and also exit from stage k. Thus, hot (cold) utilities can be used to adjust the temperature of the cold (hot) process streams in each stage. In this work, as done by Huang et al. (2012), we also use similar constraints for the energy balances for each stage and each HE, and bounds for key inlet and outlet temperature variables.

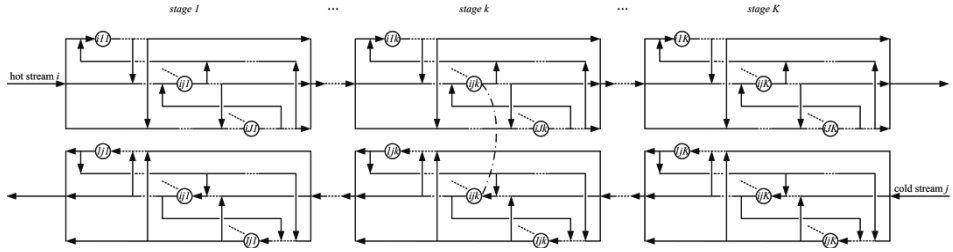

Figure 1 Hyperstructure of multistage stream superstructures

Because of mixing with cross flows, the temperatures of the substreams into the exchangers can be different from the temperature of their parent stream. Thus, we need

additional variables for the flows and temperatures of substreams and cross flows at each stage. Let f_{ijk} (g_{ijk}) denote the fractional flow of hot (cold) stream i (j) used in HE_{ijk}. Let f_{ijk}^{in} (g_{ijk}^{in}) denote the fractional flow of the substream split from hot (cold) stream i (j). let $f_{ijk}^{j'}$ ($g_{ijk}^{i'}$) denote the fractional cross flow split from the substream of hot (cold) stream i (j) following $HE_{ij'k}$ ($HE_{i'jk}$). Then, the mass balances for the mixers at the inlets of exchangers are:

$$f_{ijk} = f_{ijk}^{in} + \sum_{j'} f_{ijk}^{j'} \tag{1}$$

$$g_{ijk} = g_{ijk}^{in} + \sum_{i'} g_{ijk}^{i'} \tag{2}$$

Similarly, let f_{ijk}^{out} (g_{ijk}^{out}) be the fractional flow of the substream to reform hot (cold) stream i (j) after HE_{ijk} in stage k. Then the mass balances for the splitters at the outlets of exchangers are given by:

$$f_{ijk} = f_{ijk}^{out} + \sum_{j'} f_{ij'k}^{j} \tag{3}$$

$$g_{ijk} = g_{ijk}^{out} + \sum_{i'} g_{i'jk}^{i} \tag{4}$$

Additionally, we need the energy balance for the mixer at the inlet of HE_{ijk} to determine the corresponding flow rates of cross flows for both hot and cold streams.

Finally, the HENS objective of minimum TAC is given by,

$$\begin{aligned}\text{TAC} = {} & \sum_i \sum_j \sum_k UC_i Q_{ijk} + \sum_i \sum_j \sum_k UC_j Q_{ijk} + \\ & \sum_i \sum_j \sum_k \left[FC_{ijk} x_{ijk} + CA_{ijk} \left(\frac{Q_{ijk}}{FT_{ijk} U_{ij} LMTD_{ijk}} \right)^{\beta_{ijk}} \right]\end{aligned} \tag{5}$$

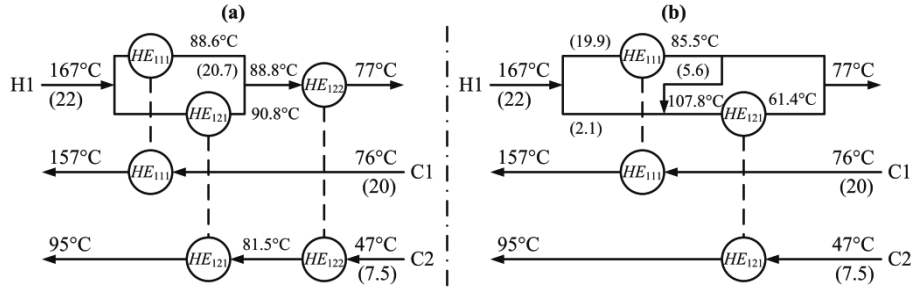
where, UC_s is the unit cost of utility s; FC_{ijk}, β_{ijk}, and CA_{ijk} are the appropriate cost coefficients for HE_{ijk}; U_{ij} is the overall heat transfer coefficient for HE_{ijk}; and $LMTD_{ijk}$ and FT_{ijk} are the LMTD and LMTD correction factor respectively for HE_{ijk}. This completes our MINLP formulation, and we call it **M**, which comprises Eqs. (1)-(5) along with the appropriate energy and mass balances, and logical constraints.

3. Examples

We now solve three examples from the published literature to demonstrate the effectiveness of our approach. We use BARON/GAMS and limit its solution time since its convergence is slow. In order to compare our approach with those existing in the literature, we assume $FT_{\text{ijk}} = 1$.

3.1. Example 1

This example from Biegler et al. (1997) involves a process with one hot process stream (H1), two cold process streams (C1-C2), one hot utility, and one cold utility. Figure 2 shows the best HENs from **M**. It has a TAC of \$76,327 with three exchangers and is the same as obtained by Huang et al. (2012). As in Figure 2(a), H1 matches first against C2 in HE_{121} at stage 1, and then it matches with C2 again in HE_{122} at stage 2. To illustrate the impact of this cyclic matching, we use $k = 1$ for this example and resolve it. **M** then gives a HEN (Figure 2(b)) with two HEs and TAC=\$77,913. Obviously, the previous optimal configuration is eliminated from the hyperstructure based model excluding cyclic matching. Thus this small example merely serves to validate our model and show the advantage by using the hyperstructure of multistage stream superstructures instead of one-stage stream superstructures.

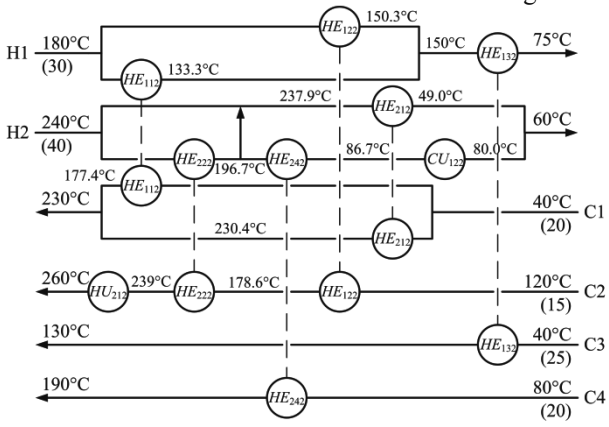


* The numbers within the brackets are heat content flows (kW/°C)

Figure 2 Final HENs from **M** for Example 1

3.2. Example 2

This is taken from Björk and Westerlund (2002). It consists of two hot (H1-H2) and four cold (C1-C4) process streams with one hot and one cold utility. **M** yields an HEN (Figure 3) with six exchangers, one heater, one cooler and TAC = \$123,398. This TAC is 3.72% and 11.3% lower than the best TACs of \$128,169 and \$139,083 reported by Huang et al. (2012) and Björk and Westerlund (2002), respectively. While the utility usage of our HEN is the same as that for the optimal HEN of Huang et al. (2012), it has lower HE areas with the same amount of exchangers.



Exchanger	Heat load (kW)	Area (m^2)
HE_{112}	21.4	0.946
HE_{122}	878.6	106.0
HE_{132}	2250.0	83.9
HE_{212}	3778.6	533.6
HE_{222}	906.4	175.2
HE_{242}	2200.0	327.3
HU_{212}	315.0	7.0
CU_{122}	315.0	5.9
Total		1240.0

Annualized utility cost = \$44,100
Investment = \$79,298
Total annualized cost = \$123,398

* The numbers within the brackets are heat content flows (kW/°C)

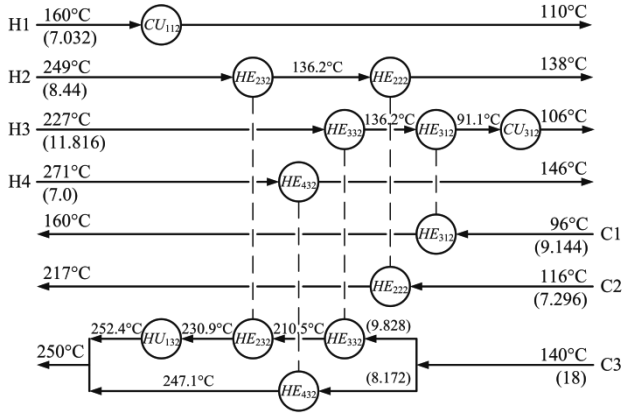
Figure 3 Final HEN from **M** for Example 2

Note that there is a cross flow between H2's substreams from the outlet of $HE_{222}$to the inlet of HE_{212}. Thus, the existing HENS formulations based on stagewise superstructure exclude such possibly optimal structures and may give suboptimal solutions as in this example. Also it is worth mentioning that there is a cooler (CU_{122}) at H2's substream, similar scenario would be eliminated by the widely used assumption that utilities are used only adjust the final stream temperatures for the sake of simplicity. Thus, an HENS model with this assumption cannot admit the HEN in Figure 3 and may give suboptimal solutions for this example.

3.3. Example 3

This example is from Trivedi (1988). It involves four hot process streams (H1-H4) and three cold process streams (C1-C3), with heating and cooling utilities provided by steam and cooling water. The optimal network (Figure 4) from **M** features a TAC of \$105,403 for eight matches, which is 7.91% lower than that (TAC = \$114,460 with 12

matches) reported by Ciric and Floudas (1991). Although the cyclic matching is not the issue with this example, our simultaneous model indeed gives a better network, since it does not rely on pinch-based transshipment model. Furthermore, as in Example 2, our HEN allows a heater (HU_{132}) at C3's substream. This configuration is also excluded in the hyperstructure based synthesis approaches by Floudas and Ciric (1989) and Ciric and Floudas (1991). Again, this example shows that our proposed formulation can obtain better results than those reported with other methodologies.



Exchanger	Heat load (kW)	Area (m^2)
HE_{222}	736.9	65.5
HE_{232}	199.9	15.2
HE_{312}	585.2	50.9
HE_{332}	693.3	39.6
HE_{432}	875.0	84.3
CU_{112}	351.6	8.2
CU_{312}	151.3	5.9
HU_{132}	211.8	4.6
Total		274.2

Annualized utility cost = \$27,000
Investment = \$78,403
Total annualized cost = \$105,403

* The numbers within the brackets are heat content flows (kW/°C)

Figure 4 Final HEN from **M** for Example 3

4. Conclusion

We presented a model based on the hyperstructure of stagewise stream superstructures for HENS. The novelties in our model include certain configurations that both the stagewise superstructure and existing hyperstructure neglect. Our model also avoids applying the pinch-based transshipment model. By solving three literature examples, we demonstrate that our model admits better solutions that existing HENS formulations cannot admit.

Improvement in Strategy for Design of Heat Exchanger Networks using Multiagent Framework

Naoki Kimura*, Kizuki Yasue, Kei Kobayashi, Yoshifumi Tsuge
Dept. of Chemical Engineering, Faculty of Engineering, Kyushu University; 744 Motooka, Nishi-ku, Fukuoka 819-0395 Japan

Abstract

In this study, a multiagent approach was applied into design of energy-saving chemical processes using pinch technology. We have introduced various strategies for simplification of heat exchanger network (HEN) to HEN design agents. Although large and complicated processes were optimized by the multiagent system, there were several cases where the HEN simplification had stopped at the insufficient and inadequate stages. Therefore we improved the strategy to make more preferable HENs. And we showed the effectiveness of improvement and our multiagent framework.

Keywords: Heat exchanger network, Multiagent system, Pinch technology.

1. Introduction

Post-Kyoto Protocol negotiations on greenhouse gas emissions reduction have been held for sustainable environment. Although there are several problems to achieve fairness, effectiveness and reasonability of the new agreements, there is a broad international consensus that reductions of the energy consumption and the emissions of greenhouse gases are required to prevent the global warming. Pinch technology is one of the commonly used energy-saving technologies in the chemical industries. Despite pinch technology has been incorporated in the process simulation software, the skilled engineers' considerations are required to make preferable heat exchanger networks (HEN). We have introduced a multiagent oriented simulation framework Kimura et al. (2010) into the HEN design to save the energy usage and to reduce the emissions of greenhouse gases. We set up several "HEN design agents" and each had different strategy to search candidate segments to be changed through the HEN. In our previous study, it was possible to optimize the HEN for the small and medium-scale processes. But there were several cases where the HEN simplification stops at the inadequate stage. In this study, we will introduce new strategies to search candidate segments. And we will show the effectiveness of the new algorithms and our multiagent framework.

2. Multiagent Framework

2.1. Multiagent Framework for HEN-Design using Pinch Technology

To design energy-saving chemical processes, we adopted "pinch technology" (Linnhoff and Flower (1978)) in our framework. In this section, the workflow of the HEN design will be explained. Fig.1 shows a schematic diagram of our multiagent framework. The *Human Operator*— who is on the upper-left of Fig.1— gives basic process information (*i.e.* PFD, stream data profile and available utilities) to the *Project Manager*.

*nkimura@chem-eng.kyushu-u.ac.jp

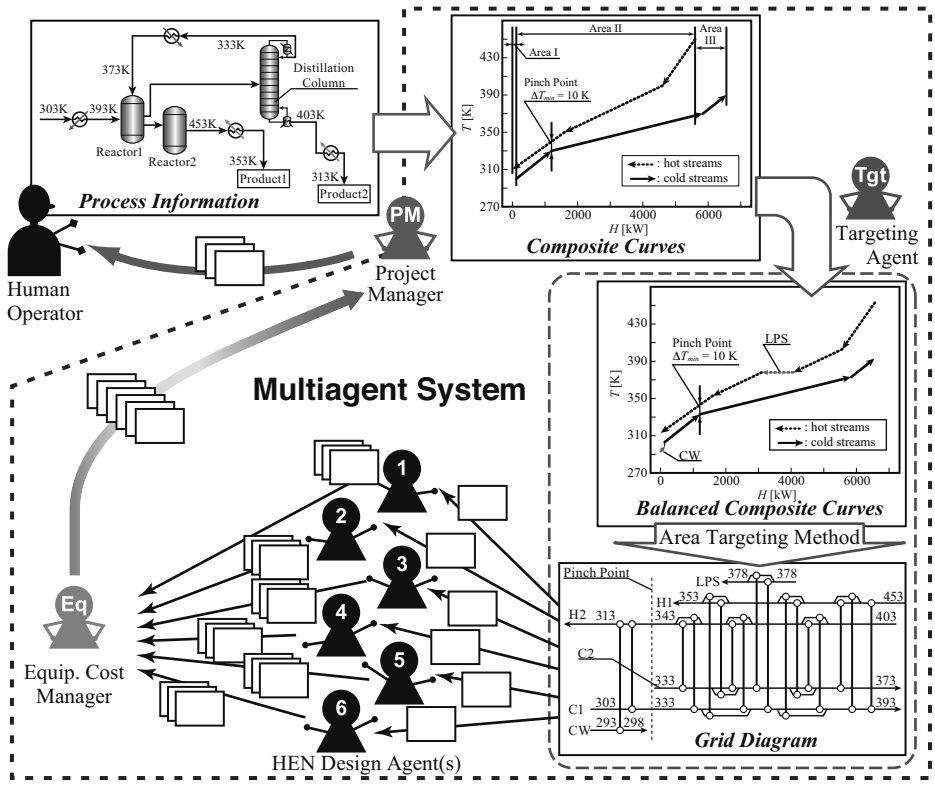

Figure 1. Schematic view of our multiagent framework.

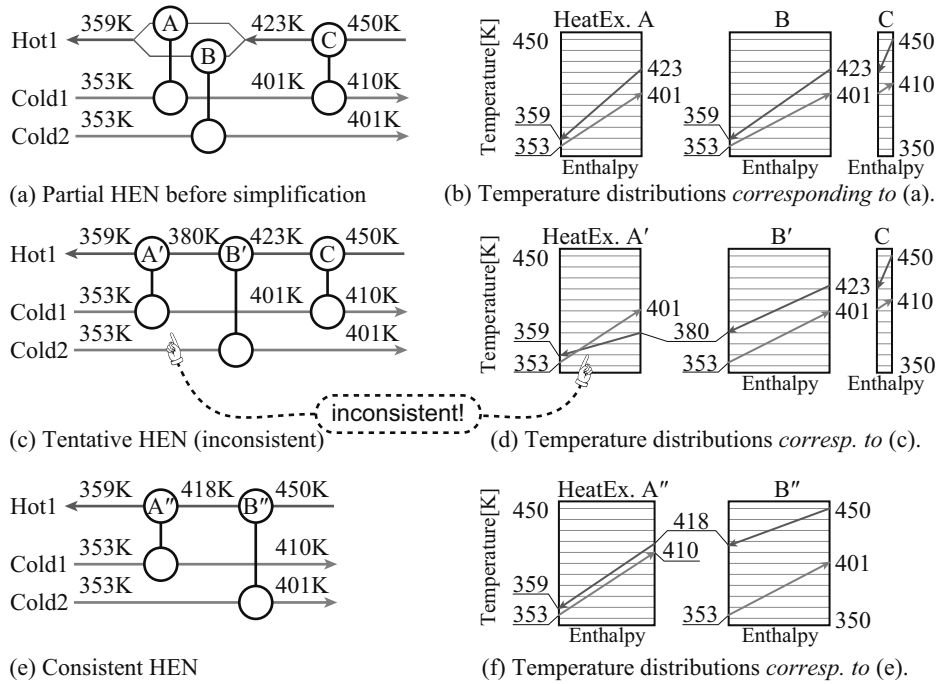
The *Project Manager* is an interface between the human operator and the multiagent system. Then, the *Project Manager* makes "composite curves" and gives it to the *Targeting Agent* (upper-right of Fig.1) via TCP/IP communication. The *Targeting Agent* decides the utility allocation and the amount of heat recovery constrained by ΔT_{min} (minimum approach temperature). As a consequence, the *Targeting Agent* makes "balanced composite curves". Then, the *Targeting Agent* converts the "balanced composite curves" into the initial HEN—which is expressed in "grid diagram"— using "area targeting method". When using the "area targeting method", the sum of heat transfer area is minimized due to the heat transfer within the each vertical section where the balanced composite curves partitioned at each inflection points. Therefore the numbers of both the heat exchangers and the branches of the process streams increase and the network gets complicated. For example, there are 17 heat exchangers and 11 branches in the grid diagram on the lower right of Fig.1. Then it would be preferable if the HEN has been simplified. In our framework, strategies for simplification of HEN were defined and each *HEN Design Agent* has different strategy. And the *HEN Design Agents* receive the initial HEN from the *Targeting Agent*. Then, each *HEN Design Agent* respectively makes alternative HENs by simplifying step by step by following its own strategy. And they send the informa-



(a) Partial HEN before simplification

(b) Temperature distributions *corresponding to* (a).

(c) Tentative HEN (inconsistent)

(d) Temperature distributions *corresp. to* (c).

(e) Consistent HEN

(f) Temperature distributions *corresp. to* (e).

Figure 2. Grid diagrams and temperature distributions of partial HENs.

tion about alternative HENs to the *Equipment Cost Manager*. When the *Equipment Cost Manager* receives information about HEN, "an equipment cost (*i.e.* investment cost) of the HEN" was calculated by summing up the each estimated equipment costs of all the heat exchangers involved in the HEN. After calculating the equipment costs of all the alternatives, the *Equipment Cost Manager* makes a shortlist of HENs, whose equipment costs are low, to send to the *Project Manager*. The *Project Manager* also picks out several alternatives from the shortlist according to the other criteria such as complicacy of the network. And the *Project Manager* sends back the selected several alternatives to the *Human Operator*. Finally, the *Human Operator* is able to make decision on the HEN design based on not only the structure information of the HEN but also the estimated values of the criteria provided from the multiagent system.

2.2. Strategy for HEN simplification

There are several steps to simplify the network structure of HEN. First of all, it is necessary to search the HEN for the specific partial structures, such as "loop"(a partial structure which consists of several heat exchangers, hot and cold streams circularly traceable in the grid diagram) and "split"(a partial structure where a hot/cold stream is split into several sub-streams to feed into parallel heat exchangers). Steps such as *"DeleteLoop"*, *"DeleteWideScaleLoop"* and *"ReduceSplit"* are defined. Fig.2(a) shows a grid diagram of partial HEN—there are one heat giving stream (Hot1), two heat receiving stream (Cold1, Cold2) and three heat exchangers (HeatEx.A, B, C). There is a branch on Hot1,

Table 1. Stream data and available utilities for 4SP problem.

Stream/Utility Name		Temperature [K]		ΔH	Utility Cost
		Inlet	Outlet	[kW]	[$/kW/yr]
Heat giving streams	H1	443.0	333.0	3,300	-
	H2	423.0	303.0	1,800	-
Heat receiving streams	C1	293.0	408.0	2,300	-
	C2	353.0	413.0	2,400	-
Heating utility	Steam	450.0	450.0	-	80.0
Cooling utility	Water	293.0	313.0	-	20.0

in which the stream is split 44%:56% to change the heat with Cold1 through HeatEx.A and with Cold2 through HeatEx.B respectively. Fig.2(b) shows temperature distributions of each heat exchangers in Fig.2(a). To simplify the HEN through a step *"ReduceSplit"*, the split on Hot1 will be reduced, that is, the relationship between HeatEx.A and B will be changed from parallel connection to serial connection (the names of heat exchangers are also changed to A′ and B′). Usually, the outcome network is consistent and different from the one before the step was carried out. And the other step would be applied to the new HEN one after another. Occasionally, the new structure of the HEN brought by the step would not meet the constraints conditions such as heat balance and temperature differences. Fig.2(c) shows a tentative HEN in which HeatEx.A′ is inconsistent. Because the temperature of the heat giving stream of HeatEx.A′ is lower than that of the heat receiving stream (shown in Fig.2(d)).

In our previous study, such a step—which brings inconsistent HEN— is not permitted to be carried out. Therefore, there are few cases where the HEN simplification stops at the insufficient stage, because any of the steps could not make consistent HEN, it just come to a dead end. In this study, we improved the strategy to permit to execute the strategies even if the resultant HENs are inconsistent—it can expect that the HENs may satisfy the constraint after some series of steps were applied. Fig.2(e) shows a consistent HEN where HeatEx.A′ and HeatEx.C in Fig.2(c) are combined through a step *"DeleteLoop"*. In this partial HEN, the number of heat exchanger was reduced from 3 (in Fig.2(a)) to 2 to simplify the HEN. However, it must be noted that the inconsistent HENs could not adopted as the final solutions.

3. Simulations and Results

3.1. 4SP problem description

This process is popular problem, studied by many research groups. There are two hot streams (H1, H2) and two cold streams (C1, C2). The stream data and available utilities are presented in Table 1. And ΔT_{min} is 5.6 K.

3.2. Simulation results

Table 2 shows the comparison of energy consumption, the numbers of the heat exchangers and branches, and annualized sum of equipment cost. The given process is consuming

Table 2. Comparison among HENs for 4SP problem.

Description	Energy consumption [kW]		Num. of heat ex. [-]	Num. of branches [-]	Annualized cost [k$/kW/yr]
	Heating utility	Cooling utility			
Given problem without heat recovery.	4,700	5,100	-	-	-
The initial HEN achieved heat recovery target w/o simplification.	0	400	15	11	139.6
An example of the optimized HEN by the previous strategy.			11	5	115.7
An example of the optimized HEN by the improved strategy.			**6**	**0**	**84.5**
The optimized HEN using differential evolution by Yerramsetty et al.	0	400	6	1	83.8
The optimized HENs using randomized algorithm by Pariyani et al.	0	400	5	0	83.3
			6	1	85.3

4700 kW of heating utility and 5100 kW of cooling utility. Using pinch technology, the energy consumption is considerably reduced to no heating utility and 400 kW of cooling utility. However the numbers of heat exchangers and branches are large in the initial HEN. By using our previous strategy, the simplification was stopped at the insufficient stage—where there are still 11 heat exchangers and 5 branches. On the other hand, by using the improved strategy, the number of heat exchanger is reduced to 6 and the number of branches is also reduced to 0. Comparing the numbers of heat exchangers and branches, and the annualized cost with the results of Yerramsetty and Murty (2008) and Pariyani et al. (2006), the optimized HEN by the improved strategy was simplified sufficiently.

4. Conclusion

In this paper, the strategy of HEN simplification using pinch technology and multiagent framework was improved. The results show that the improvement was effective and adequate to get sufficiently simplified HENs.

Abstract

This paper presents a novel method for process heat exchanger network integration and decomposition: Clustering Approach. The objective of this new approach is to reduce the complexity of the integrated structure, construction and maintenance cost simultaneously. The main idea of this approach is to divide the original system into two or more clusters (subsystems) under several optimisation constrains such as piping and other investment cost, hot and cold stream matches. The results of utilities and investment cost for both original and clustered system are compared. The outcome of this study indicates effectiveness, potential and further application of the novel method.

Keywords: process integration, decomposition, clustering, heat exchanger network, optimisation

1. Introduction

1.1. Process Integration

Heat integration was proposed by Linnhoff and Flower (1978) initially in realising the potential of energy saving through heat exchanger networks (HEN) design. Two major approaches have been developed for optimal synthesis of heat exchanger network: pinch technology (Itoh et al., 1982; Kemp, 2007; Smith, 2005) and mathematical programming methods (Biegler et al., 1997). Mathematical optimisation methods for HEN synthesis can be classified as sequential and simultaneous approaches. Works based on the simultaneous approach solve the problem without any decomposition, and can explicitly handle the trade-offs between the network's capital and operational costs.

1.2. Decomposition technique

Despite the sound development of HEN, there are deficiencies in the field of network integration that are yet to be tackled. One of which is the network complexity when dealing with large network. Long computational time and impractical remote heat exchange are resulted due to HEN complexity. Model size reduction techniques had been developed for application in various disciplines. For example, the analysis of large scale production and supply networks by Lam et al. (2011), reactive batch distillation optimisation by Khazraee et al. (2011), etc. In this paper, decomposition approach is applied to reduce the HEN complexity. Heat exchangers are grouped into two or more subsystems (clusters). A novel heat network design by integrating the decomposition approach based on heat exchanger area and network piping contribution via mathematical programming is presented.

2. Model formulation

The mathematical formulation for typical HEN optimisation can be found elsewhere in Ortega et al. (2008) and Yee and Grossmann (1990). In case of proposing decomposition method to the basic heat integration model, the following equations were added and the objective function is formulated to develop the clusters. To every heat exchangers included in the superstructure, a binary variable, y_k is associated by equations:

$$A_k \cdot y_k - A_k = 0 \qquad k \in E \tag{1}$$

where k is set of heat exchangers within the superstructure, A_k / m^2 is the area of the existing heat exchanger k, y_k is a binary variable related to heat exchanger k.

The binary variable activated by previous equations is connected with binary variable, $y_{k,c}^{Cluster}$, ensuring the heat exchanger k to be included in only one cluster c:

$$y_k - \sum_c y_{k,c}^{Cluster} = 0 \qquad k \in E \ \wedge \ c \in C \tag{2}$$

where E denotes all heat exchangers preset in the superstructure, c is a set of possible clusters and $y_{k,c}^{Cluster}$ is a binary variable connecting heat exchanger k to cluster c. It should be nothed that by fixing the value of binary variable $y_{k,c}^{Cluster}$ on zero we can forbid heat exchanger k to be included in cluster c due to the technical or operational disadvantages.

2.1. Definition of heat exchanger's contribution to a particular cluster based on the heat exchanger area

The total area of heat exchangers belonged to cluster c, $A_c^{Cluster}$ / m^2 is given by equation:

$$A_c^{Cluster} = \sum_k A_k \cdot y_{k,c}^{Cluster} \qquad k \in E \ \wedge \ c \in C \tag{3}$$

The upper and lower bound for the total area of heat exchangers in cluster c are defined to avoid the possibility to join all clusters together into one:

$$A_c^{Cluster} - A^{Cluster,UB} \leq 0 \qquad c \in C \tag{4}$$

$$A_c^{Cluster} - A^{Cluster,LB} \geq 0 \qquad c \in C \tag{5}$$

where $A^{Cluster,UB}$ / m^2 is the upper bound for the total area of heat exchangers in clusters and $A^{Cluster,LB}$ / m^2 is the lower bound for the total area of heat exchangers in clusters.

The contribution of heat exchanger k to cluster c, $a_{k,c}^A$, based on its area is calculated as a ratio between the area of heat exchanger k and the total of heat exchangers in cluster c:

$$a_{k,c}^A = \frac{A_k \cdot y_{k,c}^{Cluster}}{A_c^{Cluster}} \qquad k \in E \ \wedge \ c \in C \tag{6}$$

2.2. Definition of heat exchanger's contribution to a particular cluster based on the pipe length associated with the heat exchanger

The total length of piping connected to heat exchanger k, PL_k / m is given as:

$$PL_k = \sum_{\substack{l \\ l \neq k}} PL_{k,l}^H \cdot z_{k,l}^h + \sum_{\substack{l \\ l \neq k}} PL_{k,l}^C \cdot z_{k,l}^c + \sum_s PL_{s,k}^I \cdot y_{s,k}^{In} \qquad k,l \in \mathrm{E} \ \wedge \ c \in \mathrm{C} \ \wedge \ \mathrm{s} \in \mathrm{S} \tag{7}$$

where S denotes all hot and cold process streams in the superstructure, $PL_{k,l}^H$ / m is the length of new pipeline connecting the hot ends of heat exchangers k and l, $PL_{k,l}^C$ / m is the length of new pipeline connecting the cold ends of heat exchangers k and l, $PL_{s,k}^I$ / m is the length of new initial pipeline of stream s to heat exchanger k, $z_{k,l}^h$ is a binary variable to denote the pipeline connecting exchangers k and l at the hot ends, $z_{k,l}^c$ is a

binary variable to denote the pipeline connecting exchangers k and l at the cold ends and $y_{s,k}^{In}$ is a binary variable to denote the inlet stream s is assigned to exchanger k.

The total length of pipeline within cluster c, $PL_c^{Cluster}$ / m, is:

$$PL_c^{Cluster} = \sum_k PL_k \cdot y_{k,c}^{Cluster} \qquad k \in E \ \wedge \ c \in C \tag{8}$$

The upper and lower bound for the total length of the pipeline in cluster c are:

$$PL_c^{Cluster} - PL^{Cluster,UB} \leq 0 \qquad c \in C \tag{9}$$

$$PL_c^{Cluster} - PL^{Cluster,LB} \geq 0 \qquad c \in C \tag{10}$$

where $PL^{Cluster,UB}$/ m is the upper bound for the total length of the pipeline in clusters and $PL^{Cluster,LB}$ / m is the lower bound for the total length of the pipeline in clusters.

The contribution of heat exchanger k to cluster c, $a_{k,c}^{PL}$, based on the associated piping length is given:

$$a_{k,c}^{PL} = \frac{PL_k \cdot y_{k,c}^{Cluster}}{PL_c^{Cluster}} \tag{11}$$

The objective function for the clustering model is to minimise the contribution of heat exchangers to the clusters:

$$Obj = \sum_k \sum_c a_{k,c}^{A} + \sum_k \sum_c a_{k,c}^{PL} \tag{12}$$

3. Case study

A case study, which considers four hot and four cold non-isothermal process streams and the network pipelines, is developed. In the superstructure, 10 heat exchangers are available for service. The streams data for the case study is presented in Table 1. The piping costs parameters are tabulated in Table 2 and Table 3.

The MINLP models formulated are solved in GAMS 23.4.3 with the solver DICOPT. The HEN is first divided into 3 clusters by applying the previously described approach and then heat integration is performed within each cluster. A general model based on minimum utility requirement in Figure 1 and a clustered model in Figure 2 are presented as the outcomes of HEN optimisation. The results of the models are listed in Table 4. The resulting heat exchanger area requirement and piping cost are compared.

Table 1: Stream data for case study.

10	6364	3162	3905	5000	2062	3536	3354	2121	2550	0

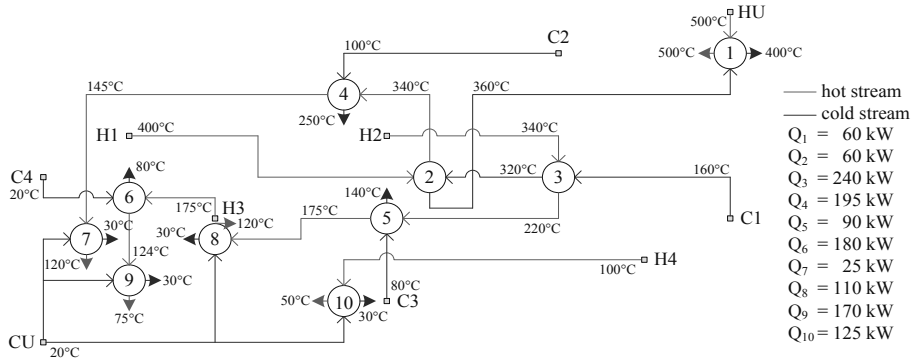

Figure 1: The existing heat exchanger network of the general model.

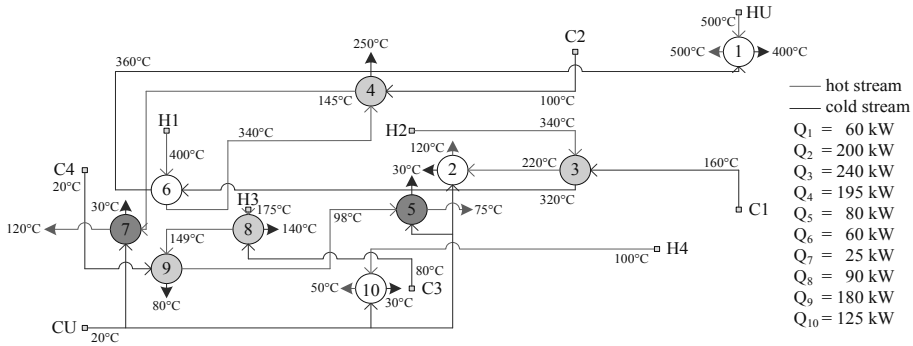

Figure 2: The clustered heat exchanger network based on optimised clustering model.

Table 4: Results comparison for case study.

	Existing model	Clustered model
Total heat exchanger area (m^2)	31.00	31.24
Total exchanger area cost ($/yr)	11778	11869
Total utility cost ($/yr)	14600	14600
Total capital piping cost ($/yr)	69278	63537
TOTAL annual cost ($/yr)	95656	90006

* Heat exchanger area cost = $380/$m^2$.yr

* Utility cost = $100/kW.yr for hot utility and $20/kW.yr for cold utility.

The clustering of the model network yields a cost saving from the reduction in piping costs incurred. However, it is noted that the clustered model brings an increment to the heat exchanger area requirement, thus incurring higher heat exchanger capital cost.

Better result may be obtained if other indicator such as maintenance cost is considered. It should be noted that the utility requirement is not static but varying with the HEN design and any additional utility allocation. The model clustering may render the annual cost saving in certain cases due to any additional utility needed.

Nevertheless, the clustering approach is effective in model size reduction. This improves the computational performance by capping a limit to the number of variables. The approach will be particularly useful for large HEN retrofit, i.e. petro-chemical refineries, as well as other outsized models, i.e. country supply chain optimisation.

4. Conclusions and Future Work

This paper investigates the effectiveness of clustering approach on heat network size reduction. A clustering method based on heat exchanger area and piping length contribution is formulated. 6% of annual cost saving is achieved through the implementation of clustering approach on HEN design, even for a small HEN.

Future work should implement the clustering approach on greater size case study that consists of more than ten hot and ten cold streams to significant the contribution of the approach. A more detailed formulation should be generated which considers more accurate piping cost, piping insulation, maintenance cost, heat exchanger incurred cost together with the utility costs. A multi-objective integration is suggested to solve this extended problem.

Controllability of three types of dividing wall columns

Chuan-Chen Chao and Jeffrey D. Ward

Department of Chemical Engineering, National Taiwan University, No. 1, Sec. 4, Roosevlt Road, Taipei, 106, Taiwan

Abstract

We investigated the pairing of controlled and manipulatd variables and the overall controllability of three types of dividing wall columns (with the dividing wall in the upper, lower and middle section of the column; DWCL, DWCU and DWCM, respectively) using steady-state and dynamic controllability measures. Dividing wall columns were designed for the separation of a mixture of three species with constant relative volatilities, for different values of the relative volatilities and feed compositions. The steady-state processes were simulated in Aspen Plus and the relative gain arrays, non-square relative gain array and condition number were determined for each case using the steady-state model. Finally, the dynamic responses of the processes were simulated in Aspen dynamics and an integral error criteria was used to compare the performance of different control structures. The results indicate that generally DWCL is favorable if the intermediate-boiling species is most plentiful in the feed, and DWCU is preferable in other cases.

Keywords: Divided Wall Column, Process Control

1. Introduction

A dividing wall column, first proposed by Wright[1] in 1949, is a kind of integrated process in which separation between three or more species is accomplished in a single vessel through the use of one or more dividing walls. Pioneering research on the design of dividing wall columns using Underwood's method was conducted by Fidkowski and Krolikowski.[2–3] Studies have shown that in some cases dividing wall columns can significantly reduce capital and energy cost compared to conventional multi-column processes.[4–5] However, industrial application of dividing wall columns remains relatively limited, in part because of the increased difficulty of designing and controlling the integrated unit.[6]

Control of divided wall columns has received some attention in the literature.[6–18] However, almost all research conducted so far on the control of dividing wall columns has considered the case where the wall is located in the middle of the column and there is only a single reboiler and condenser. Another option which as received much less attention is for the dividng wall to extend to either the top or bottom of the column so that there are two condensers or reboilers, respectively. This changes the number of degrees of freedom and the control options.

In this work we investigate control loop pairing and controllability of three different types of dividing wall columns for a variety of feed compositions and different values of the ease of separation index (ESI).

2. Model development and column design

2.1. Thermodynamic model

In this work, a ternary system with species A, B and C is considered. All species are assumed to have constant relative volatilities. Three different cases are considered, which correspond to different values of the ease of separation index (ESI) which measures the relative difficulty of the A/B split to the B/C split: ESI>1 ($\alpha_A/\alpha_B/\alpha_C$=7.1/2.2/1), ESI=1 ($\alpha_A/\alpha_B/\alpha_C$=4/2/1) and ESI<1 ($\alpha_A/\alpha_B/\alpha_C$=4/2.4/1). This was achieved in Aspen by modeling the saturation vapor pressure using Antoine's equation and adjusting the values of the Antoine coefficient A and the normal boiling point of the species to give the desired constant relative volatility.

2.2. The three types of dividing wall columns

Three different types of dividing wall columns were considered as shown in Figure 1. For DWCL, the dividing wall is located in the lower part of the column and touches the bottom, so there are two reboilers and one condenser. DWCM is the most common type of dividing wall column, in which the dividing wall is locatd in the middle of the column and there is one condenser and one reboiler. Finally, for DWCU the dividing wall is located at the top of the column and there is one reboiler and two condensers.

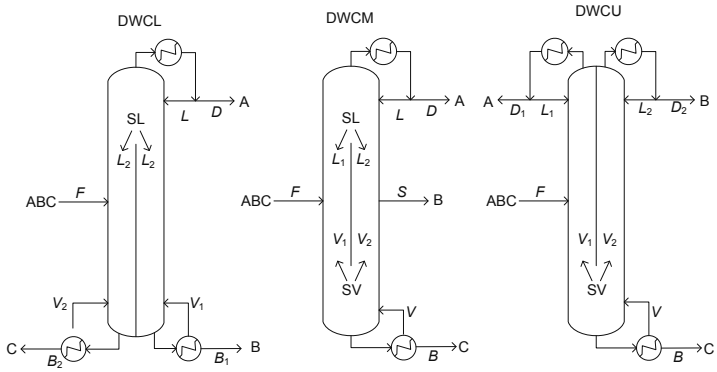

Figure 1. Three types of divided wall columns with notation.

For each reboiler there is an associated boilup ratio BR and for each condenser there is an associated reflux ratio RR. For example, for DWCL, there are two boilup ratios BR1=V_1/B_1 and BR2=V_2/B_2 and one reflux ratio RR=L/D. The liquid split SL is defined by SL=L_1/L_2, and the vapor split is defined by SV=V_1/V_2. Although some authors consider the use of SV as a manipulated variable, in practice it is difficult to measure or adjust SV with adequate precision, therefore in this work we do not consider SV as a possible manipulated variable. We further assume that flowrates D and B are used to control the inventory in the distillate receivers and reboilers respectively. The control objective is to maintain the purity of the three product streams.

For DWCL, there are four candidate manipulated variables: RR, SL, BR1 and BR2. For DWCM, there are also four candidate manipulated variables: RR, SL, S and BR, where S is the sidedraw flow rate. Finally, for DWCU, there are only three candidate manipulated variables: RR1, RR2 and BR.

2.3. Column design and analysis

For each feed composition and ease of separation index, the three dividing wall columns were designed using the method of Chu et al.[19] This method determined the

number of stages in each column section as well as the liquid and vapor splits and boilup and reflux ratios. A linear steady-state model of each column was then developed by modeling each column in Aspen plus and making small modifications to the input variables in order to determine the steady-state gain between each of the input variables and all of the controlled variables (the compositions of the product streams). It was then possible to calculate the non-square relative gain array[20] for each column and relative gain array[21] and the condition number[22] for each set of three manipulated variables. (For DWCM and DWCL, which have four possible manipulated varibles, there are four possible choices for the set of three manipulated variables.)

Finally, the steady-state models in Aspen Plus were converted into dynamic models in Aspen Dynamics. For control structures that were identified as promising based on steady-state analysis, the tuning parameters for the flow, level and pressure controllers were assigned certain fixed values, and the PI tuning parameters for the thrree composition controllers were determined using sequential relay auto tuning.[23] Finally, the dynamic response of the process was simulated for +/− 10% changes in the feed flow rate. For each control structure, the IAE and ITAE of the three composition controllers were determined and added together to determine the combined IAE and ITAE.

Table 1. Pairings recommended by RGA and CN analysis.

	0.8/0.1/0.1	0.1/0.8/0.1	0.1/0.1/0.8	0.33/0.33/0.33
DWCL ESI>1	RR-BR1-BR2	RR-BR1-BR2	RR-BR1-BR2	RR-BR1-BR2
		RR-SL-BR2	RR-SL-BR2	RR-SL-BR2
DWCL ESI=1	RR-BR1-BR2	RR-BR1-BR2	RR-BR1-BR2 RR-SL-BR2	RR-BR1-BR2
DWCL ESI<1	RR-BR1-BR2	RR-BR1-BR2	RR-SL-BR2	RR-SL-BR2

	S-SL-RR			

3. Results

3.1. RGA Analysis

Table 1 shows the results of the RGA analysis. The column headings indicate the feed compositoin in mole fraction of A/B/C. The entries in the table indicate the preferred control structure or structures. For example, for a DWCL when ESI>1 and when the feed composition is 80% A, 10% B and 10% C, the preferred pairing is RR-BR1-BR2, meaning that x_A should be controlled by manipulating RR, x_B should be controlled by manipulating BR1 and x_C should be controlled by manipulating BR2. When two possible controller pairings are listed, it indicates that the two pairings gave similar results and a conclusive decision about which was better could not be made. DWCU

does not appear in the table because there is only one set of three controlled variables, and in all cases it was found that the preferred pairing is RR1-RR2-BR.

3.2. Dynamic Response Analysis

Table 2 shows the prefered pairings between controlled and manipulated variables based on the ITAE dynamic performance criteria. A star (*) indicates that the result is different from the result based on steady-state analysis. Table 3 shows the numerical value of the best achievable ITAE for each column, ESI and feed composition. Generally, DWCU performs the best, except for the case where the intermediate-boiling speices B is the most plentiful, in which chase DWCL is preferred.

Table 2. Pairings recommended by ITAE.

	0.8/0.1/0.1	0.1/0.8/0.1	0.1/0.1/0.8	0.33/0.33/0.33

DWCM ESI>1	S-SL-BR	RR-S-BR	RR-SL-S*	S-RR-BR
DWCM ESI=1	S-SL-BR*	RR-S-BR	RR-SL-S	S-SL-BR*
DWCM ESI<1	S-SL-BR*	RR-S-SL*	RR-SL-S	RR-SL-BR

Table 3. Best achievable ITAE.

	0.8/0.1/0.1	0.1/0.8/0.1	0.1/0.1/0.8	0.33/0.33/0.33
DWCL ESI>1	0.5962	0.0173	0.2087	0.2016
DWCL ESI=1	2.0973	0.0555	2.4944	0.4745
DWCL ESI<1	1.7823	0.0760	0.7393	0.5145
DWCM ESI>1	0.5617	0.4441	0.0663	1.0997
DWCM ESI=1	1.3552	1.0528	0.0960	0.2354
DWCM ESI<1	2.3915	1.2887	0.0463	0.2682
DWCU ESI>1	0.1664	0.0516	0.0274	0.0590
DWCU ESI=1	0.0533	0.0563	0.0286	0.0413
DWCU ESI<1	0.0757	0.1299	0.0421	0.0597

4. Conclusions

The controller pairings and overall controllability for three types of dividing wall columns was analyzed for different feed compositions and ESI values using steady-state and dynamic methods. The results suggest that from a controllability standpoint, DWCU is favorable in all cases except when the feed contains predominatly the middle boiling component, in which case DWCL is preferred. If a different column

configuration is preferred for economic reasons, the results can also be used to suggest the best pairing between controlled and manipulted variables.

The dynamic analysis conducted so far does not consider changes in the set-points of the composition controllers or disturbances in feed the feed composition. In the future it may be worthwhile to consider these changes. Furthermore, it has been assumed that the composition of the three streams can be measured online. It may also be interesting to compare the performance of different control structures when the product composition is inferred by temperature measurement.

A systematic procedure for synthesis of intensified simple column configurations for multicomponent distillations

Ben-Guang Rong*, Massimiliano Errico

University of Southern Denmark,Institute of Chemical Engineering, Biotech. and Env. Tech., Niels Bohrs Alle 1, Odense 5230, Denmark. Email: bgr@kbm.sdu.dk

Abstract

In this work, we have presented a systematic procedure for synthesis of intensified simple column configurations (ISC) for multicomponent distillations, which constitutes a new specific subspace of distillation configurations that has not been approached in the earlier works. The intensified simple column configurations fulfill the process intensifications principle that they have reduced the number of columns as well as the number of heat exchangers. More importantly, they keep the similar features as the conventional simple column configurations, that each column produces an overhead product with a condenser and bottoms product with a reboiler. As a consequence, these new intensified simple column configurations keep the similar simplicity in terms of systems design, control and operation as the conventional simple column configurations. However, they have the potential to reduce the energy consumption and especially capital costs substantially due to the improved separation efficiency and reduced number of equipment units. The procedure can be generalized to synthesize the intensified simple column configurations for any traditional distillation configurations of an N-component mixture with both sharp and sloppy splits.

Keywords: systematic procedure, synthesis, intensified simple column configuration, process intensification

1. Introduction

To achieve N nearly pure products for an N-component mixture by distillation, it is traditionally believed that the minimum number of simple columns in a conventional simple column configuration is N-1 (Thompson and King, 1972). Each of the N-1 simple columns receives a feed and produces two products, i.e. an overhead product with a condenser in the rectifying section and a bottoms product with a reboiler in the stripping section. Such conventional simple column configurations are commonly used in the workplace of process industries, primarily due to its simple and easy in design, control and operation. However, they are energy inefficiency due to the inevitable remixings and thermodynamic irreversibility, and are characterized with high energy consumption and capital costs (Petlyuk et al., 1965). To reduce the energy consumption and capital costs, many different distillation configurations have been proposed, among others, the heat-integrated distillation systems (Rathore et al., 1974) and dividing-wall columns (Wright, 1949) are the most impressive ones, and have been successfully applied in certain cases. However, these systems are also more complex than the simple column configurations and in many cases increased the difficulty in system's design, control and operations. Moreover, they are more difficult to be used to replace the existing distillation plants. Therefore, distillation configurations with similar simplicity

as simple column configurations while have potential to reduce both energy and capital costs are desired. In this work, we present a systematic procedure to synthesize the intensified simple column configurations with such features.

2. The systematic synthesis procedure

Starting from the simple column configurations, a step-by-step procedure has been formulated which can systematically synthesize the intensified simple column configurations. The procedure is based on thermal coupling technique and is shown in Figure 1. The key mechanism is to produce the thermodynamically equivalent structures (TES) in which there exist *single-section transport side column(s)*. The transport-side-column can be eliminated and leave the submixtures transport directly between the columns. We have formulated two criteria for a TES structure that could finally lead to the ISC configurations.

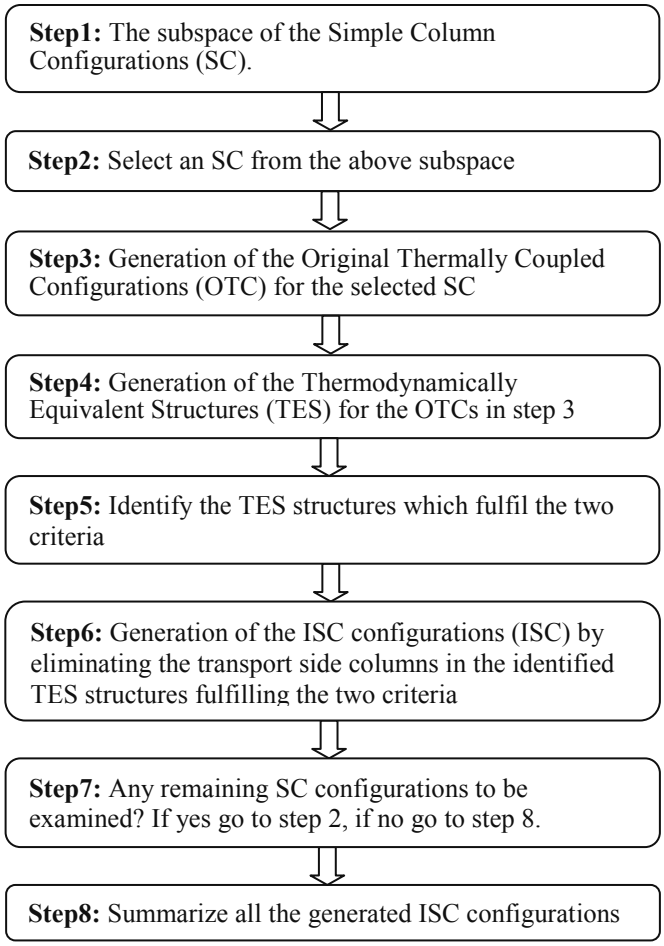

Figure 1. The procedure for synthesis of ISCs from simple column configurations

Criterion 1: The TES must contain the single-section transport-side-column.

Criterion 2: Except the transport side columns, each of the other columns in the TES must keep the simple column features that each column produces an overhead product with a condenser and a bottom product with a reboiler.

Therefore, to achieve the possible ISC configurations for an N-component mixture, we need systematically examining the TES structures and identifying those TES structures which fulfill the two criteria. In the following, the procedure is illustrated for a five-component mixture to generate the ISCs which applicable to any N-component mixture.

3. Synthesis of the ISCs for a five-component mixture

Step1. The SC configurations for a five-component mixture. In total, there are 14 simple column configurations for a five-component mixture.

Step2. Select an SC configuration. Let us select the SC configuration which is from the separation sequence of A/BCDE(1)→BCD/E(2)→B/CD(3)→C/D(4).

Step3. Generate the OTCs for the selected SC configuration. For any traditional distillation configurations, all of possible original thermally coupled configurations can be generated by replacing the heat exchangers associated with submixtures individually or combinatorially (Rong et al., 2002). For above selected SC configuration, in total 7 OTCs can be generated. Figure 2 presents 4 OTCs which would finally generate ISCs.

Steps4 and 5. Generate the TES structures and identify the TES structures fulfilling the two criteria. For any original thermally coupled configuration, there are a certain number of movable column sections, which are designated by the introduced thermal couplings. By recombining the column sections through moving the movable section individually or combinatorially, all of the TES structures can be generated (Rong et al., 2004). Figure 3 presents the identified TESs for the OTCs in Figure 2.

Step6. Generation of the ISC configurations from the identified TES structures in step 5. It is obvious that each of the identified TES structures shown in Figure 3 contains a transport side column. By eliminating the transport side columns, the corresponding ISC configurations are readily generated which are presented in Figure 4.

Step7. Select another SC and repeat from step 2 to step 6 until all of the 14 SC configurations are selected.

Step8. Summarize all the generated ISC configurations.

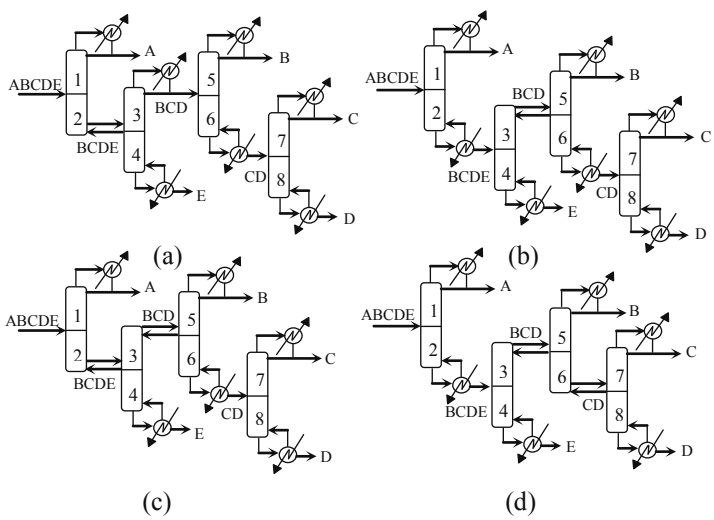

Figure 2. The original thermally coupled configurations generated from the selected SC

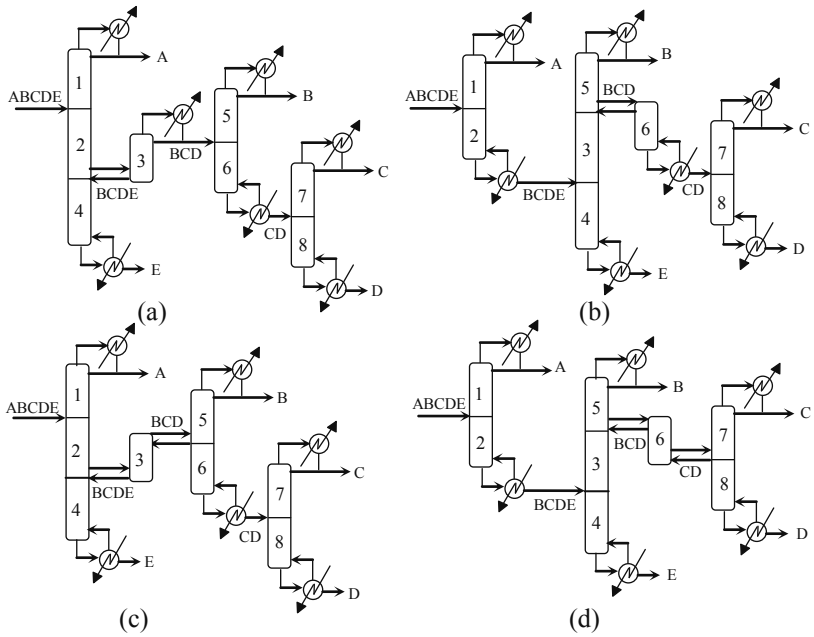

Figure 3. The identified TES structures fulfilling the two criteria for the selected SC

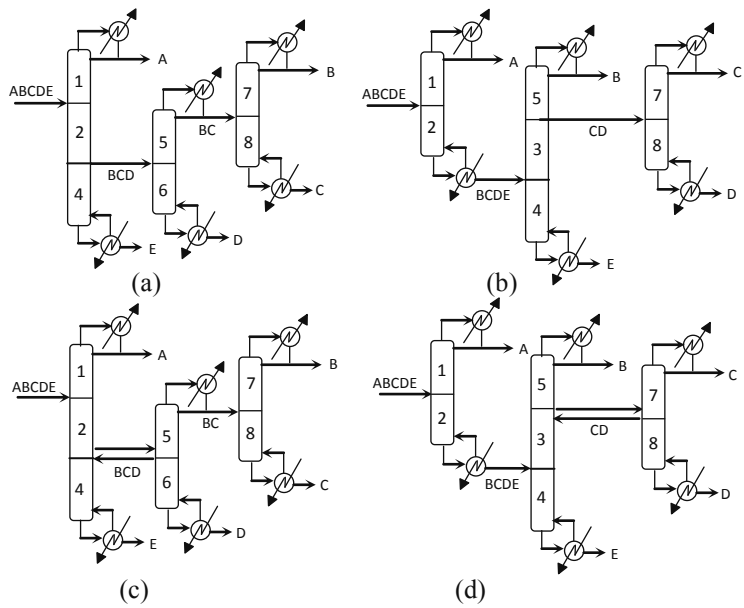

Figure 4. The ISC configurations with one-way and two-way transports from the TESs in Figure 3

Following the procedure, in total, 12 ISCs with one-way transport of a submixture between intermediate locations of two columns are generated from the 14 SCs. Correspondingly, 12 ISCs with two-way transport of a submixture between intermediate locations of two columns are generated from the 14 SCs. Compared to the SC, each of the ISCs in Figure 4 has reduced 1 column and 2 heat exchangers to obtain the same five products.

4. Discussion and Conclusion

The systematic procedure can be generalized to generate the ISCs from the SCs for any N-component mixture. It is expected that there will reduce more columns and more heat exchangers when the number of the components is increased in the feed mixture. It is observed that the similarity between the ISCs and their corresponding SCs exist in that each column produces an overhead product with a condenser and a bottoms product with a reboiler. However, the ISCs are generated by modifying the corresponding SCs, they have some different features from the SCs.

a) An ISC configuration uses less than N-1 columns for an N-component mixture.
b) Each column has an overhead condenser and a bottom reboiler.
c) There exist submixtures transporting between intermediate locations of columns in one-way or in two-way.
d) A column in an ISC can have more than two column sections.

These structural features of the intensified simple column configurations can be regarded as the relaxation to the definition of the classical simple column configurations. Now, taking these structural features into consideration, the procedure in Figure 1 can be generalized to synthesize the ISC configurations from the traditional distillation configurations (TDC) containing both sharp and sloppy splits. The generalized procedure will be introduced in a full paper which will show that a complete new subspace of ISC configurations can be generated from the TDCs with both sharp and sloppy splits for any N-component mixture. Therefore, the ISCs constitute the intensified alternatives of the corresponding TDCs. The present work has focused on the development of the systematic synthesis procedure together with the new subspace of the ISC systems. Work concerning the quantitative comparison between the intensified columns and the conventional columns is expected to develop heuristics for their selection and application. Furthermore, dynamic performance and control studies for such intensified systems are also important for their specific applications.

In conclusion, the ISCs have the potential to reduce both energy consumption and capital costs. Therefore, the ISCs should be included in the optimization search space to look for the optimal configuration for both grassroot designs as well as retrofitting existing distillation plants.

Abstract

The objective of this study is to present a feasible design and control structure for the esterifications of ethanol (EtOH) and n-butanol (BuOH) mixtures with acetic acid (HAc). This alcohol mixture is frequently obtained in semiconductor industry as a waste by-product, thus a detailed study of how to re-use this stream to produce high-value ester products is a worthy research. In our previous paper[1], the design and control of mixed-alcohol reactive-distillation process, categorized as Type-II system[2], has been developed. In this study, a new more difficult to design reactive-distillation process, categorized as mixed Type-II/Type-III system, will be studied. After comparing several alternative design sequences, an indirect design sequence containing a reactive distillation column and a stripper gives the lowest total annual cost (TAC).

In the control strategy, a traditional inventory control structure shows that this process would exhibit multiple steady states. An improved inventory control strategy is proposed to alleviate this complex dynamic behavior. The most important inventory control loop is the bottom liquid level of the reactive distillation column. A rather unusual inventory control strategy which manipulates the reboiler duty should be used. The dynamic results show that the proposed plant-wide control structure is capable of holding product specifications despite disturbances from throughput and feed composition changes. Overall control strategy with tray temperature control loops are proposed for the plant-wide control structure.

Keywords: Reactive Distillation, Inventory Control, Esterification

1. Introduction

Manufacturing processes in the semiconductor and pharmaceutical industries often produce massive organic liquid wastes including alcohol mixtures. Therefore, the esterifications of alcohol mixtures may be a beneficial strategy in reusing wastes from these industries. The purpose of this paper is that an alcohol mixture of EtOH and BuOH can be used as a feed stream for further processing. The existing literature on this topic by esterifications of either EtOH or BuOH with acid (e.g., acetic acid) to obtain ethyl acetate (EtAc) or butyl acetate (BuAc) in a RD system is relatively scarce.

In this study, the EtOH and BuOH alcohol mixture is fed in the RD process as a single stream. NRTL-HOC thermodynamic model is used for modeling the vapor-liquid and vapor-liquid-liquid equilibrium. The reactions are catalyzed by using Amberlyst-15 catalyst. Based on the thermodynamic properties and reaction kinetics, this paper

investigates two alternative design concepts which contain three kinds of feasible design flowsheets for the overall system.

2. Conceptual Design of the Process Flowsheet

This section compares the minimum TAC of two design concepts for this mixed alcohol system. The first thinking is "separation first" which means to separate the mixed alcohols from the upstream process first, and then feeds the EtOH and BuOH into different reactive distillation systems to produce EtAc or BuAc. The other thinking is "reaction first," which means feeding the mixed alcohols stream into a RD column directly, and then separates the two ester products and water. This design thinking includes two alternative flowsheets. One is "direct-sequence" design flowsheet. The other is "indirect-sequence" design flowsheet. All the conceptual design of the alternative process flowsheets are shown in Figure 1.

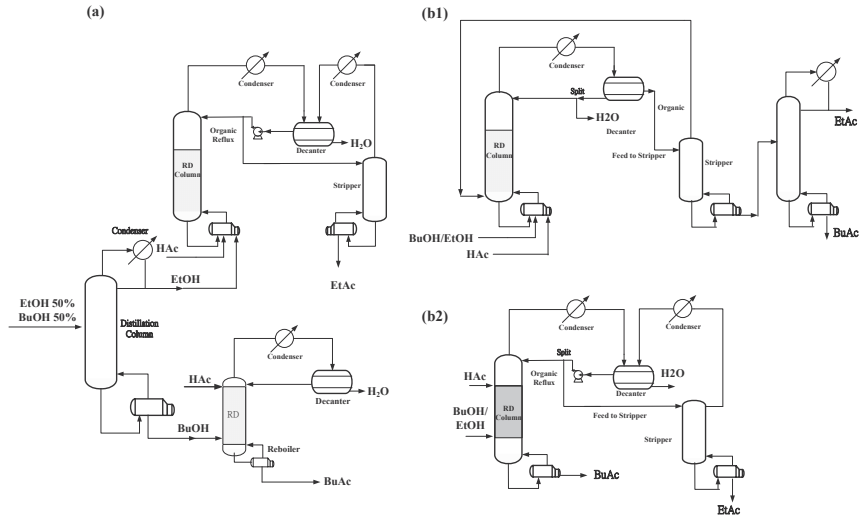

Figure 1. (a) "Separation first" flowsheet; (b1) "direct-sequence"; and (b2) "indirect-sequence" of the "reaction first" flowsheet.

2.1. "Separation First" Design

The "separation first" design flowsheet includes one traditional distillation column, two RD columns and a stripper. The first column separates the EtOH and BuOH from the feed stream as shown in Figure 1-(a). Then the purified EtOH and BuOH are fed into their own RD columns and react with HAc. The final products of EtAc and BuAc are obtained at the bottoms of the stripper and RD column, respectively. Furthermore, water is discharged from the outlet at the top of the decanter for the EtAc system and is obtained as distillate of the RD for the BuAc system. This study makes several assumptions in the following simulation: the mixed alcohols feed stream (EtOH/BuOH) is set to be equal molar, and the total flow rate is 100 kmol/h. The feed stream of pure reactant HAc is used and also set at 100 kmol/h flow rate. Product specifications are set as follows: x_{EtAc} = 99 mol %; x_{BuAc} = 99 mol %. The x_{HAc} in the EtAc and BuAc product stream must be less than 50 ppm. The results in Tang et al.[2] provided the optimal design of EtAc and BuAc RD processes. Therefore, determining the optimal design of the first distillation column is the only additional task for this design flowsheet.

There are two design variables for the distillation column: total number of stages and feed tray location. In all Aspen Plus simulation runs, the column top composition is set at 99.99 mol % EtOH by varying the reflux ratio, and the bottom BuOH composition is set at 99.99 mol % by varying the reboiler duty. High-purity EtOH and BuOH are required to use the optimal design proposed in Tang et al.[2] for the remaining two RD processes. The minimum TAC of this distillation is $588.1 ($1000/year). Upon combining the results of the other two RD processes from Tang et al.[2], the energy consumption of the overall "separation first" process is 10791.74 kW and the minimum TAC of the overall process is $ 2283.58 ($1000/year).

2.2. "Direct-sequence" of the "Reaction First" Design

Figure 1-(b1) shows the flowsheet of the "direct-sequence" design. In this design, all the reactants are fed into the bottom of the RD column. The overhead stream of the RD column enters the decanter, and the entire organic stream is fed into the stripping column. A part of the aqueous phase H_2O from the decanter is removed as the water product; the other part of H_2O is recycled back to the top of the RD column. Because of the aqueous reflux, BuOH tends to form the ternary minimum boiling azeotrope BuOH/BuAc/H_2O at top of RD column, and the separation will be easier. The stripping column separates the other components with the ester mixtures. The third column is used to separate the two products of EtAC and BuAC.

This study makes the same assumption for the feed composition and feed flow rate as in the "separation first" design. The decanter temperature is again set at 40 ° C. The EtAc and BuAc product specifications are also the same as in the "separation first" design. If the HAc composition of the stripping column bottom stream is greater than 0.3 mol %, this residue reactant affects product purity levels, and product specifications cannot be met in the third product column. Therefore, the reboiler duty of the stripping column is used to meet the HAc composition requirement of 0.3 mol % at the bottom of the stripping columns. Then the reflux ratio and reboiler duty of the third product column are used to meet the EtAc and BuAc specifications, respectively. The total TAC of "direct-sequence" design is $2542.46 ($1000/yr) and the overall reboiler duty is 13429 kW.

2.3. "Indirect-sequence" of the "Reaction First" Design

Figure 1-(b2) shows another possible flowsheet, the "indirect-sequence" design. Unlike the "direct-sequence" case, the "indirect-sequence" flowsheet collects the heaviest product, BuAc at the bottoms of the RD column. The other product, EtAc is obtained at the bottoms of another stripping column, which is fed by the organic stream from the decanter at the top of the RD column. This study proposes a design flowsheet of organic reflux with no aqueous reflux. The purpose of the organic reflux is to put ester back into the RD column, carrying water to the top by forming the ternary minimum boiling azeotrope of EtOH/EtAc/H_2O.

There are five design variables in this flowsheet which includes the stage numbers of the reactive section (N_{rxn}), the rectifying stage numbers of RD column (N_r), the HAc feed location (NF_{HAc}), the mixed alcohols feed location (NF_{OH}) and the total stage numbers of the stripping column (N_S). The product specifications are the same as in the previous two cases. The minimum TAC of "indirect-sequence" design is $1841.23 ($1000/yr) and the overall reboiler duty is 6898 kW.

Table 1 shows that the "indirect-sequence" of the "reaction first" design flowsheet is better than the "separation first" design strategy. The overall savings of the reboiler duty and TAC are 36% and 19%, respectively, in comparison with the "separation first"

design. For the mixed EtOH and BuOH esterification system, the "indirect-sequence" with organic reflux is a better process flowsheet than the "direct-sequence" flowsheet.

Table 1. Optimal TAC and Overall Reboiler Duties of Each Case

Case	Separation First	Direct-Sequence	Indirect-Sequence
Product flow rate (kmol/hr)	97.72	97.4	98.07
Total reboiler duty (kw)	10805	13429	6898
Annualized Capital cost	1232.17	1077.54	903.46
Operating cost	956.65	1373.20	720.44
Catalyst cost	94.77	91.72	217.33
TAC ($1000/yr)	2283.59	2542.46	1841.23

3. Control Strategy Design

In the following, we will investigate the proper overall control strategy of the "indirect-sequence" design flowsheet. For the RD column with the decanter, the aqueous-phase level is controlled by manipulating the aqueous outlet flow; the column top pressure is controlled by manipulating the top vapor flow; and the organic phase level is controlled by manipulating the partial organic flow where it is fed to the stripper. One important loop pairing in this system is that the column bottom level is controlled by manipulating the reboiler duty. Figure 2 shows that this process exhibiting multiple steady states if the column bottom level is controlled by manipulating the bottom BuAc product flow. For the stripping column, the column bottom level is controlled by the bottom EtAc product flow; and the column pressure is controlled by the top vapor flow.

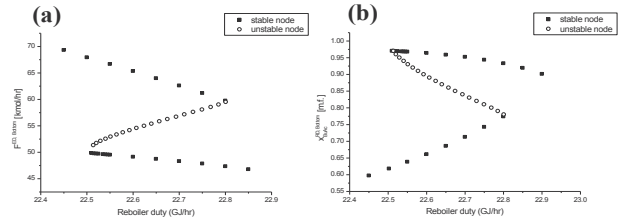

Figure 2. (a)Reboiler duty vs. RD column bottom flow; (b) Reboiler duty vs. composition of EtAc product

The remaining manipulated variables for the RD column are the feed ratio and the bottom flow, and the remaining manipulated variable for the stripping column is the reboiler duty. Close-loop sensitivity analysis is used to determine the tray temperature control point for both the RD column and the stripping column. Stage 10 and stage 33 of the RD column and stage 7 of the stripping column are selected as the temperature control points. PI control is used in these three temperature control loops. With additional open-loop test information, the control pairings should use feed ratio to control the 10th stage temperature and use bottom flow rate to control 33th stage temperature. For the stripping column, the reboiler duty is used to control the 7th stage temperature. The overall control strategy is shown in Figure 3.

Three types of disturbances will be used to test the proposed control strategy. The disturbance of unmeasured fresh feed composition changes will be considered first. A large variation of -10% changes in the feed stream of HAc composition is tested with the closed-loop results shown in Figure 4. For the second disturbance, variations of ±10% changes in the mixed alcohols composition are tested with the closed-loop results

shown in Figure 5. From these two figures, the two product compositions are all maintained at high purity. Another disturbance test is the throughput changes. Figure 6 displays the responses with ± 20% changes in the mixed alcohols flow rate. Again, the two RD controlled temperatures returned quickly to their set point values and with small deviations of the two product purities.

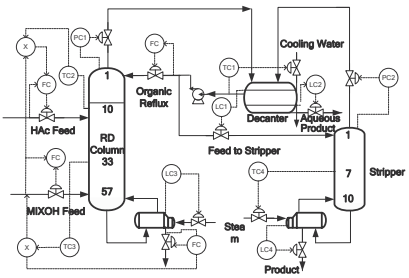

Figure 3. Proposed overall control strategy.

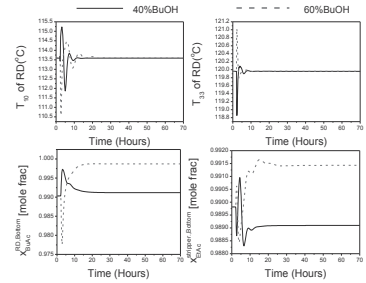

Figure 4. Dynamic responses with - 10% HAc composition changes

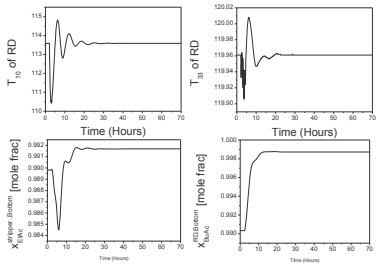

Figure 5. Dynamic responses with ±10% mixed alcohols composition changes

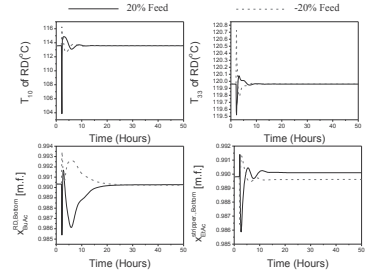

Figure 6. Dynamic responses with ±10% mixed alcohols feed flow rate

4. Conclusions

This study presents a feasible design for the esterification of EtOH and BuOH mixtures with HAc. Three design flowsheets are explored in this work: one "separation first" design and two "reaction first" designs. The best choice among these different design configurations is based on TAC savings and energy consumption. Comparing these three cases, it is shown that the "indirect-sequence" of "reaction first" design with organic reflux is the best design flowsheet having the least TAC and the energy consumption.

In the control strategy, the most important control loop is the bottom level of the RD column. This level should be controlled by manipulating the reboiler duty. Simulation results show that the proposed control strategy is capable of holding product specifications despite disturbances from throughput and feed composition changes.

Abstract

The semiconductor and pharmaceutical industrial process often produces alcohol mixture byproducts. This study discusses the esterification process of an n-amyl alcohol (AmOH) and n-hexanol (HexOH) mixture with acetic acid (HAc). In the previous paper[1], the optimal design of the same type III mixed alcohol reactive distillation (RD) process was developed. In that paper the mixed alcohol feed contains n-butanol and n-amyl alcohol and the indirect sequence containing a RD column with heavier amyl acetate product and a second column to product bottom butyl acetate product gives the lowest total annual cost (TAC). In this study, with different mixed alcohol feed although of the same type, we find that the direct sequence design is more economically favorable. We then propose an integration of this design into a reactive divided wall column (RDWC) configuration for further savings in energy consumption. The result shows that 14% operating energy can further be saved by using RDWC configuration.

In the dynamic simulation, the RDWC is much more complicated and hard to control and operate, therefore proper selection and pairing of controlled and manipulated variables is very important. The control strategy in this study is determined by using the open loop sensitivity analysis. Dual-temperature control strategy works satisfactory for this RDWC column to indirectly hold the product specifications. The disturbances such as the throughput, the feed composition, and the vapor ratio changes are used in the closed-loop simulations.

1. Introduction

Manufacturing processes in the semiconductor and pharmaceutical industries often produce massive organic liquid waste including alcohol mixture. Therefore, the esterification of the alcohol mixture may be a more beneficial way in reusing wastes from these industries. The purpose of this paper is to use an alcohol mixture of AmOH and HexOH as a feed stream to produce esters for further usage. However, existing literature on investigating the design and control of an esterification process with an alcohol mixture as a feed stream is relatively scarce.

In this study, the esterificaiton reactions of AmOH and HexOH are used to build-up the RD process. NRTL-HOC thermodynamic model is used for modeling the vapor-liquid and vapor-liquid-liquid equilibrium. The reactions are catalyzed by using Amberlyst-15 catalyst. Based on thermodynamic properties and reaction kinetics, this study presents three kinds of design alternatives for the overall RD system.

2. Conceptual Design of the Process Flowsheet

This section demonstrates and compares the minimum TAC of three kinds of design alternatives for a type III mixed alcohols system. The first is "direct-sequence" configuration. In this design configuration, the ester mixture is produced in the bottoms of RD column. This bottom stream is fed into an additional distillation column which collects the main products, AmAc and HexAc, at top and bottoms of this distillation column, respectively. The second is "indirect-sequence" configuration which collects the heaviest product, HexAc at the bottoms of RD column; the other product, AmAc, is obtained at the bottom of an additional distillation column. The feed stream of the additional distillation column comes from the organic stream of the top RD decanter. Another design configuration is to further integrate energy from "direct-sequence" configuration into a reactive dividing wall column (RDWC) configuration. All the design alternatives of the esterification process are shown in Figure 1.

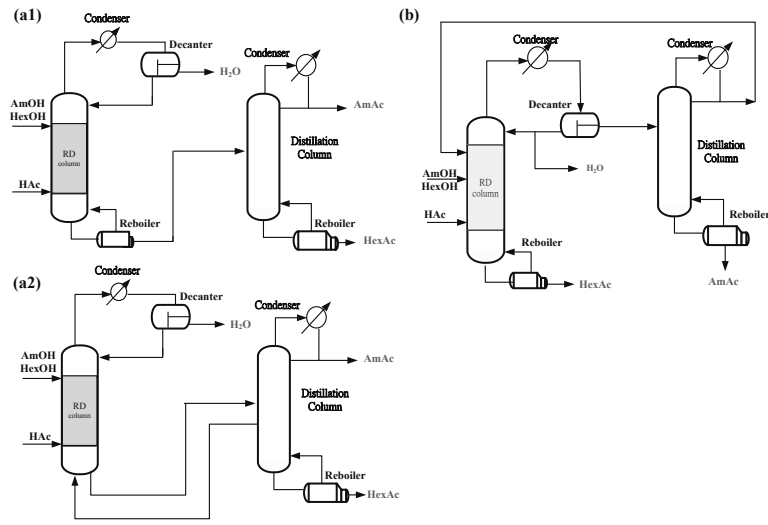

Figure 1. (a1) "direct-sequence"; (b) "indirect-sequence"; and (a2) "RDWC" configuration.

"Direct-sequence" design

Figure 1-(a1) shows the design configuration of the "direct-sequence". The major concept of this configuration is an extension of type III RD system (c.f. Tang et al.[2]) with an additional distillation column to separate two esters. Figure 2 displays a minimum boiling alcohol-ester-water azeotrope inside the large two-liquid region. In this liquid-liquid region, one end of the tie-line is directed to the pure water. The overhead stream of the RD column enters the decanter, and the organic rich stream is totally refluxed back to the RD column to carry water up the RD column. The bottom stream enters another distillation column to separate the two esters. The heaviest component, HexAc, is thus easily obtained at the bottoms of the distillation column and the AmAc product is obtained at the top of this column.

In all the Aspen Plus simulation runs, the mixed alcohols feed stream is set to equal molar, and the total flow rate of this stream and HAc feed stream are 100 kmol/h. The distillation column top composition is set at 99 mol % AmAc by varying the reflux ratio, and the bottom HexAc composition is set at 99 mol % by varying the reboiler duty. The eight design variables of this case are the stage numbers of the reactive section (N_{rxn}),

the stage numbers of the rectifying section (N_R), the stage numbers of the stripping section (N_S), the HAc feed location (NF_{HAc}), the mixed alcohols feed location (NF_{OH}), reboiler duty of the RD column, the total stage numbers of the distillation column (NT), and the feed location (NF) of the distillation column. After running the optimization procedure, the minimum TAC of "direct-sequence" configuration is \$1640.5 (\$1000/yr) and the overall reboiler duty is 4725.5kW.

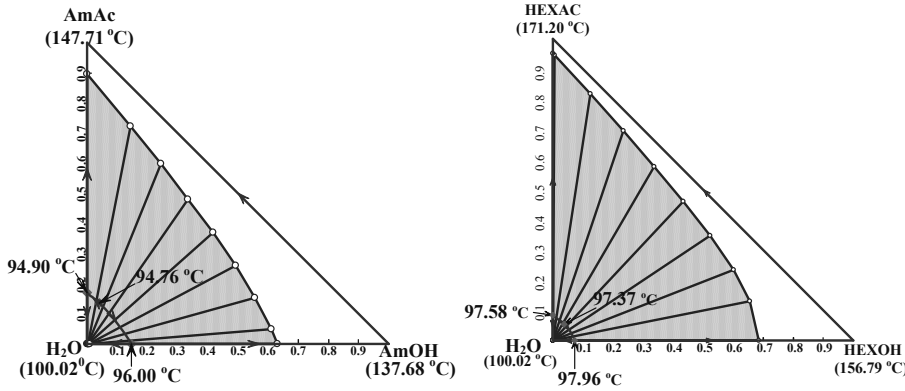

Figure 2. LLE of AmOH-AmAc-H_2O and HexOH-HexAc-H_2O ternary system under 1atm.

"Indirect-sequence" design

Figure 1-(b) shows another design configuration, of the "indirect-sequence". Unlike the "direct-sequence" configuration, the "indirect-sequence" configuration only collects the heaviest product, HexAc, at RD column bottoms. The other product, AmAc, is obtained at the bottoms of an additional distillation column which is fed by the organic stream from the top of the RD decanter. This study uses a configuration with partial aqueous reflux stream. The purpose of the partial aqueous reflux stream is to feed water back into the RD column to carry the heavier AmAc component by forming the ternary minimum boiling azeotrope of alcohol-ester-water.

The design variables considered in this configuration are nine including: the stage numbers of the reactive section (N_{rxn}), the stage numbers of the rectifying section (N_R), the stage numbers of the stripping section (N_S), the HAc feed location (NF_{HAc}), the mixed alcohols feed location (NF_{OH}), the aqueous split ratio, the total stage numbers of the distillation column (NT), the feed location (NF) of the distillation column, and the reflux ratio of this column. All product specifications are met in the optimization steps. The minimum TAC of "indirect-sequence" configuration is \$2506.8 (\$1000/yr) and the overall reboiler duty is 8045.0 kW.

Reactive Dividing Wall Column Design

Figure 1-(a2) shows a process integration of the "direct-sequence" configuration into a reactive dividing wall column (RDWC) for further savings of the operating energy. This design is similar to "direct-sequence" with the differences of removing a reboiler from the RD column and side-drawing a vapor stream from the distillation column to provide the heat source to the RD Column. Liquid and vapor streams are interchanged between the bottoms of the RD and a stage of the distillation column.

In this process, notice that the vapor flow rate is used as the design degrees of freedom to minimize the total TAC, and the reflux ratio and reboiler duty of the

distillation column are used to satisfy two purity specifications of AmAc and HexAc, respectively. Other seven design variables of this configuration are: the stage numbers of the reactive section (N_{rxn}), the stage numbers of the rectifying section (N_R), the stage numbers of the stripping section (N_S), the HAc feed location (NF_{HAc}), the mixed alcohols feed location (NF_{OH}), the total stage numbers of the distillation column (NT), and the side-draw location (NF) in the distillation column. After running optimization procedure, the minimum TAC of RDWC configuration is \$1434.2 (\$1000/yr) and the overall reboiler duty is 4065.05 kW.

Results and Discussion

Table 1 gives the comparison of the "direct-sequence", "indirect-sequence", and RDWC configurations. Unlike the result of Lee et al.[1], "indirect-sequence" seems not to provide any benefit on energy saving and TAC. Its energy requirement increases almost 70% comparing with the "direct-sequence". The reason is due to large recycle flow rate back to the RD column in the "indirect-sequence". The configuration from "direct-sequence" to RDWC results in further energy saving due to the reduction of the remixing effect in the RD bottom section. The result in Table 1 shows that the overall savings of the reboiler duty and TAC are 14.0% and 12.6%, respectively. Comparing these three designs show that the RDWC is the best configuration.

Table 1. Optimal TAC and Overall Reboiler Duties of Each Configuration

Design	"Direct-sequence"	"RDWC"	"Indirect-sequence"
Qr (kw)	4725.5	4065.0	8045.0
Qr saving	-	-14.0%	70.2%
Total capital cost/3 (\$1000/yr)	983.08	947.87	1289.22
Total operating cost (\$1000/yr)	657.42	486.33	1217.58
TAC (\$1000/yr)	1640.5	1434.2	2506.8

3. Control Strategy Development

In the following, the proper overall control strategy of the RDWC configuration will be investigated. There are nine inventory control loops included six level and three pressure loops which are shown in Figure 3. The remaining manipulated variables are the reflux flow rate and the reboiler duty of the distillation column, and feed ratio of the RD column. With the close-loop and open-loop test information, the 35th stage temperature should be controlled by the feed ratio. For the distillation column, the 11^{th} stage temperature should be controlled by the reflux flow rate. The reboiler duty is ratioed to the mixed alcohol feed.

Three types of disturbances will be used to test the proposed control strategy. For outer disturbance, the unmeasured fresh feed composition changes are considered. Changes in the mixed alcohol and the HAc compositions are tested. The results of closed-loop performance are shown in Figure 4. Another disturbance test is the throughput changes. Figure 5 displays the responses with ± 10% changes in the mixed alcohols flow rate. For inner disturbance, the vapor ratio change (to the RD vs. to the other column) is also considered. Figure 6 displays the responses with ± 10% changes in the vapor ratio. The two controlled temperatures returned quickly to their set point values and the two products are still maintained at high-purity. We are currently

investigating using dual-temperature control loops on the RD side to further improve the product composition performance.

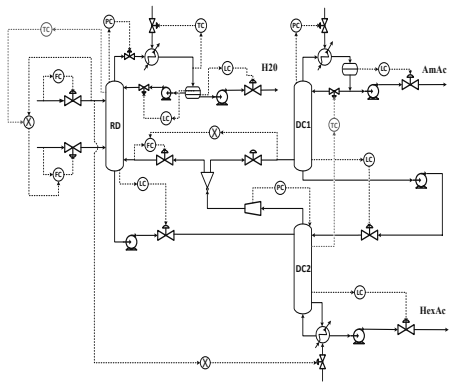

Figure 3. Proposed overall control strategy.

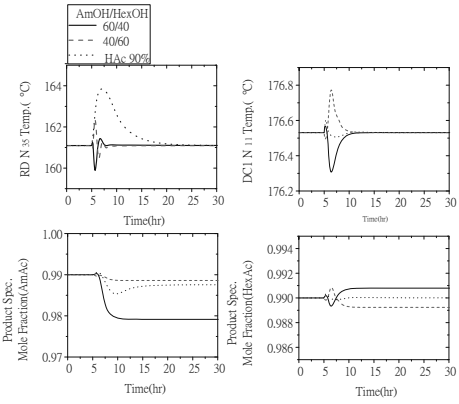

Figure 4. Dynamic responses with Feed composition changes

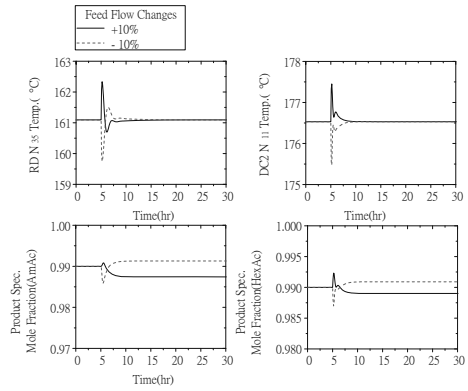

Figure 5. Dynamic responses with ±10% throughput changes

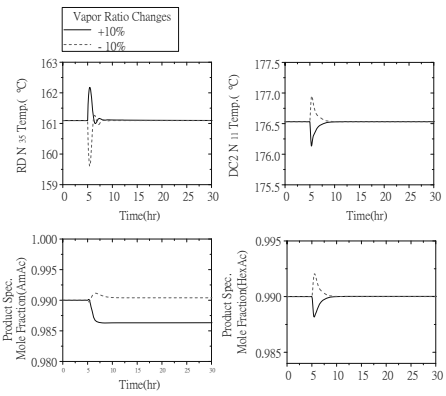

Figure 6. Dynamic responses with vapor ratio changes

4. Conclusions

This study investigated the feasible design for the esterification of AmOH and HexOH mixtures with acetic acid. Three design configurations are explored in this work: “direct-sequence”, “indirect-sequence”, and RDWC configurations. Comparing these three design configurations, it is shown that the RDWC has the best potential to provide maximum energy saving and cost reduction.

In the dynamic simulation, the results show that dual-temperature control strategy performs satisfactory to maintain high-purity of the two products in the face of three disturbances such as the throughput, the feed composition, and the vapor ratio changes.

Abstract

Aggregate models are frequently used for online optimization of distillation columns because of their balance of accuracy and simplicity. When applied to high-purity distillation columns with large numbers of trays in a section, however, traditional group methods cannot accurately depict the strongly nonlinear features along the trays. On the other hand, absorption/stripping factors of the components along the trays were observed as a traveling sigmoidal wave, with the absorption/stripping factors at the top and bottom trays hardly changing with the reflux ratio. An improved group method based on the wave propagation theory is thus proposed to simulate the high-purity distillation columns. Applications are also conducted through process simulation on an argon sidearm column in a cryogenic air separation process. Excellent performance of the proposed method in terms of accuracy and converging rate is observed.

Keywords: Aggregate model; Wave propagation theory; Group methods

1. Introduction

Accurate and easy-to-converge models are always demanded for advanced control and real-time optimization of industrial processes. In many complex applications, the nonlinearity of multi-stage countercurrent gas-liquid contactors, such as high-purity distillation columns, cannot be well addressed through the shortcut method or linear correlations. Thus, rigorous tray-by-tray models are preferred for multi-stage columns. However, such models become large and expensive for high-purity columns with large numbers of trays, which hinders convergence in on-line applications. Considering the balance between model precision and difficulty in calculation, other methods, such as aggregate models (Fenske,1932; Gilliland, 1940; Kremser, 1930), are therefore investigated to describe the features of high-purity systems.

The group method is a type of aggregate method that provides reasonably accurate predictions with simple model structures. In the traditional group method, the effective absorption and stripping factors of the components, which represent the average values of the absorption and stripping factors for all trays, are applied in the model to simplify the rigorous tray-by-tray description. Usually, these factors are calculated by averaging the absorption and stripping factors at the top and bottom trays of the column. However, this method cannot accurately describe the strongly nonlinear performance of the column, especially for high-purity distillation columns with large numbers of trays. In the present paper, an improved aggregate model using the wave propagation theory to describe the nonlinear feature of the absorption and stripping factors is proposed for

high-purity distillation columns. The good performance of the proposed method is demonstrated using a high-purity argon sidearm column with 198 stages; comparisons with the traditional method are also presented.

2. Aggregate model of distillation column

The aggregate model relates the outlet stream properties to the inlet stream and other specifications by providing simplified MESH equations for a section of stages of the column. They consist of the mole balance,

$$V_{N+1}y_{N+1,i} + L_0x_{0,i} = V_1y_{1,i} + L_Nx_{N,i} \quad i \in C \tag{1}$$

the energy balance,

$$V_1H_1^V + L_NH_N^L = V_{N+1}H_{N+1}^V + L_0H_0^L \tag{2}$$

and the summation equations,

$$\sum_{i\in C} y_{1,i}/K_{1,i} = 1, \sum_{i\in C} K_{N,i}x_{N,i} = 1 \tag{3}$$

$$\sum_{i\in C} y_{1,i} = 1 \ , \sum_{i\in C} x_{N,i} = 1 \tag{4}$$

Unlike the tray-by-tray rigorous model that uses stage equilibrium equations to calculate the composition profile, the aggregate model usually correlates component recovery to key parameters through a performance equation. The group method (Kremser, 1930) provides only an overall treatment of the stages in the cascade, without considering detailed changes in temperature and composition of the individual stages. The most important contribution of the method is the derivation of the component recovery factor in the cascade by Horton (1940) and Edmister (1957). Horton (1940) gives the performance of the cascade by,

$$V_{1,i}y_{1,i} = V_{N+1,i}y_{N+1,i}\phi_{A,i} + L_{0,i}x_{0,i}(1-\phi_{S,i}) \tag{5}$$

where $\phi_{A,i}$ and $\phi_{S,i}$ denote the recovery factors for absorption and stripping, as follows:

$$\phi_{A,i} = \frac{1}{A_{1,i}A_{2,i}\cdots A_{N,i} + A_{2,i}A_{3,i}\cdots A_{N,i} + \cdots + A_{N,i} + 1} \tag{6}$$

$$\phi_{S,i} = \frac{1}{S_{1,i}S_{2,i}\cdots S_{N,i} + S_{1,i}S_{2,i}\cdots S_{N-1,i} + \cdots + S_{1,i} + 1} \tag{7}$$

$$A_{j,i} = L \big/ K_{j,i}V_j \ , S_{j,i} = 1 \big/ A_{j,i} \ , i \in C, j \in N \tag{8}$$

However, the phase equilibrium constants cannot be calculated using the aggregate model. The following effective absorption/stripper factors are normally substituted into Eqs. (6)-(8) in the Edmister group method (1957).

$$\phi_{A,i} = \frac{A_{e,i}\text{-}1}{A_{e,i}^{N+1} - 1}, \quad \phi_{S,i} = \frac{S_{e,i}\text{-}1}{S_{e,i}^{N+1} - 1} \tag{9}$$

$$A_{e,i} = \left[A_{N,i}(A_{1,i}+1) + 0.25\right]^{0.5} - 0.5 \tag{10}$$

$$S_{e,i} = \left[S_{1,i}(S_{N,i}+1) + 0.25\right]^{0.5} - 0.5 \tag{11}$$

where $A_{e,i}$ and $S_{e,i}$ are the effective absorption and stripping factors that represent the average values of the absorption and stripping factors along all trays in the cascade.

Thermodynamic methods are also applied to calculate the equilibrium constants and the vapor/liquid enthalpies,

$$K_{1,i} = f(x_1, y_1, T_1), \ K_{N,i} = f(x_N, y_N, T_N), \ i \in C \tag{12}$$

$$H_1^V = f(y_{1,i}, T_1), \quad H_N^L = f(x_{N,i}, T_N) \tag{13}$$

For the variables L_1 and V_N, which cannot be calculated using any of these equations, the approximate equation (Kamath, 2010) can be used,

$$L_1 - L_N \approx V_1 - V_N \tag{14}$$

The group methods have been used in some cases (Souders,1932; Horton,1940; Edmister,1943; Kamath, 2010), however, it sometimes fails to capture the nonlinear feature of the system with large numbers of trays. The predicted purity error can differ in orders of magnitude.

3. Modification of recovery factors in the group method

The key problem in the traditional group method is its incapability to address the nonlinear feature of the recovery factors for large numbers of trays using Eqs. (9)-(11). To overcome the precision problem in the Edmister group method, the wave propagation theory is proposed in the present study to correlate the nonlinear feature of the recovery factors. For example, using an argon sidearm column in a cryogenic air separation unit with 198 equilibrium stages, the absorption and stripping factors of the components along the trays and the change in the reflux ratio at about 40 to 50 are illustrated in Fig. 1. It can be observed that the A/S profiles are normally sigmoidal. As the reflux ratio increased, the upper front of the curve travels towards the upper boundary with an initially constant shape, as a so-called "constant pattern wave". In addition, the absorption and stripping factors at the top and bottom trays of the column hardly change, but the values in the intermediate section changed greatly, which lead to large deviations in the calculation of the effective absorption and stripping factors using Eqs. (9)-(11).

In the present paper, an aggregate model based on group method and wave propagation theory is proposed for high-purity distillation columns. The wave propagation theory (Huang, 1991; Kienle, 2000), which can give the dynamic composition profiles of distillation column, was used to describe the nonlinear feature of the recovery factors as follows,

$$A_{i,j} = A_{i,1} + \frac{A_{i,1} - A_{i,N}}{1 + \exp[-\gamma_i (j - s_i)]}, \quad j \in N \tag{15}$$

where s_i denotes the wave position, γ_i is a parameter relating to wave slope. Combining Eqs. (6), (7), and (15) to replace Eqs. (9)-(11) can provide a better correlation of the nonlinear features of high-purity columns.

Table 1 Feed conditions and specifications of column in Fig. 1

Number of trays	198	Feed composition	
Top/Bottom pressure, bar	1.244/1.39	mol fraction O_2	0.904
Reflux ratio	40 - 50	mol fraction Ar	0.096
		mol fraction N_2	210ppm

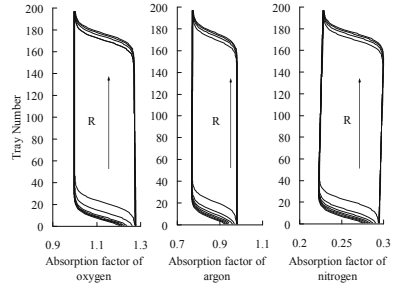

Fig. 1. Absorption factors profiles of argon sidearm column.

4. Results and discussion

An argon sidearm column in the cryogenic air separation unit was used to demonstrate the performance of the proposed method. The column is designed for the separation of oxygen from a ternary mixture of nitrogen/argon/oxygen. The column has a cascade of 198 equilibrium stages between the vapor feed at the bottom and the partial condenser at the top. The specifications and feed conditions of the column are presented in Table 1. Both the proposed wave group method and the Edmister group method were performed. For comparison, the rigorous tray-by-tray model with Soave-Redlich-Kwong equation of state was also developed in AspenPlus®.

The parameters in Eq. (15) were estimated using data at different reflux ratios generated by AspenPlus®. The oxygen recovery factors of the tray cascade, $\phi_{A,O2}$ and $\phi_{S,O2}$, at different reflux ratios were calculated. The comparison of the results between the proposed *wave group method*, the *Edmister group method* (Edmister, 1957), and the *rigorous group method* (Kremser, 1930; Horton, 1940) are illustrated in Fig. 2 using logarithmic coordinate. The absorption/stripping factor profile along the tray cascade used in the rigorous group method are generated by AspenPlus®. We can be seen that the $\phi_{A,O2}$ and $\phi_{S,O2}$ calculated by wave group method fit very well the results of rigorous group method. However, the absorption and stripping factors of the Edmister group method differ by several orders of magnitude, respectively. These results indicate that the average values derived through Eqs. (9)-(11) cannot address the nonlinear feature of the system well. On the other hand, the proposed wave method, as illustrated in Fig. 2, suits the recovery factors of the high-purity column very well.

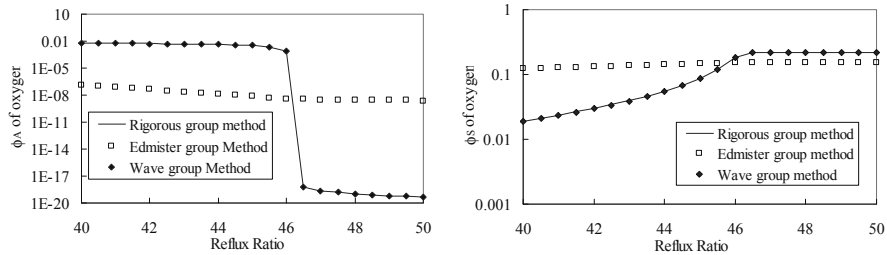

Fig. 2. Oxygen recovery factors of tray cascade.

The simulation results of the column with different aggregate models were obtained at varying reflux ratios. Comparison of the oxygen compositions at the top and bottom calculated using each method is illustrated in Fig. 3. The solutions of the wave group method, which solves 28 equations, closely resemble the results of the rigorous model. However, the Edmister group method, also with 28 equations, has obvious errors at lower reflux ratios. At the part where the reflux ratio and the purity of the products were both high, the relative error in the Edmister group method was even worse, with a difference of several orders of magnitude.

The solver performance of the aforementioned methods was also compared on the same platform. All the methods were coded in Matlab® and were solved using the function *fsolve*. The reflux ratio was changed from 40 to 45 and the solution of the former is used to initialize the solution for the latter. Both aggregate models converged very quickly; the Edmister group method required 1.06 s and the wave group method required 3.21 s as it has more intermediate variables to calculate the recovery factors. On the other hand, the rigorous method, which solves a system of 2377 equations, required a much longer period of about 7254 seconds to converge. These results further prove that our proposed

model accurately depicts the nonlinear feature of the high-purity column and is also suitable for online use.

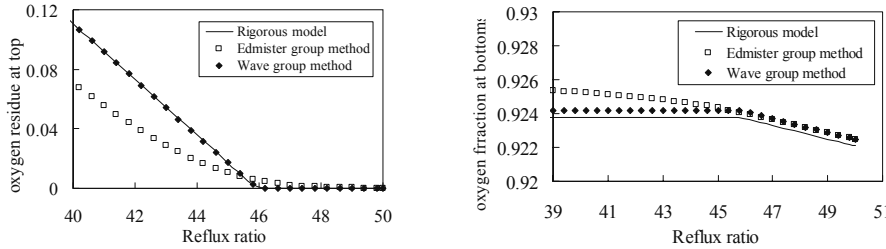

Fig. 3. Oxygen compositions of the column products.

5. Conclusion

A wave group method is proposed to improve the application of the aggregate model to high-purity distillation columns. The proposed method accurately depicts the nonlinear feature of the recovery factors using a sigmodal wave profile. The simulation results show that the proposed method is easier to converge than the rigorous model and is more precise than the Edmister group method, thereby providing good performance and potential for online use.

An exergy grand composite curve based procedure for arranging side exchangers on distillation columns

Zhiqiang Wei, Shengyuan Wu, Bingjian Zhang, Qinglin Chen*
School of Chemistry and Chemical Engineering/Key Lab of Low-carbon Chemistry & Energy Conservation of Guangdong Province, Sun Yat-Sen University, Guangzhou 510275, China

Abstract

This paper presents an exergy grand composite curve based procedure for arranging a side-exchanger on a distillation column. The novel method is proposed to identify the original value of the location, heat duty of the side-exchanger and the criterion of modifying the column stage number. A benzene-toluene column is used to demonstrate the performance of the procedure. The results show that the location, heat duty of the side-exchanger, stage number modification on the column can be effectively identified, and the feeding stage optimization is also considered as the stage number modified. The procedure can guide the arrangement of a side-exchanger in a relatively simple, systemic and reliable way.

Keywords: distillation column, side-reboiler, side-condenser, exergy.

1. Introduction

It is a common known that adding side-exchangers (side-reboilers and/or side-condensers) can effectively improve the thermodynamic efficiency of a distillation column. To arrange a side-exchanger, three questions must be answered firstly: (1) Where is the proper location? (Naka et al., 1980; Terranova et al., 1989; Björn et al., 2002; Pinto et al., 2011; Agrawal et al. 1996; Bandyopadhyay, 2007; Björn et al. 2006) (2) How much heat duty shoule be assigned? (Naka et al., 1980; Terranova et al., 1989; Björn et al., 2002; Pinto et al., 2011) (3) How to modify the stage number when a side-exchanger is arranged? (Pinto et al., 2011; Agrawal et al. 1996). Few researchers could provide a comprehensive answer, or the results are obtained in a comparatively complex way. Motivated to answer the questions mentioned above and facilitate for industrial applications, this paper proposes a procedure to place a side-reboiler and a side-condenser on a distillation column, in which exergy grand composite curve (EGCC) and avoidable exergy destruction curve (AEDC) are employed. A benzene-toluene column is used to demonstrate the performance of the procedure.

2. EGCC and AEDC

The major difference between column grand composite curve (CGCC) and EGCC is the parameter on the *y*-axis. Temperature (T) or stage number (*N*) is used in CGCC, while Carnot parameter (ε) is made use of in EGCC, as shown in Fig 1. It is clear that the dashed area represents the avoidable exergy destruction of the column by arranging a side-rebioler (refer to area a) or a side-condenser (refer to area b). On the energy-

* Correspondence author; email: chqlin@mail.sysu.edu.cn.

savings aspect, the optimum location to place a side-reboiler or a side-condenser is the stage where the corresponding dashed area is maximized. The corresponding heat duty is the proper heat duty of the side-reboiler or side-condenser.

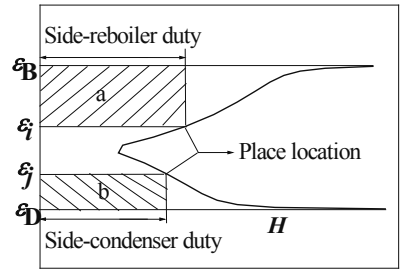

Fig. 1 Diagram of an exergy grand composite curve (EGCC)

The avoidable exergy destruction of the column through arranging a side-rebioler ($\dot{E}_{\mathrm{D,side\text{-}re}}$) or a side-condenser ($\dot{E}_{\mathrm{D,side\text{-}con}}$) is calculated as below, where H_{EGCC}, i, p represent the enthalpy value in EGCC, the stage number and the pinch point stage, respectively.

$$\dot{E}_{\mathrm{D,side\text{-}con}} = H_{\mathrm{EGCC},\,i}(\varepsilon_B-\varepsilon_i) \quad (p\le i\le n) \tag{1}$$

$$\dot{E}_{\mathrm{D,side\text{-}re}} = H_{\mathrm{EGCC},\,i}(\varepsilon_i-\varepsilon_D) \quad (1\le i\le p) \tag{2}$$

According to Eqs (1) and (2), the avoidable exergy destruction for each stage can be calculated. Changes of avoidable exergy destruction along the column are reflected in AEDC, in which the y-axis is defined as the avoidable exergy destruction, and x-axis is the stage number. The maximum value between the 1st and p-1th stage is the proper location to place the side-reboiler, and the maximum value between the p+1st and nth stage is the proper location for the side-condenser. The corresponding value of H_{EGCC} is the heat duty of the side-reboiler or side-condenser.

A benzene-toluene column is used to demonstrate the performance of AEDC. Specifications of the column are listed in Table 1, and the AEDC of benzene-toluene column is shown in Fig. 2. It can be seen that the 8th and 16th stages are the reasonable locations for the side-reboiler and side-condenser, respectively.

Table 1 Feed, product, and column specifications

Feed properties		Column characteristics		Feed molar fractions	benzene	0.50
Molar flow kmol/h	100	Stage number	20		toluene	0.50
Temperature K	365	Feed number	10	Column specifications	$x_{\mathrm{D,benzene}}$	0.99
Pressure MPa	0.1	Condenser	total		$x_{\mathrm{B,toluene}}$	0.99

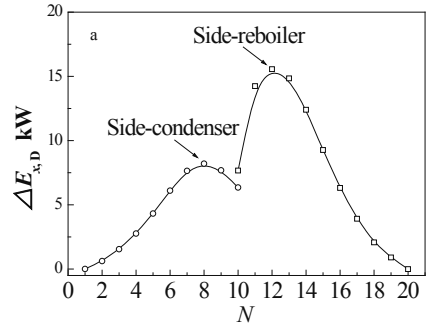

Fig. 2 AEDC of a benzene-toluene column

3. Criterion of modifying the column stage number

The relationship between placing side-reboilers or side-condensers on a distillation column and modifying the stage number is denoted in a McCabe-Thiele diagram, as shown in Fig. 3. It is clear that once the side-reboiler or side-condenser is placed, both the rectifying and stripping section operating lines are moved towards the equilibrium lines. To meet the separation requirement, more stages are needed. Otherwise, the reflux ratio should be increased. Indeed, the energy-savings of the side-reboiler and side-condenser are all at the expense of separation efficiency, and increasing the stage number or reflux ratio can re-meet the requirement of separation processes.

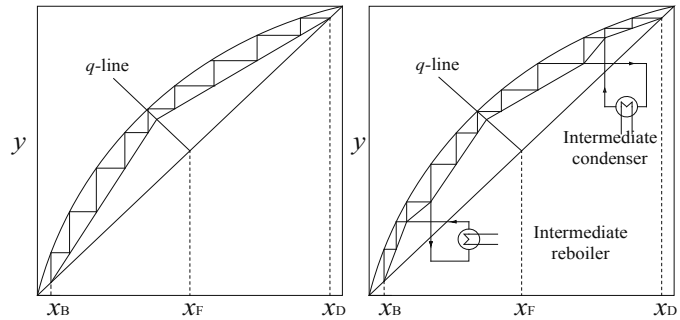

Fig. 3 McCabe-Thiele diagram of a binary system

For the existing distillation column, a balance between stage number and reflux ratio is carried out on the basis of the design process. To meet the separation requirement and maintain the balanced stage number and reflux ratio, increasing the stage number is a preferred alternative for practical industrial processes. Therefore, the criterions of modifying the column stage number are outlined as below.

(1) For a side-reboiler, the modified reflux ratio should not be larger than the existing reflux ratio.

(2) For a side-condenser, the modified reboiled ratio should not be larger than the existing reboiled ratio.

4. Calculation procedure

The calculation procedure of arranging a side-reboiler or a side-condenser on a distillation column is presented in Fig. 5, and described as below.

1) Identify the optimum feed stage $N_{F,opt}$, the optimum reflux ratio $R_{0,\,opt}$ (side-reboiler), or the optimum reboiled ratio $V_{B0,\,opt}$ (side-condenser).

2) Identify the original value of the location $N_{side\text{-}re,i}$ ($N_{side\text{-}con,i}$) and the heat duty $Q_{side\text{-}re,i}$ ($Q_{side\text{-}con,i}$) of the side-reboiler (side-condenser) through EGCC and AEDC.

3) Determine the new reflux ratio R_i' (reboiled ratio $V_{B,i}'$) after the side-reboiler or condenser arranged.

4) If R' ($V_{B,i}'$) is not larger than $R_{0,\,opt}$ ($V_{B0,\,opt}$), the option of adjusting the stage number is unnecessary, and the information of the side-reboiler or side-condenser: $N_{side\text{-}i}'$, $Q_{side\text{-}i}'$ ($_{i\,=\,re,\,con}$) can be output and the calculation is ended.

5) If R_i' ($V_{B,i}'$) is larger than $R_{0,\,opt}$ ($V_{B0,\,opt}$), add one stage to the column, and optimize the feed stage.

6) Return to the second step, recalculate until R_i' ($V_{B,i}'$) is not larger than $R_{0,\,opt}$ ($V_{B0,\,opt}$), output the information of the side-reboiler or condenser: $N_{side\text{-}j}'$, $Q_{side\text{-}j}'$, N_{add}, N_F' ($_{j\,=\,re,\,con}$)

and the procedure is ended.

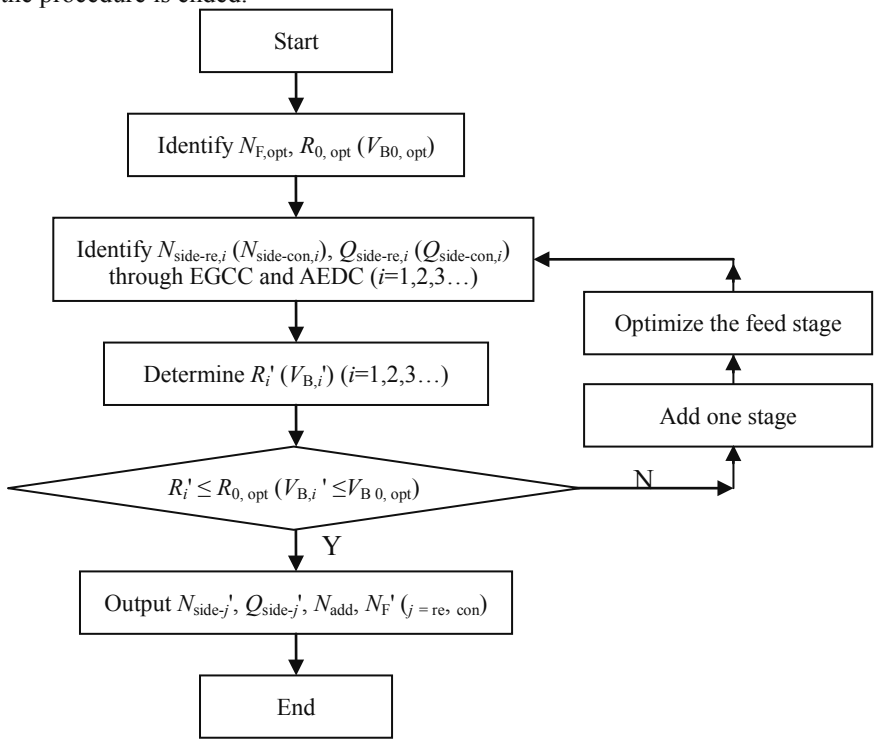

Fig. 5 Procedure for arranging side-reboilers/condensers on a distillation column

The benzene-toluene column mentioned above is used to demonstrate the performance of the proposed procedure. The detailed results of arranging a side-reboiler on the benzene-toluene column are listed in Table 3. It can be seen that in order to arrange a side-reboiler on the benzene-toluene column, three iteratives are needed to perform the calculation. With the increasing of the stage number the optimal feed stage is changed from the 10th stage to the 11th stage, and the proper location of the side-reboiler is varied from 12th stage to the 15th stage, and the heat duty is decreased from 590 kW to 520 kW. When the third stage is added to the column, the modified reflux ratio is lower than that of the original one. Then, the calculation is ended, and information to arrange the side-reboiler is output, i.e. three stages should be added, the feed stage is the 11th stage, the placing location is the 15th stage, and the side-reboiler duty is 520 kW.

Table 3 Information of arranging side-reboilers on benzene-toluene column

Iteration	R_i	$N_{F,i}$	$N_{side\text{-}re,i}$	$Q_{side\text{-}re,i}$ / kW	$N_{add,i}$
Base case	2.06	10	12	590	0
1	2.23	10	13	560	1
2	2.09	11	14	535	2
3	1.95	11	15	520	3

For placing a side-condenser, the detailed results are listed in Table 4. According to the procedure, two iteratives are needed to perform the calculation. With the stage number increased, the optimal feed stage is changed from the 10th stage to the 11th stage, and the placing stage is remained to the 8th stage, and the heat duty decreased from 390 kW to 330 kW. When the second stage is added, the modified reboiled ratio is lower than that of the original value. Then, the calculation is ended, and information to arrange the side-

condenser is output, i.e. two more stages are needed, the side-condenser duty is 330 kW, and the feed stage, the placing location are the 11th and 15th stages, respectively.

Table 4 Information of arranging a side-condenser on benzene-toluene column

Iteration	$V_{B,i}$	$N_{F,i}$	$N_{\text{side-con}}$	$Q_{\text{side-con},i}$ / kW	$N_{\text{add},i}$
Base case	2.85	10	8	390	0
1	2.95	10	8	360	1
2	2.79	11	8	330	2

As detailed above, one can conclude that the energy-savings of the side-reboiler and side-condenser are all at the expense of separation efficiency. In practical, the increasing of the stage number is the preferred alternative to re-meet the requirement of separation processes. With the stage numbers increased, the optimal feed stage, proper side-exchanger arranging location and heat duty are all changed. Therefore, re-considering those parameters is necessary. The procedure being proposed can address these issues in a simply, systemic and reliable way.

5. Conclusions

A procedure functioning to arrange a side-exchanger on the distillation column is proposed in this paper. EGCC and AEDC are used to identify the original value of location, heat duty of the side-exchanger. The criterion of modifying the column stage number is outlined, i.e. the modified reflux ratio (side-reboiler) should not be larger than the existing reflux ratio, and the modified reboiled ratio (side-condenser) should be less than the existing reboiled ratio. A benzene-toluene column is used to demonstrate the performance of the proposed procedure, and the optimal location and heat duty of the side-excahnger, stage number modification on the column are presented. The results indicate that the procedure is effective in arranging a side-exchanger on the distillation column.

Optimization of Complex Column Networks with Hybrid Genetic Algorithm

Seon B. Kim[a] and Andreas A. Linninger[a]

[a]*Departments of Chemical Engineering and Bioengineering, University of Illinois at Chicago, Laboratory for Product and Process Design. Chicago, IL 60607, USA*

Abstract

Complex column networks including Petlyuk, Kaibel, divided wall columns, side-stripper and rectifiers have better energy efficiency than simple separation networks. We present automatic and systematic computer-aided design and synthesis of complex column networks with heat-integrated configurations to separate multicomponent mixtures. Automatic synthesis of complex column is a challenging problem because the rigorous mass, equilibrium, summation and heat (MESH) equations lead to non-smooth fragmented search spaces. Therefore global optimization methods involving both structural and parametric degrees of freedom can currently not handle this problem and find realizable optimal energy efficiency in practice.

To tackle the network synthesis problem, we proposed the following design and optimization approaches. First we apply an inverse design methods based on temperature collocation which substantially reduces the problem dimension. This method identifies the design feasibility keeping final product purities. Second, we developed hybrid genetic algorithm, in which stochastic GA elements can be combined with a local deterministic search. At first stage, GA explores the design space until individual network solutions begin to coalesce and confines the region with niche technique. The gradient-based local optimizer refines a solution to local optimality. This hybrid scheme enables to find out all global and local solutions and thus improves computation speed and accuracy of the solutions.

Our novel methods allow the global search for feasible, effective and optimal energy efficient designs of the complex distillation column network in a fully automatic fashion. We used the rigorous commercial flowsheet simulator AspenPlus to validate the result and both results are very close each other. The automatic and rigorous flowsheet synthesis is apt to systematically address industrial-size process design problems such as the synthesis of energy-efficient separation networks, layout of biorefineries with novel feedstocks or sustainable process for reduction of greenhouse gases emissions.

Keywords: Temperature Collocation, Complex Column Networks, Hybrid Genetic Algorithm

1. Introduction

The large-case petrochemical and bio-separation process inherently contains purification structures for the final product value. One of the main units on the purification process is the distillation unit which is by far mostly utilized and prevalent in the industry. In the USA, there are approximately 40,000 distillation columns and those energy consumption is about 6% of the entire energy use of the USA (Lucia et al. 2010). Although energy consumption from distillation unit takes up great amount, industry is still operating simple column network which are built when the energy

consumption had minor impact on its consideration. However the rising energy cost and concerns over atmospheric carbon emissions redefine the design objectives for industrial separations with a new focus on energy conservation and the emission reduction associated with it.

Recently, heat-integrated complex column network have been revisited critically from several research group. The complex column configurations have the potential of achieving up to 70% energy savings over simple column networks (Hilde K. Engelien 2005). The well considered Petlyuk complex column configuration is an excellent example to realize energy efficient separations. Also Wright proposed the divided wall column, in which the prefractionator is transferred inside the second tower and its energy efficiency is better than conventional simple column configurations (Wright 1949). Linnger's group has also contributed to the systematic design method of complex column networks for last ten years (Zhang and Linninger 2004, 2006; Seon Kim et al. 2010, 2011)

However, there are no automatic and systematic algorithm to design and synthesize the entire complex column network. This challenge can be explained mathematically with two reason. First, problem size increases as the number of stages approximates infinity close to singular points of the composition space (e.g. saddle, pinch points). Secondly, in column design problems it is not known a priori whether a set of desired specifications has a feasible solution. In case of an infeasible specification, all direct performance design methods don't converge. To overcome these design problems, we have implemented a temperature collocation method specially for its use in column design including simple and complex column configuration. Also we propose two level optimization problem to meet both feasible design specification and energy efficiency criteria simultaneously. The hybrid genetic algorithm was applied to solve two level optimization problem. In the optimality of energy efficient design, the feasibility is necessary condition and lower vapor flowrate is sufficient condition for the this optimization problem. In this article, we will review the implemented collocation method and show hybrid GA optimization result with the case study.

2. Methodology

2.1. Inverse design procedure

Our design approach starts from the final product purities and inversely goes to find design parameters which was initially guessed from classical performance design approaches. Specifying required product purities, column profiles of both rectifying and stripping sections go to the stationary point named pinch points respectively. In the complex columns, we have equivalent rectifying or stripping section depending on the feed or product stream, a pair of both section constitutes one objective for the bubble point distance algorithm which should be optimized necessarily. For the sake of reduced search space of minimum distance for both profiles, our group discovered a thermodynamics transformation of the continuous model proposed by Hildebrandt's group (Tapp et al, 2003) by replacing the column stage number, n, with the equilibrium bubble point temperature, T. This thermodynamically motivated transformation offers massive size reductions in the column profile computations and is a key feature in a rigorous feasibility criterion based on minimum bubble point distance functions which eases the search (eq.1). In the case that there exists a pair of compositions with BPD = 0 at the same bubble point temperature, it guarantees feasible design and other cases vice versa.

$$\frac{\partial x_i}{\partial T} = -\left(\left(1+\frac{1}{R_\Delta}\right)\left(x_i - y_i\right)+\frac{1}{R_\Delta}\left(X_{\Delta i} - x_i\right)\right)\frac{\sum_{i=1}^{c}\left(\frac{\partial K_i}{\partial T}x_i\right)}{\sum_{i=1}^{c}\left[\left(\left(1+\frac{1}{R_\Delta}\right)\left(x_i - y_i\right)+\frac{1}{R_\Delta}\left(X_{\Delta i} - x_i\right)\right)K_i\right]} \qquad (1)$$

$$R_\Delta = \frac{L}{\Delta}, \quad X_{\Delta i} = \frac{Vy_i - Lx_i}{\Delta}$$

2.2. Two-level Optimization and Hybrid Genetic Algorithm

According to the generalization of the minimum bubble point distance approach, a complex column is feasible if the sum of all profile distances of all adjacent sections is within a small tolerance in eq. 2. This optimization is called a first level optimization and its solution is a necessary optimality condition.

$$\psi = \min_{xp,r}\left(\sum_{i=1}^{N}\sum_{j=1}^{k}\phi_{i,j} < \varepsilon\right) \qquad \begin{array}{l} i\text{: } i^{th} \text{ column for total N column network} \\ j\text{: } j^{th} \text{ pair of sections in } i^{th} \text{ column} \end{array} \qquad (2)$$

In this optimization, ε are set to 10^{-3} for the quaternary mixtures case study with reasonable match with AspenPlus simulation result. Once BPD optimization has converged, the algorithm seeks to minimize the energy requirement by reducing the vapor flowrate in the second level optimization as shown in eq. 3.

$$\omega = \min_{xp,\psi}\sum V(r) \qquad (3)$$

The design algorithm aims to achieve the final product purity with minimum energy requirement. However, in complex networks the decisions on sloppy slits in prefractionator columns as well as intermediate product purities are key variables to achieve energy efficiency. Accordingly, our algorithm explores intermediate products specifications and operating conditions for all columns. Also sloppy slits for multi-product columns are investigated, which is not possible with most existing design methods. The global approach does not optimize individual columns, but explores the entire network, since optimal conditions in a single column does not mean the network is optimal. Thus, minimum vapor flowrate for all columns in a network is solved simultaneously with two level optimization, all intermediate product purities and operating condition such as reflux ratio will be adjusted in the optimization procedure.

In the proposed two level optimization, it is critical to identify all local and global candidate solutions of the BPD criterion. Hybrid niche genetic algorithm (HNGA) was successfully implemented as a reliable multimodal optimizer with reasonable performance. It uses a niche technique to find all solutions sequentially. Basically, once one extremum is precisely located, a niche demarcating the area of attraction around the local minimum is recorded. The sequential process proceeds to search for additional extrema. The detailed description and performance test can be found elsewhere (Moon and Linninger, 2009). Figure 1 shows flowchart for the two level optimization with HNGA.

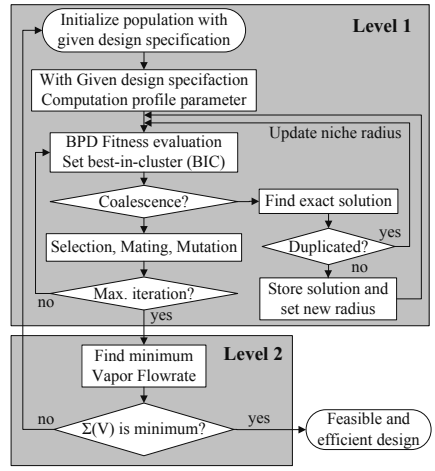

Figure 1. Hybrid niche genetic algorithm for two level optimization. The level 1 find solution for minimum BPD and level 2 seeks for minimum vapor flowrate.

3. Case Study

In mixtures with four or more components, the design problem involves the search for one or more compositional degree of freedom of any product stream. This multi-dimensional global optimization problem is solved using a hybrid method that combines stochastic genetic algorithm (i.e. product specification) with rigorous finite element collocation of column profiles (Zhang and Linninger 2006).

3.1. Separation of Quaternary Mixture

We performed case study to illustrate the potential energy saving of complex column configuration over simple column sequences for the separation of a quaternary mixture of benzene, toluene, octane and nonane. For the rigorous test to find best candidate from all 18 structures shown in Figure 2, the optimization for the least total vapor flow rates in each network was computed. The feed was set as 100 *kmol/hr* with equimolar concentration and the assumptions - constant molar overflows, no pressure drop by column height, monotonic behavior temperature, etc. - were applied for the simplification and DELPHI program was used for the numerical computation.

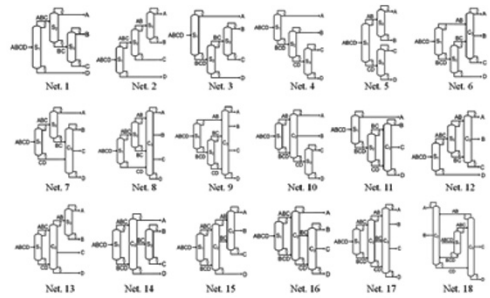

Figure 2. (a) Separation flowsheets to separate a quaternary mixture. All simple and basic Complex configurations are shown.

The selected optimization results for BPD and vapor flowrate, V, were listed in Table 1 and reboiler heat duty were obtained from the AspenPlus simulation. After rigorous testing for 18 networks, Net.10 has the minimum vapor flowrate and least reboiler heat duty. Comprehensively, all complex column networks have better efficiency than other simple column networks as shown in Table 1. From this result, net. 10 have 70% energy saving comparing to simple column net. 2.

Table 1. Selected results of design and synthesis calculation of 18 structures to separate alkane mixture (benzene/toluene/octane/nonane)

Network	10	13	16	12	4	1	3	5	2
Total BPD	1.32e-3	6.34e-4	5.22e-3	1.65e-3	2.08e-4	6.29e-3	8.49e-3	3.50e-3	8.26e-3
Total V	**202.02**	223.41	264.45	282.59	299.09	310.15	500.38	614.28	722.76
Total Q (MJ/hr)	16699	17646	20469	21980	23662	24353	38167	45160	54651

3.2. Initialization of complex distillation networks with AspenPlus

Figure 3 shows the complex network and composition profiles optimized with our temperature collocation profiles (top) and AspenPlus simulation results (Bottom). In the performance design approach, finding design variables to initialize AspenPlus simulation needs time-consuming trial and error method. However, our approach automatically finds all those variables by solving optimization with thermodynamically transformed composition profile equation (eq. 1). The AspenPlus simulation from the result of our approach converged with only one or two iterations. This result confirms the accuracy of our methodology is acceptable for a design and synthesis calculations. Our methodology using automatic interface with Aspen flowsheet simulator, will be also useful as an industrial practice for implementing this design idea of complex column networks.

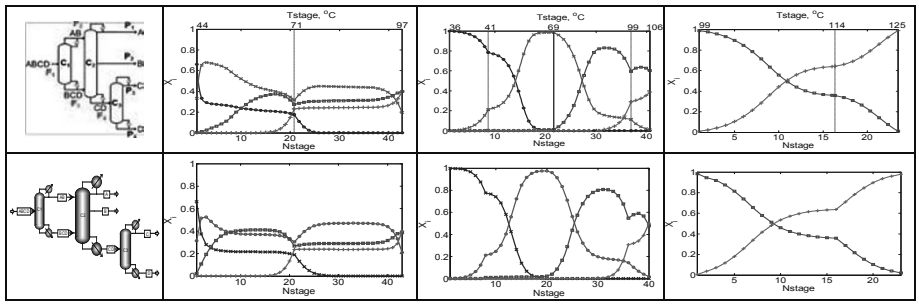

Figure 3. Liquid composition profiles in the stage domain found by temperature collocation model (top), and AspenPlus simulation results (bottom) for prefractionating complex column network NW10.

4. Conclusions

In this article, we advocated the recent progress for optimized energy efficient complex distillation networks. A two level optimization approach with hybrid genetic algorithm towards a generalized solution of the complex distillation problem is presented. This approach makes it possible the automated and systematic design procedure satisfying both feasibility and low energy consumption. Inverse design procedure fully assisted with hybrid niche genetic algorithm, thermodynamically transformed composition profiles, and minimum bubble point distance algorithm were the effective way to find a feasible separation by intercepting profiles. In finding optimal solution, two level optimization was performed to discriminate the energy efficiency. The case study demonstrates the potential to 70% of energy savings using a complex column network compared to the simple column configuration. Our design approach also demonstrates that current state of the art of separation synthesis in conjunction with computer simulations is now ready to address to fully integrate complex separation networks. In the future, this methodology will be applied for cases of nonideal mixtures such as homogeneous or heterogeneous azeotropes.

Using PSE to develop innovative cryogenic air separation processes

Chao Fu, Truls Gundersen

Department of Energy and Process Engineering, Norwegian University of Science and Technology, Kolbjoern Hejes vei 1.A, NO-7491 Trondheim, Norway

Abstract

The double-column distillation scheme is the basis for most existing cryogenic air separation plants. When the scheme is used for low pressure O_2 production, power is wasted in compressing O_2 in the air feed. A vapor recompression air distillation scheme has been developed to avoid O_2 compression. Distributed reboiling is used to reduce the irreversibilities in the distillation column. Column Grand Composite Curves are used to determine the load and location of the reboilers. Compared to a value published by authors representing the air separation industry, the power consumption has been reduced by 10.7% in the intermediate vapor recompression cycle presented in this paper.

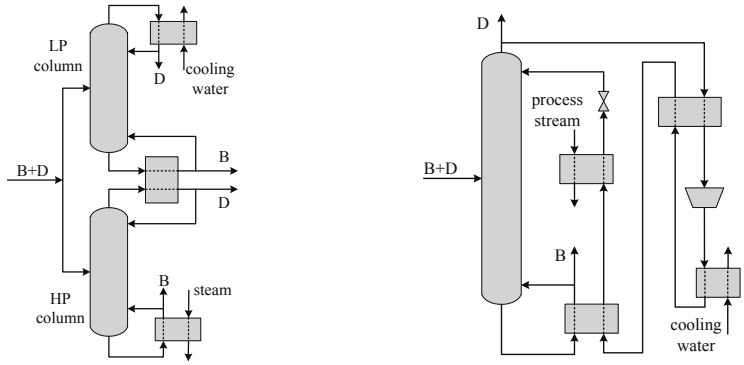
Keywords: cryogenic air separation; vapor recompression; Column Grand Composite Curve

1. Introduction

Due to the increased concern about CO_2 emissions, oxy-combustion power plants represent a new large scale application of air separation units (ASUs) (Higginbotham *et al.*, 2011). Commercially available air separation technologies for large volume O_2 production are based on cryogenic distillation. For oxy-combustion power plants, the O_2 purity is around 95 mole% and the supply pressure is slightly above atmospheric pressure (around 120 kPa). These new specifications on the O_2 product provide considerable opportunities for improving the ASUs (Higginbotham *et al.*, 2011).

The double-column air separation cycle was developed by Linde in 1910 (Latimer, 1967, Kerry, 2007), and has been used as the basis for most existing air separation plants. All the air feed is compressed to a pressure high enough (usually 400-600 kPa) to allow reasonable pressure losses along the flow path and enough temperature driving forces in the condenser/reboiler exchanger. An exergy analysis of a conventional double-column air separation cycle (termed as "Cycle 1") indicates that the air compression process and the distillation system are responsible for the two largest exergy losses: 38.4% and 28.2% respectively (Fu and Gundersen, 2011). The irreversibilities in distillation columns can be reduced by using "distributed reboiling" (Gaumer, 1967). For the air compression process, the power consumption can be reduced by (i) improving the compressor efficiency, (ii) reducing the compression ratio, (iii) lowering the operating temperature, and (iv) reducing the mass flow through the air compressor. This paper focuses on the last of these measures. For oxy-combustion power plants, the O_2 product does not need to be delivered at elevated pressure, thus power is wasted in the compression of O_2 in the air feed in Cycle 1. A vapor recompression air distillation scheme has been developed in this paper to avoid the compression of O_2 (Lynd and Grethlein, 1986, Agrawal and Yee, 1994, Fu *et al.*, 2011). Furthermore, Column Grand Composite Curves (CGCCs) are applied to investigate the load and level (location) of distributed reboilers in distillation columns (Dhole and Linnhoff, 1993).

2. An innovative vapor recompression air distillation scheme



(a) Thermally coupled distillation (b) Vapor recompression distillation

Figure 1. Distillation schemes

Thermally coupled distillation is the basis of the double-column air separation scheme. Figure 1 (a) shows a typical thermally coupled distillation scheme at above-ambient temperature. The two columns are operated at different pressures so that the overhead vapor product from the higher pressure (HP) column can be condensed by the bottom liquid from the lower pressure (LP) column, thus steam is only consumed in the HP column. The feed to the HP column has to be compressed to the operating pressure of the HP column. By using a vapor recompression distillation scheme, the compression of the bottoms product (B) can be avoided. Such a scheme for sub-ambient application is shown in Figure 1 (b). A portion of the distillate product (D) is heated to ambient temperature, compressed and then condensed against the boiling liquid in the bottom of the column after cooling, and finally used as reflux for the column. When this scheme is used for air separation, one can avoid compressing the O_2.

2.1. The vapor recompression air distillation cycle

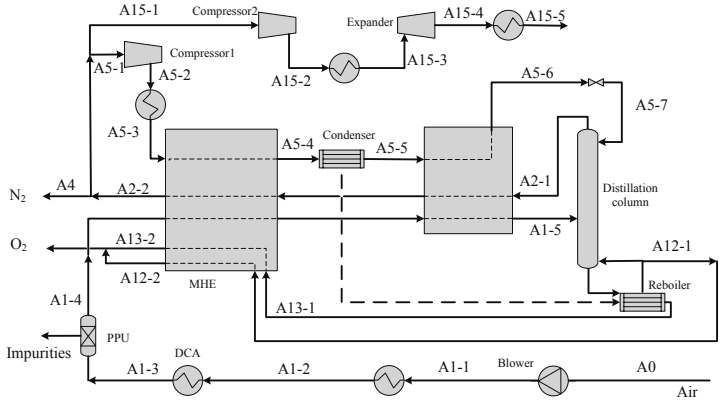


Figure 2. Cycle 2: a vapor recompression air distillation cycle

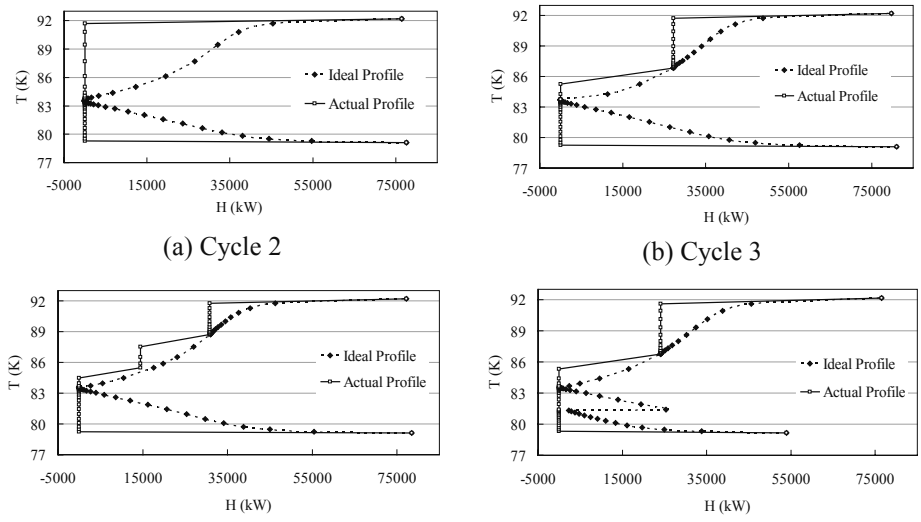
A vapor recompression air distillation cycle has been developed and is shown in Figure 2, termed as "Cycle 2". In this cycle, the air feed (A0) is slightly compressed to compensate for the pressure losses along its flow path. The compression heat and

impurities are removed from the air. The air (A1-4) is cooled to its dew point (A1-5) and separated into O_2 and N_2 in a distillation column. The O_2 (A12-1 and A13-1) and N_2 (A2-1) are heated to ambient temperature in the multi-stream heat exchangers. A portion of the N_2 product (A5-1) is compressed and cooled to its dew point (A5-4), and then condensed against the boiling O_2 at the bottom of the distillation column. The condensed N_2 (A5-5) is sub-cooled, expanded and returned back to the distillation column as reflux. Another portion of the N_2 product (A15-1) is used as the working fluid in a refrigeration cycle. This refrigeration cycle provides necessary cold energy for the main heat exchanger (MHE). Since only a portion of the N_2 is compressed for the production of reflux, one avoids compressing the O_2 in the air feed significantly, thus power consumption is reduced.

2.2. The dual-reboiler cycle

Distributed reboiling in the distillation column can reduce the irreversibilities and save energy. The Column Grand Composite Curve (CGCC) has been applied to investigate the load and level (location) of the distributed reboiling (Dhole and Linnhoff, 1993). The CGCC for the distillation column in Cycle 2 is shown in Figure 3(a). The large area between the ideal profile curve and the actual profile curve indicates the improvement potential by using distributed reboiling. A simplified dual-reboiler cycle is shown in Figure 4, termed as "Cycle 3". Only the most important parts that reflect the idea of distributing the reboiling are presented. With reference to Figure 2, the dashed lines without stream connections in the main heat exchanger (MHE) in Figure 4 are for O_2 streams. Compared to Cycle 2, the main difference is that the N_2 used for reflux is compressed to two pressures (A5-2 and A7-2). The higher pressure N_2 stream (A5-2) is cooled and condensed in the bottom reboiler of the distillation column (Condenser1/Reboiler1 exchanger), while the lower pressure N_2 stream (A7-2) is cooled and condensed in an intermediate reboiler (Condenser2/Reboiler2 exchanger). The power consumption is reduced since a portion of the N_2 for reflux production can be compressed to a lower pressure (A7-2). The CGCC for Cycle 3 is shown in Figure 3(b).



(a) Cycle 2 (b) Cycle 3

(c) Cycle 4 (d) Cycle 5

Figure 3. Column Grand Composite Curves

2.3. The three-reboiler cycle

Similar to the dual-reboiler cycle, a three-reboiler cycle, termed as "Cycle 4", has been studied but not presented in detail in this paper due to space limitations. In this cycle, the N_2 is compressed to three pressures for reflux production and condensed in a bottom reboiler and two intermediate reboilers in the distillation column. The CGCC for this cycle is shown in Figure 3(c). Compared to Figure 3(b), the area between the ideal profile curve and the actual profile curve has not been significantly reduced, thus the power saving potential by using more reboilers is limited.

2.4. The intermediate vapor recompression cycle

Figures 3(a) and (b) show that the irreversibilities of the rectifying section of the distillation column can also be reduced, even though the potential is not as large as in the stripping section. An intermediate vapor recompression cycle has been developed based on the idea of reducing the irreversibility of the rectifying section, as shown in Figure 5, termed as "Cycle 5". The main difference between this cycle and Cycle 2 is that a portion of impure N_2 (A7-1) is extracted at an intermediate location of the rectifying section of the distillation column. This N_2 stream is compressed after being heated to ambient temperature, and then condensed in an intermediate reboiler in the column after being cooled to its dew point, and finally returned back to the column. The main advantage is that the intermediate N_2 stream can be compressed to a much lower pressure (A7-3) compared to the overhead N_2 compression (A5-2). The CGCC is shown in Figure 3(d).

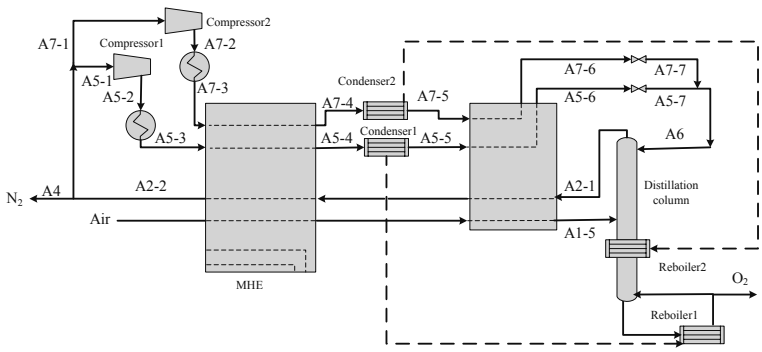


Figure 4. Cycle 3: a dual-reboiler cycle

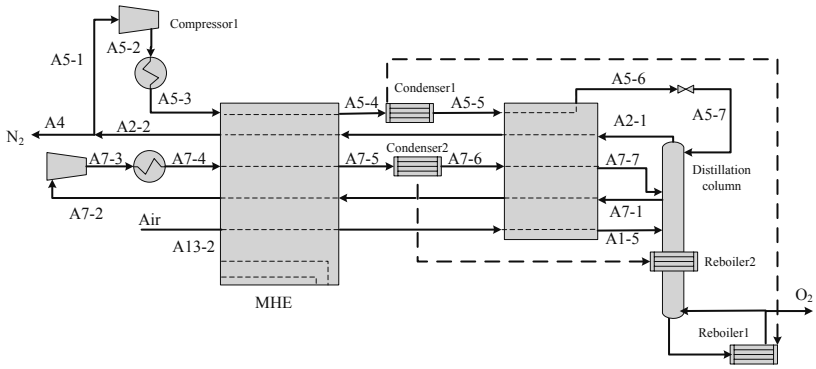

Figure 5. Cycle 5: an intermediate vapor recompression cycle

3. Plant performance comparison

All the cycles have been simulated without optimization. A three-column cycle reported by Higginbotham *et al*. (2011) has been used as the reference case (Cycle 0). The same ambient conditions (288.15 K, 101.3 kPa, 60% relative humidity) and cooling water temperature (288.15K) are used. Specific shaftwork for separation (the shaftwork for producing 1 kg O_2 contained in the O_2 product at 101.3 kPa) is compared. The plant performance data are listed in Table 1. Compared to Cycle 1, the power consumption has been reduced by 7.8% in the vapor recompression distillation cycle (Cycle 2) and by 14.0% in the dual-reboiler cycle (Cycle 3), and further reduced by 16.6% and 17.6% in Cycle 4 and Cycle 5. However, the investment cost will increase if distributed reboiling is used. The reference cycle (with three columns and two reboilers) is designed based on the double-column distillation scheme. Compared to this cycle, the power consumption has been reduced by 10.7% in Cycle 5. An economic study is necessary for further comparison of the various cycles; however, this is beyond the scope of this study.

Table 1. Plant performance comparison

	Cycle 0	Cycle 1	Cycle 2	Cycle 3	Cycle 4	Cycle5
O_2 purity, mole%	95.0	95.0	95.4	95.5	95.5	95.1
O_2 recovery rate, %	97.7	99.3	98.4	98.5	98.5	97.9
Specific shaftwork for separation, kWh/kgO_2	0.178	0.193	0.178	0.166	0.161	0.159

4. Conclusion

The double-column air separation cycle has been used as the basis for most existing air separation plants. This cycle causes unnecessary compression of O_2 when low pressure O_2 is the desired product. By applying the vapor recompression distillation scheme, the mass flow through compressors can be reduced with corresponding energy savings. The power consumption has been reduced by 7.8% in the vapor recompression cycle. When the principle of distributed reboiling is applied, the power consumption has been reduced by 14.0% and 16.6% in a dual-reboiler and a three-reboiler cycle, respectively. Compared to a value published by representatives of the air separation industry, power consumption has been reduced by 10.7% in the best of the cycles presented in this paper.

Abstract

A general model of batch heteroazeotropic distillation is proposed, in which both liquid phases present in the decanter can be refluxed or withdrawn as distillate, their hold-up can be increased, decreased or kept constant, as well. A feasibility study is performed with the assumption of maximal separation, that is, that the composition of the condensate always equals to that of the heteroazeotrope. The still path directions are determined for all the 16 possible operation policies, and the results are validated by rigorous simulations for three cases not published yet. The still path can be steered in any direction by changing the operational parameters, allowing the recovery of a pure component in the still.

Keywords: heteroazeotropic distillation, operational policies, rigorous simulation.

1. Introduction

The separation of azeotropic and close-boiling mixtures requires the application of special distillation methods. Batch heteroazeotropic distillation is one of the possible methods: a third component (entrainer, E) is added to the mixture, leading to the formation of two liquid phases, which can be separated by decantation.
Decantation is performed in a decanter placed after the condenser. In the model of Pham and Doherty (1990) both liquid phases are refluxed. The model of Rodríguez-Donis et al. (2002) allows the reflux of any fraction of either phase; distillate is withdrawn from the E-lean phase, and the hold-up of the E-rich phase in the decanter is variable. Skouras et al. (2005) distinguished two modes of batch heteroazeotropic distillation. By Mode I, decantation and distillation are performed sequentially, and the reflux is heterogeneous. By Mode II, the phase separation and distillation are simultaneous. Mode II has two versions: Strategy A, where the E-rich phase is refluxed entirely, and Strategy B, where it is refluxed partially. In the model of Lang and Modla (2006) any fraction of either liquid phase can be refluxed, while the hold-up of both phases are constant. Distillate can be withdrawn from both phases.

2. Model description

Figure 1 shows the scheme of the heterogeneous distillation column of our generalised model. The condensate of the top vapour, which has a molar flow rate of V and molar composition of y_2, gives rise to two-phase liquid stream with a flow rate of L_0, composition of x_0, and a split ratio of ω (ratio of the E-rich phase and total flow rate).

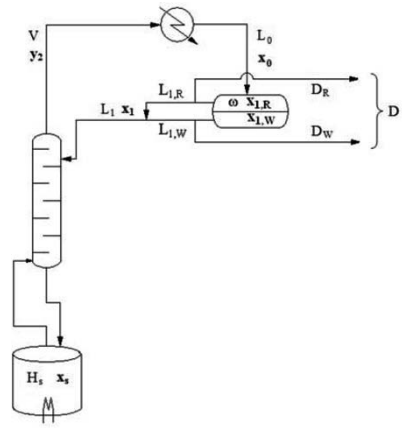

Figure 1. Heteroazeotropic distillation column scheme for the generalised model.

Both liquid phases can be refluxed or withdrawn as distillate. Besides, the hold-up of both phases can be increased, decreased or kept constant in the decanter. The change in the hold-up of the E-rich (resp. E-lean) phase is characterised by the variables θ_H (resp. φ_H), which are defined as the ratio of the amount of E-rich (resp. E-lean) phase removed from and entering the decanter:

$$\theta_H = \frac{L_{1,R} + D_R}{L_{0,R}} \qquad (1) \qquad\qquad \varphi_H = \frac{L_{1,W} + D_W}{L_{0,W}} \qquad (2)$$

where $L_{0,R}$ and $L_{0,W}$ are the flow rates of the E-rich and E-lean phase in the condensate, D_R and D_W are the flow rates of E-rich and E-lean phases withdrawn as distillate, $L_{1,R}$ and $L_{1,W}$ are those refluxed, respectively. If the value of θ_H is lower than one, the hold-up of the E-rich phase increases, if it is higher, the hold-up decreases.

The variables θ_{refl} and φ_{refl} determine the ratio of the amount refluxed and the total amount leaving the decanter for the E-rich and E-lean phases, respectively:

$$\theta_{refl} = \frac{L_{1,R}}{L_{1,R} + D_R} \qquad (3) \qquad\qquad \varphi_{refl} = \frac{L_{1,W}}{L_{1,W} + D_W} \qquad (4)$$

Multiplying θ_H and θ_{refl} (resp. φ_H and φ_{refl}), the ratio of the refluxed E-rich (resp. E-lean) phase is obtained, which value can be higher than one:

$$\theta = \theta_H \theta_{refl} = \frac{L_{1,R}}{L_{0,R}} \qquad (5) \qquad\qquad \varphi = \varphi_H \varphi_{refl} = \frac{L_{1,W}}{L_{0,W}} \qquad (6)$$

The following simplifying assumptions are applied in the feasibility analysis:

- the composition of the condensate is constant and equals to that of heteroazeotrope,
- the vapour and liquid hold-ups of the column and of the condenser are negligible,
- constant molar overflow.

The first assumption also means that ω, $x_{1,R}$ and $x_{1,W}$ are not changing in time, although they may change slightly during a real operation (Pommier et al., 2008).

The flow rate of the condensate (equal to that of the top vapour, V):

$$L_0 = L_{0,R} + L_{0,W} = \omega L_0 + (1-\omega) L_0 = V \qquad (7)$$

The total flow rate of reflux stream is the following:

$$L_1 = L_{1,R} + L_{1,W} = \theta L_{0,R} + \varphi L_{0,W} \qquad (8) \qquad\qquad L_1 = \theta\omega V + \varphi(1-\omega) V \qquad (9)$$

The component flow rates of the reflux flow:

$$L_1 x_1 = L_{1,R} x_{1R} + L_{1,W} x_{1,W} \qquad (10)$$

The evolution of the still composition is described by a differential equation, which can be derived from the total and component (differential) material balances of the still pot.
The total material balance (assuming constant molar overflow):

$$\frac{dH_S}{dt} = L_1 - V = (\theta - 1)\omega V - (1-\varphi)(1-\omega)V \tag{11}$$

The component material balance:

$$\frac{d(H_S x_S)}{dt} = L_1 x_1 - V x_0 = (\theta - 1)\omega V x_{1,R} - (1-\varphi)(1-\omega)V x_{1,w} \tag{12}$$

By applying the product rule of differentiation, the equation of the still path:

$$H_S \frac{dx_S}{dt} = \frac{d(H_S x_S)}{dt} - x_S \frac{dH_S}{dt} \tag{13}$$

The final form of the equation describing the evolution of the still composition:

$$\frac{dx_S}{dt} = (1-\theta)\omega \frac{V}{H_S}(x_S - x_{1,R}) + (1-\varphi)(1-\omega)\frac{V}{H_S}(x_S - x_{1,W}) \tag{14}$$

The two terms represent the removal of the E-rich and the E-lean phase from the system, respectively, by either withdrawal as distillate, or accumulating in the decanter.

3. Operational policies

Based on the values of two operational parameters θ and φ, 16 different cases can be distinguished, shown in Table 1. If θ (resp. φ) is 0, the E-rich (resp. E-lean) phase is not refluxed. If θ (resp. φ) is 1, the E-rich (resp. E-lean) phase is refluxed entirely. If θ (resp. φ) is greater than 1, the amount of the E-rich (resp. E-lean) phase refluxed to the column is greater than what is removed from it with the top vapour. To supply this difference in the flow rates, the hold-up of the respective phase must be decreased.
In Eq. 14, the terms related to the refluxing of a phase (θ_{refl} and φ_{refl}) and to the change in its hold-up (θ_H and φ_H) are only present with their products (θ and φ). That is, the same effect can be achieved either by accumulating one of the phases, or by withdrawal as distillate. The practical implementation of withdrawal is easier. Accumulating one of the phases in the decanter may be useful, e.g. in order to ensure the existence of two liquid phases. However θ or φ can only be greater than 1, if the hold-up is reduced. In Table 1 examples are given for some operational policies.
The still path can be characterised by the direction of the derivative vector of the still composition. This can be written (Eq. 14) as the sum of two other vectors, whose magnitude depends on θ and φ, respectively. Their direction can even be reversed, if θ or φ is greater than 1. Therefore, the direction of the resultant vector depends on the operation policy and the value of the operational parameters θ and φ. The results are illustrated with a mixture of A, B and E. A and the entrainer E form a binary heteroazeotrope, which is the only unstable node of the system.
The two vectors influencing the still path are presented in Fig. 2a. The vector corresponding to the E-lean phase points away from $x_{1,W}$, if φ<1, and towards it, if φ>1. The other vector, corresponding to the E-rich phase points away from $x_{1,R}$, if θ<1, and towards it, if θ>1. If θ or φ equals 1, the respective vector does not exist.
Fig. 2b shows the possible directions of the derivative vector, that is, the instantaneous direction of the still path for every possible operational policy shown in Table 1. By directing the still path appropriately, through choosing the right values of θ and φ, B can be recovered in the still, thus eliminating the need of a further separation step.

Table 1. The possible operational policies (reintr.: reintroduction - a greater amount of liquid is refluxed than what leaves the column as distillate).

	θ	φ	Reflux	Example
1	0	0	No reflux	
2		<1	E-lean phase (partial)	
3		1	E-lean phase (total)	
4		>1	E-lean phase (reintr.)	
5	<1	0	E-rich phase (partial)	Mode II, Strategy B (Skouras et al., 2005); Mode II, Strategies 2' and 2" (Gerbaud and Rodríguez-Donis, 2010)
6		<1	E-rich (partial) and E-lean phase (partial)	
7		1	E-rich (partial) and E-lean phase (total)	
8		>1	E-rich (partial) and E-lean phase (reintr.)	
9	1	0	E-rich phase (total)	Mode II, Strategy A (Skouras et al, 2005); Mode II, Strategy 1 (Gerbaud and Rodríguez-Donis, 2010)
10		<1	E-rich (total) and E-lean phase (partial)	Operation with reflux from E-lean phase, as well
11		1	E-rich (total) and E-lean phase (total)	Total reflux operation
12		>1	E-rich (total) and E-lean phase (reintr.)	
13	>1	0	E-rich phase (reintr.)	Mode II, Strategy 3 (Gerbaud and Rodríguez-Donis, 2010)
14		<1	E-rich (reintr.) and E-lean phase (partial)	
15		1	E-rich (reintr.) and E-lean phase (total)	
16		>1	E-rich (reintr.) and E-lean phase (reintr.)	

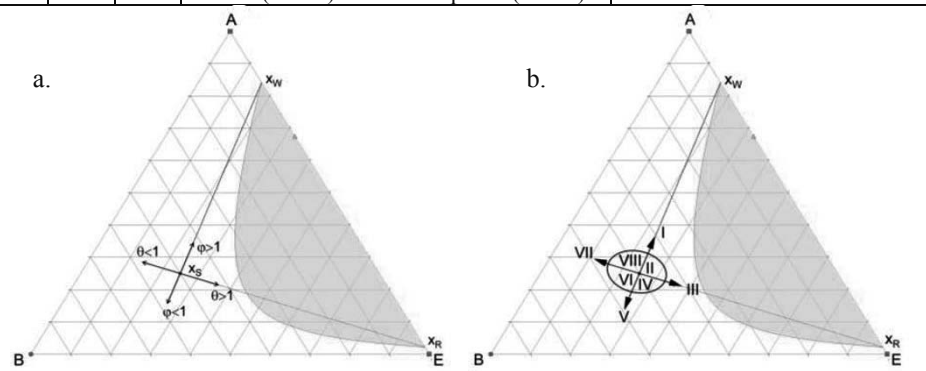

Figure 2 a. The possible directions of the vectors influencing the still path. b. The direction of the still path for the different operational policies.

4. Rigorous simulation results

In order to validate the model, rigorous simulations are performed with the professional flowsheet simulator CHEMCAD. Operational policies 8, 12 and 16 are applied in order to demonstrate that the still path can be turned into directions previously not reported, that is, towards the E-lean phase. The column has 50 theoretical plates; the mixture to be separated is water (A) – formic acid (B) – propyl formate (E). The vapour-liquid-liquid equilibria are described with the NRTL model. The mixture A – B exhibits a minimum boiling-point homoazeotrope, while A and E form a heteroazeotrope, enabling the separation of the A – B mixture.

The hold-up of the decanter is 0.5 dm^3; that of the column is 0.01 dm^3/plate. The charge has a molar amount of 160 mol and a composition of 52.5 mol% A, 40.5 mol% B and 7% E. The heat duty applied is 2 kW. The column is operated for 40 minutes under total reflux, after which one of the policies previously mentioned is applied. At the end of the total reflux period, the volumes of liquid phases in the decanter are equal. The values of the operational parameters are: $\varphi = 1.21$, $\theta = 0.986$ (Policy 8), 1.0 (Policy 12), and 1.014 (Policy 16), respectively. The respective still paths are shown in Fig. 3. Each path starts from the composition at the end the total reflux period ($x_{S,\infty}$). For Policy 12, the still composition moves towards that of the entrainer-lean phase, while for Policies 8 and 16, the path deviates from this direction as predicted: towards the edge A-B (Policy 8) or vertex E (Policy 16). That is, the still path directions are in accordance with the results of the feasibility analysis.

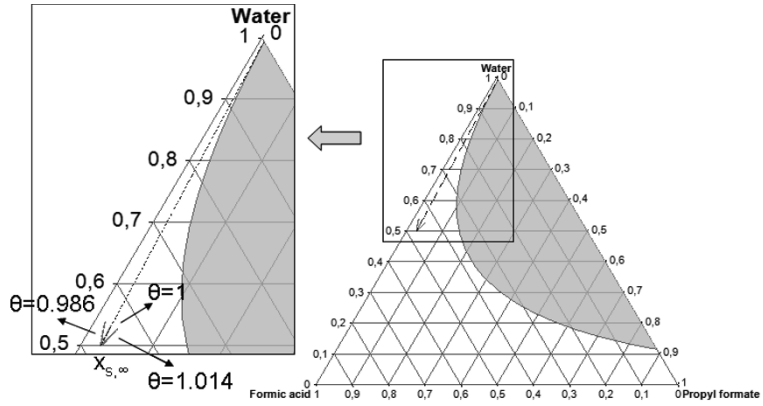

Figure 3. The calculated evolution of still composition (operational policies 8, 12, 16)

5. Conclusions

A general model of batch heteroazeotropic distillation was proposed. Both liquid phases present in the decanter can be refluxed or withdrawn as distillate, their hold-up can be increased, decreased or kept constant, as well. By assuming maximal separation, that is, that the condensate is always the heteroazeotrope, the still path equation was derived and the vectors determining the evolution of still composition were identified. The still path directions were determined for all the 16 possible operation policies. The results were validated by rigorous simulations for three cases not published yet. By using appropriate operational policies, it is possible to steer the still path in any desired direction, making possible to recover a pure component in the still.

Abstract

An economic nonlinear model predictive control (NMPC) framework is proposed to minimize utility cost for energy intensive applications in volatile electricity markets. In the *day ahead pricing* scheme, an economic objective function is used to minimize the future cost. On the other hand, a time series model must be incorporated to predict future electricity prices for *real time pricing*. A multicriterion objective function is proposed to minimize variation due to either pricing scheme. The proposed framework is demonstrated on an air separation unit and nearly 10% in cost reduction is observed.
Keywords: economic NMPC, electricity price prediction, Air separation unit

1. Introduction

Energy prices are often subject to high fluctuations in today's electricity markets, because electricity is not readily stored and has to be used or wasted after production. As a result, utility companies resort to complex pricing schemes to allocate resources. These schemes include *day ahead pricing* and *real-time pricing* strategies where electricity price can vary by an order of magnitude over the course of a day, especially in the latter case. This fluctuation can significantly impact the operating cost of a plant, especially for energy intensive applications. In Ierapetritou et al. (2002) and Baumrucker and Biegler (2010), short-term optimization schemes were proposed to take advantage of varying power price.

To deal with process dynamics, model predictive control (MPC) and nonlinear MPC (NMPC) have been widely used in industry, as they readily handle constraints and multi-input-multi-output systems. However, the majority of (N)MPC applications have been posed as setpoint tracking problems, where, the setpoint is normally calculated by the so-called real-time optimization (RTO) layer, based on a steady state first principle model. Furthermore, most theoretical analyses of (N)MPC are restricted to set-point tracking formulations (Rawlings and Mayne, 2009). Nevertheless, model inconsistency may lead to an unreachable setpoint or suboptimal solution by simply tracking the given setpoint as fast as possible (Rawlings and Amrit, 2009). As a result, interest has significantly increased in economically oriented NMPC, which directly optimizes the economic performance. Recently, several NMPC studies have reported good practical performance by using economically-oriented NMPC or, equivalently, dynamic RTO formulations that directly optimize the plant's economic performance (Rawlings and Amrit, 2009; Bartusiak, 2007; Diehl et al., 2011). Meanwhile, stability analyses of economic NMPC have also appeared in the literature (Aske et al., 2009; Diehl et al., 2011). In particular, our previous work (Huang et al., 2011, 2012) established the nominal and robust stability properties of NMPC for cyclic processes. Moreover, around 30% cost reduction has been achieved for an energy intensive air separation unit.

In this work, we present a framework to implement economically-oriented NMPC to control energy-intensive applications. This framework incorporates a time series model to predict prices from the volatile electricity market. This predicted price is used in the NMPC objective function to carry out the prediction in the controller. This framework is demonstrated by controlling an energy intensive air separation unit, which has been studied in our previous work (Huang et al., 2009). The rest of the paper is organized as the follows. Section 2 briefly discusses the economically-oriented NMPC formulation while Section 3 presents the time series model for the electricity price forecasting. Section 4 describes the simulation results and Section 5 concludes the paper.

2. Economically-oriented NMPC formulation

In this section, we consider the nominal discrete time nonlinear system

$$x_{k+1} = f(x_k, u_k); \qquad x_k \in \mathbf{X}, u_k \in \mathbf{U}, \tag{1}$$

where at time step k, x_k is the plant state in the domain $\mathbf{X}$ and u_k is the control input in the domain $\mathbf{U}$. As a result, the economically-oriented NMPC formulation is written as the following nonlinear programming (NLP) problem,

$$\min_{x,u} \sum_k l(x_k, u_k) \text{ s.t. } x_{k+1} = f(x_k, u_k), x_k \in \mathbf{X}, u_k \in \mathbf{U}, \tag{2}$$

where $l(x_k, u_k)$ is the economical cost function at the time step k for the plant (1). The objective of the NMPC controller is to minimize the economic cost over the predictive time horizon. Here unlike conventional setpoint-tracking NMPC, the cost function $l(x_k, u_k)$ usually does not take a quadratic form. In the following, we present two economic cost function to minimize the utility cost in the volatile electricity market. Let p_k be the electricity price at the time step k. This price information can be achieved from published data by utility companies, or from the prediction of time series model discussed in the next section. In addition, let g_k be the amount of the energy consumed at the time step k, and $g_k = h(u_k)$ is a function of the control inputs. Hence the cost function of NMPC (2) at time step k can be chosen as $l_k = p_k g_k$. Clearly, the economic NMPC (2) with the cost function (3) is to minimize the utility cost in a deterministic framework. On the other hand, the future electricity price may suffer from uncertainties, especially when the price is predicted from a time series model. In this case, the stochastic performance should also be considered in the economic NMPC formulation. Hence, the cost function is modified as

$$l_k = W_1 E(p_k) g_k + W_2 var(p_k) g_k, \tag{3}$$

where $E(p_k)$ and $var(p_k)$ are the expected value and variance of the predicted electricity price p_k at time step k, respectively, and W_1 and W_2 are the weights. As a result, the economic NMPC (2) with the objective function (3) is to minimize the utility cost in the volatile electricity market while minimizing the uncertainty of the control policy subject to the uncertainties in the predicted electricity price. Similarly, the economic NMPC formulation can be modified by choosing $l_k = E(p_k) g_k$ and adding an inequality constraint $\mathrm{var}(\mathrm{p_k}) \leq \kappa(\max\ var)$ to the optimization problem (2). In this work, we use the economic NMPC formulation (2) with objective function (3).

Finally, it is worth noting that the objective function (3) may not guarantee the stability of the NMPC controller (2) in reaching an equilibrium point. This can be avoided by introducing quadratic regularization terms in the objective function, as will be further illustrated in the simulation example in Section 4.

3. Volatile electricity pricing schemes

The price of electricity depends on many different factors such as time of day, location and so on. In this section, we focus on two complicated pricing schemes, namely *day ahead pricing* and *real-time pricing* schemes, which are commonly used in industrial sectors *Day ahead pricing* changes the electricity price every hour. Utility companies estimate the production cost and the energy demand for the next day to come up with the energy price they charge. This price is usually published 24 hours in advance, and the pricing scheme is similar to the commodities future contract price. *Real time pricing* also changes the electricity price hourly, but this is based on the real time market-balancing price, i.e., the last price paid by the utility for electricity in the time period. This is similar to the spot market price or clearing price. Since the day-ahead electricity price is available 24 hours in advance, it can be directly used in the NMPC prediction problem. However, in the real time pricing scheme, the electricity price is only available at the end of every hour, which is not suitable for the prediction problem. Hence, a price forecast model is developed to predict the future price based on the past information. There is an extensive literature in the development and application of forecasting techniques. A survey and detailed comparison of various methodologies can be found in (Box et al., 1994). Here a commonly-used Autoregressive Integrated Moving Average (ARIMA) model is used to predict the future real time electricity price over next 24 hours.

More specifically, the ARIMA model is referred to as an ARIMA(*p,d,q*) model where *p*, *d* and *q* are non-negative integers that refer to the order of the autoregressive, integrated, and moving average parts of the model respectively. An add-on Microsoft Excel statistics tool XLSTAT, from www.xlstat.com, is used for model construction. We analyze the electricity price in the period of 3/20 -3/23/2011 from Ameren (https://www2.ameren.com/RetailEnergy/realtimeprices.aspx), a utility company in St. Louis. ARIMA (2,1,1) shows the best balance of model complexity and predictability, and is characterized by the following forecasting equation

$$\hat{y}_{k+1} = \mu + y_k + \phi_1(y_k - y_{k-1}) + \phi_2(y_{k-1} - y_{k-2}) - \theta e_k \qquad (4)$$

where y_k, y_{k-1} and y_{k-2} are the actual prices of the latest three time steps, while $\hat{y}_{k+1}$ is the predicted price at the next time step. μ is a constant term which represents the moving average, $\phi_1$and ϕ_2 are the first and the second order autoregressive coefficients, repectively, θ is a constant multiplier and $e_k = y_k - \hat{y}_k$ is the lagged forecasting error, representing the integrated part. The ARIMA model is constructed by finding the set of constants μ, ϕ_1, ϕ_2 and θ that minimizes certain objectives such as Akaike information criterion (AIC) and Schwarz Bayesian criterion (SBC) over a historical data set.

New electricity price information is available at the end of each hour in the real time pricing scheme, and we update the ARIMA(2,1,1) model at the end of each hour based on moving horizon framework (Rao et al., 2003). Figure 1 shows the predicted price after moving horizon problem is solved 24 times based on 96 hrs of historical data from Ameren. In addition, covariance information of predicted electricity price is also available from XLSTA. For instance, the grey lines in Figure 1 are upper and lower bounds for the predicted price with 80% confidence interval. This information can be used in the objective function (3) where we also consider minimizing the variation of utility cost.

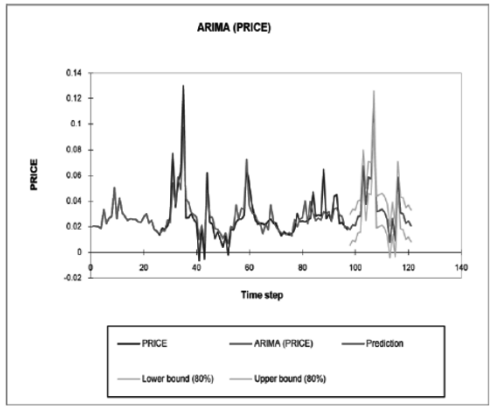

Figure 1 Predicted real time price.

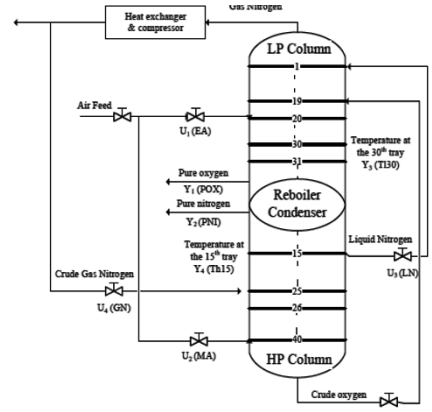

Figure 2 Air separation unit

4. Simulation results

Air separation unit is an energy intensive application because ambient air is compressed and cooled to extremely low temperature (-170℃ to -195℃). Since the raw material (ambient air) is free, the major operational cost is the energy consumed for compression. Here we revisit the ASU system (Figure 2) presented in [10] and assume that the energy used in by the ASU is proportional to the main air feed ($\boldsymbol{U_1}$-MA) and expanded air feed ($\boldsymbol{U_2}$-EA). As a result, the objective function (3) at time step *k* is chosen as $\boldsymbol{l_k = W_1 p_k \times (EA_k + MA_k) + W_2 var(p_{T_k}) \times (EA_k + MA_k) + reg_k}$, where $\boldsymbol{reg_k = (Y_k - Y_{set})^T \mathcal{Y} (Y_k - Y_{set}) + (U_k - U_{ref})^T \mathcal{U} (U_k - U_{ref})}$, $\boldsymbol{Y_k}$ represents controlled variables; $\boldsymbol{U_k}$ represents manipulated variables and $\boldsymbol{Y_{set}}$ and $\boldsymbol{U_{ref}}$ are setpoint and reference values for controlled and manipulated variables, respectively. Here, $\boldsymbol{\mathcal{Y} = diag[10^{-4}, 10^{-4}, 3\times10^{-2}, 3\times10^{-2}]}$ and $\boldsymbol{\mathcal{U} = diag[10^{-4}, 10^{-5}, 10^{-5}, 10^{-5}]}$ are diagonal weighting matrices. The regularization term, $\boldsymbol{reg_k}$ guarantees stability and improves numerical performance of the optimization problem (2). In addition, weights are set to $\boldsymbol{W_1 = W_2 = 10^{-3}}$. Therefore, the problem is strongly regulated around the equilibrium point. To achieve better economic performance, one could increase W_1 and W_2 and add inequality constraints to obtain the required performance, e.g., O_2 production and purity.

In the first scenario, the electricity price is taken from the *day ahead pricing* scheme of Ameren for 48-hour period (3/23/2010-3/24/2010). The economic NMPC formulation (2) with the objective function (3) is solved. The prediction horizon is chosen to be 120 minutes and the sampling time is 6 minutes. Fig. 3 presents the input variables in the day ahead pricing scenario. The economical NMPC renders an operational cost of $12,511 over this 48-hour period, while the operational cost of the conventional setpoint tracking NMPC with a fixed setpoint (Y_{set} and U_{ref}) is $13,042. Hence, it generates 4.25% cost reduction by using the economical NMPC. In the second scenario, the electricity price is predicted from the ARIMA(2,1,1) model and economic NMPC (2) with objective function (3) is used. Figure 4 presents the input variables in the *real time pricing* scenario. Here the operational cost in the 24-hour period (3/24/2011) is $4,347.2/day while setpoint tracking NMPC leads to a $4,768.9/day operational cost, a 9.7% cost reduction. After full discretization, the NLP has 117,140 variable, 116,900

constraints, and is solved using AMPL and IPOPT. For both scenarios, IPOPT requires from 8 to 18 iterations and 180 to 380 CPUs (Intel core i7 2.8GHz, 8 GB memory). In addition, advanced step NMPC [10] reduces computational delay to below 1 CPUs. Advanced step NMPC and ideal NMPC are identical, as seen in Figures 3 and 4.

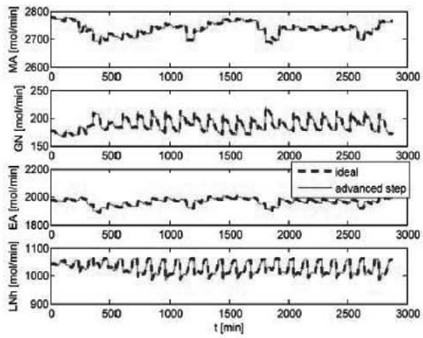

Figure 3 Input in day ahead scenario

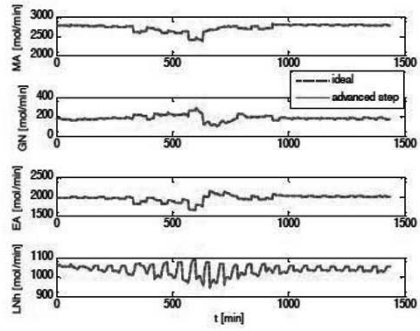

Figure 4 Input in real time scenario

5. Conclusion

This work presents a framework for economically-oriented NMPC that directly minimizes the operational cost of energy intensive applications to exploit *day ahead* and *real time pricing* electricity markets. ARIMA model based on moving horizon framework is proposed to forecast the future electricity price in a real time pricing scheme. The proposed framework is implemented on an air separation unit and more than 9% cost reduction is observed compared to the setpoint-tracking NMPC.

Abstract

The aim of this work is to present an integrated framework for the on-line control of a Polymer Electrolyte Membrane (PEM) fuel cell system using an optimization-based control methodology. The framework consists of a nonlinear model predictive control (NMPC) scheme and an on-line supervisory control and data acquisition system (SCADA). The solution of the NMPC problem is achieved by a direct optimization method which involves the use of orthogonal collocation on finite elements and represents the optimal control problem as a nonlinear programming problem (NLP). The on-line application of the multivariable controller shows that the proposed framework can accomplish the desired objectives for power fulfilment in the context of a safe operating region. Furthermore the controller exhibits excellent performance in terms of computational requirements and can follow load changes with a negligible error in its response.

Keywords: on-line implementation nonlinear model predictive control, experimental fuel cell unit, dynamic optimization, power tracking, starvation avoidance, excess ratio

1. Introduction

A Fuel Cell (FC) is a complex system with various phenomena evolving while it operates, which thus posing interesting control challenges, while the appropriate determination of the operating region leads to different behavior of the system regarding its response. Characteristics such as fast time response, subsystem interactions and conflicting operating objectives can be handled through the development of an advanced control framework, which enables the adjustment of the manipulated variables according to changes in the underlying process and simultaneously ensures fast response and precise tracking of the defined set-points. Nonlinear Model predictive control (NMPC) has the ability to handle state and input constraints, dynamic nonlinearities of the process into consideration while it simultaneous satisfies economic and operating objectives under an integrated optimization methodology. Within this scope a NMPC framework along with its on-line deployment to an experimental small-scale unit is developed and analysed.

2. Experimental Unit Setup and Automation System

An integrated FC Unit consists of various electrochemical, mechanical and electronic components and subsystems and it is important to measure the variety of the physical quantities of the subsystems along with the voltage and the current density of the FC. In this context a small scale plant has been designed and constructed at CPERI/CERTH. The unit is comprised of two mass flows for the regulation of the gases flow rates, a humidification system, two PID controllers for the anode and cathode pressure control, fan assisted air cooling and an electrical heat up subsystem along with the necessary power conditioning device.

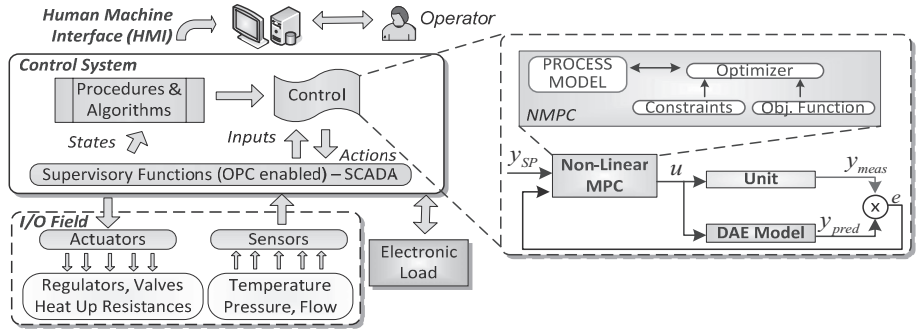

Figure 1 Information flow and NMPC structure

The automation of the unit is based on a Supervisory Control and Data Acquisition system (SCADA) which was used for the monitoring and control of the unit's input/output (I/O) field. In the SCADA system data are organized in a process database (PDB) and each I/O signal is assigned to a record named tag. Each tag can be sampled at different rates selected accordingly to the nature of the measured variables. This sampling is performed at predefined regular time intervals. Although the data from the I/O field can be acquired at smaller intervals, dictated by the communication protocol and the driver (polling time), the values at PDB are updated based on the scan period setting. The SCADA system enables us to measure the available signals and control the appropriate variables. All system components (pumps, heaters, valves, etc) are controlled by digital commands and pre-programmed procedures. The temperatures and pressures are maintained at the required set points by the SCADA system, via PID controllers, while the excess ratio level (λ_{o2}) and the power are controlled by the developed NMPC controller. The information flow from the I/O field to the operator, including the advanced control methodology approach is shown in Fig 1.

3. Nonlinear Model Predictive Control Framework

Nonlinear Model predictive control (NMPC) performs on-line optimization for future control actions over a prediction horizon. At each sampling time a finite horizon optimal control problem is solved using the current state of the process as the initial state. Using a process model, the effect of past inputs on future outputs is predicted. The deviation of the model prediction from the actual response is recorded and considered as the error of process model. The calculated error defines a bias term that is used to correct future predictions and it is assumed constant for the entire prediction horizon.

3.1. Dynamic Fuel Cell Model

A semi-empirical isothermal dynamic model was utilized in the NMPC scheme which is oriented towards process operation and control and takes into account main variables,

such as the operating temperature, the partial pressures of all gases and the fuel cell current (Ziogou, 2011). The model relies on first-principle equations and it accounts for mass dynamics in five control volumes: the gas flow channels, the gas diffusion layers and the membrane. It has been validated against experimental data generated by the PEM fuel cell unit and it provides the basis for the proposed on-line control framework.

3.2. Dynamic Optimization

The optimization method which is applied in the current work is a direct method which uses an augmented Lagrangian solver (Murtagh, 1998) and the problem formulation involves orthogonal collocation on finite elements (OCFE). The constrained optimization problem is converted into a large scale but sparse nonlinear programming problem (NLP), which is exploited to achieve an efficient solution (Biegler, 2002, Kiparissides, 2002). The method of OCFE approximates manipulated (input) and the state variables' profiles and consequently the output (controlled) variables' profiles with a family of Lagrange polynomials on finite elements (FE). The time horizon is divided into a series of finite elements ($i = 1..NE$) in such a way that wide variations of the transition profiles can be handled. Within each FE the dynamic profiles of inputs, states and outputs are further discretized around collocation points ($j = 0..N_{cop}$) determined as the shifted roots of Legendre polynomials. The solution is approximated at each FE:

$$x(t) \approx \sum_{j=0}^{Ncop} x^{i,j}\Omega_j(t),\ \ i = 1..NE\ \ ,\ \ t \in [t_i, t_{i+1}] \tag{1}$$

$$\Omega_j(t) = \prod_{k=0,k\neq j}^{Ncop} \frac{(t - t_{i,k})}{(t_{i,j} - t_{i,k})} \tag{2}$$

where *Ncop* is the total number of the internal collocation points of each element, *NE* is the number of the finite elements, $x^{i,j}$ is the value of the state vector at collocation point j of the ith finite element. Respectively the algebraic variables ($z^{i,j}$) and input (manipulated variables) variables ($u^{i,j}$) are approximated. After the discretization of the DAE model, the optimization problem (3) is expressed as an NLP problem in the form:

$$\min_{x^{i,j}, z^{i,j}, u^i} \sum_{i=1}^{NE}\sum_{j=1}^{Ncop} w_{i,j}\phi\left(x^{i,j}, z^{i,j}, u^{i,j}\right) \tag{3}$$

$$\text{s.t. :} \qquad \sum_{k=0}^{Ncop} \dot{\Omega}_k(\tau_{i,j}) x^{i,k} = h_i f_d\left(u^{i,j}, x^{i,j}, z^{i,j}\right) \tag{3a}$$

$$0 = f_a\left(u^{i,j}, x^{i,j}, z^{i,j}\right) \tag{3b}$$

$$x^{1,0} = x_0, \quad x(t_f) = \sum_{j=0}^{Ncop} x^{NE,j}\Omega_j(1) \tag{3c}$$

$$x^{i,0} = \sum_{j=0}^{Ncop} x^{i-1,j}\Omega_j(1),\ \ \mathrm{i} = 2..NE \tag{3d}$$

To enforce continuity of the states at adjacent finite elements, connecting equations are used (3d). Furthermore u, x, y are constrained within upper and lower bounds.

3.3. Problem Formulation

The control objectives of the system are to fulfil the power demand and to avoid oxygen starvation using the current and the air mass flow rate as manipulated variables. The effective control of the oxygen concentration in the cathode ensures safe operation during load changes and avoids oxygen starvation, a phenomenon which greatly affects

the lifetime of the fuel cell. The excess ratio level (λ_{o2}) is an unmeasured variable that can be expressed as the inlet flow of oxygen to the rate of oxygen consumption. The prediction (T_p) and control horizon (T_c) are set at 5s. The nonlinear model is comprised out of 8 differential equations and 1 algebraic which are discretized at 10 finite elements having 4 collocation points each. The resulting discretized system has 371 variables and 342 equations. The Jacobian matrix has 2430 non-zero elements (density = 1.915%).

3.4. On-line Implementation

Verification and validation of the framework is performed by deploying the multivariable controller on-line to the unit. An OPC-based interface was developed for the synchronization of the NMPC framework and the SCADA system. The NMPC algorithm is executed on-line on a PC which is communicating in real time with the control system, having a sampling rate of 1s. The response of the NMPC framework to various load (power) demands and different stoichiometric ratios was studied at specific operating conditions of temperature and pressure (T=338K, Pt=1Barg) with constant hydrogen flow (flows: H_2=350cc/min).

4. Results and Discussion

The proposed NMPC framework was deployed to the system and a number of on-line experiments were performed in order to verify the efficiency and the response of the controller at often power demand changes. A prerequisite for the online application of the controller is to exhibit both fast response and minimize the error towards the set-point. Therefore the analysis focuses on these two metrics through two scenarios. In the first scenario the power profile changes while the oxygen excess ratio remains at a constant level while in the second scenario both profiles are modified.

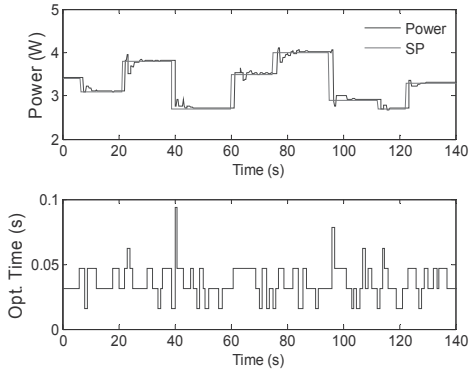

Figure 2 a)Power b)Optimization time

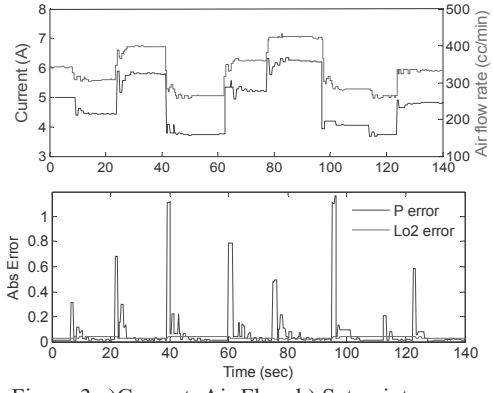

Figure 3 a)Current, Air Flow b) Set point error

Fig 2a shows the power response to the corresponding control actions of the manipulated variable (Fig 3a) as the power demand changes while the oxygen excess ratio remains at a constant set point (λ_{o2}=3). The controller is able to steer the fuel cell power to any admissible set-point while maintaining the required excess ratio level. This is better illustrated from the absolute error analysis in Fig 3b. The mean square root error is 43mW for the power and the average oxygen excess ratio error is $3*10^{-3}$. Also it is observed (Fig 2b) that the maximum optimization time is 93ms while the average optimization time is 36ms. From Fig 2 we observe that the optimization time is less the 100ms but since the scan time is 1s, the new output will be applied at that time interval. Therefore there is always a lag between the implementation of the output signal and the update of the input information, performed at the next scan interval. In the second scenario where both profiles are modified (power and oxygen excess ratio) the

same behaviour is observed (Fig 4, Fig 5). Overall the optimization time remains lower than 65ms with an average time of 39ms (Fig 5b) and it is not affected by the changes of the set points.

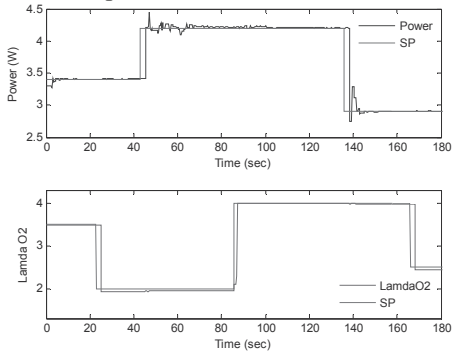

Figure 4 a)Power b)O2 excess ratio

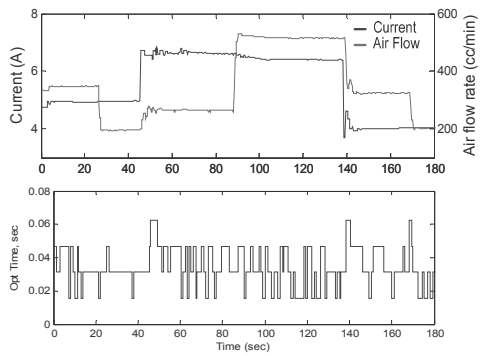

Figure 5 a)Current, Air Flow b) Optimization time

At low oxygen excess ratio ($\lambda_{o2}=2$) some fluctuations of the power profile around the new set point occur when the power demand increases, from 3.4W to 4.2W. This is caused by the fact that although the current increases in order to reach the new power set point and consequently increases the required oxygen (consumed), the air flow rate is not increased respectively due to the low oxygen excess ratio requirement (set point). As the excess ratio increases to converge to the new lamda set point ($\lambda_{o2}=4$) we observe that the fluctuation of power diminishes after a few seconds. That means that NMPC satisfies increased load demand in a smoother way when operating at higher values of oxygen excess ratio. Overall the proposed framework can efficiently provide the necessary control actions in order to follow the power set-point changes and adjust the air flow rate according to the requirement for oxygen excess ratio and thus avoid oxygen starvation.

5. Conclusions

The proposed NMPC framework combines two operational objectives and guarantees an operation that on the one hand satisfies the power demand in a safe and controlled way and on the other can adapt to sudden power demand changes. The controller was deployed to the SCADA system and on-line experimental studies showed that the control framework was able to maintain the stability of the system. The multivariable controller was successfully evaluated at the fuel cell unit under varying operating conditions leading to fast response time and negligible offset from the desired set points. Overall the NMPC approach guarantees that the PEMFC performs within its operating objectives and illustrates an excellent potential for on-line applications in order to manage the produced energy in an optimum manner.

Online Model Predictive Control of Municipal Water Distribution Networks

Gokul Siva Sankar, Sridharakumar Narasimhan * and Shankar Narasimhan
Department of Chemical Engineering, Indian Institute of Technology Madras, India

Abstract

Optimal operation of municipal Water Distribution Networks (WDNs) is based on optimizing one or more performance metrics while meeting consumer demands and satisfying supply side and storage constraints. This can be achieved by implementing advanced control schemes such as Model Predictive Control (MPC). With the alarming decrease in fresh water supplies, the primary focus of online control strategies should be to conserve water. A novel control strategy that can handle both water sufficient and deficient cases is proposed for WDNs with storage facilities. Performance of the developed model based online control strategy is tested by numerical simulations of an illustrative WDN.

Keywords: water distribution network, model predictive control, optimization, storage tanks

1. Introduction

Municipal water distribution networks supply water from sources such as dams, lakes and ponds to the consumers at the demand points through a network of pipes, valves and pumps such that their demands are met at desired pressures. WDNs have to be operated efficiently and reliably to supply the guaranteed amount of water in both directly pumped (24×7) and intermittent (possible in networks with storage facilities) modes of supply. In addition, depletion of water resources, shortage in water availability for supply and growth in demand have necessitated improved and sustainable water management practices in distribution systems. Traditionally, optimal operation of WDNs is concerned with minimizing the total cost of operation while maintaining water quality, regulating pressure in the pipelines to prevent leaks, and meeting consumer demands, assuming that sufficient water is available for meeting consumer demands (Kumar, 2008). However, in several countries such as India, overhead tanks and underground sumps are available at individual households for storage of water. These tanks can serve as intermediate storage elements when peak demand requirements cannot be met. Hence, an optimal control strategy has to be devised that considers the supply side and storage constraints to meet demand requirements. We introduce a novel MPC based control strategy for WDNs which takes into account the limitations of the actuators and storage tanks to address both water deficient and water surplus scenarios.

2. Modelling Water Distribution Networks

2.1. Pipes, Nodes and Node Resistance

A WDN consists of pipes, pumps, storage tanks, and valves. It has nodal points where water is withdrawn/supplied or where two or more pipes meet (Bhave and Gupta, 2009).

*sridharkrn@iitm.ac.in

A WDN can be modelled using mass balances for all storage tanks and nodal points, and the relations between pressure drop/rise and flow rate for pipes, pumps and valves. In addition, for a pressure-driven outflow model, relations between the pressure at the demand points and outflows are also included. The model equations are as follows.

Pressure drop in pipes is given by

$$\Delta h_j = \frac{\gamma L_j \text{sign}(Q_j)|Q_j|^{1.85}}{\lambda_j^{1.85} D_j^{4.87}}, \quad j = 1, ..., P \tag{1}$$

where λ_j is Hazen-William roughness coefficient of pipe j, Δh_j is the head loss in pipe j, L_j and D_j are the length and diameter of pipe j in m, Q_j is the flow through j^{th} pipeline in m^3/s and γ is the factor depending on the dimensional system used, is 10.7 when SI system of units is followed.

Mass balance at nodal points is given by

$$\sum_{j=1}^{p} a_{ij} Q_j - d_i = 0, \quad i = 1, ..., N \tag{2}$$

where d_i is the demand (or supply) at node i, N and P are the total number of nodes and pipes in the network respectively and a_{ij} is a coefficient that has a value 0 if pipe j is not linked to node i and has a value +1 or -1 otherwise, depending on whether the flow in pipe j is towards node i or away from it, respectively.

Outflow rate at a demand point is related to the pressure at that node by

$$p_i = k_i d_i^2 \;\; i = 1, ..., N \tag{3}$$

where p_i and and k_i are the pressure and resistance offered to outflow at node i.

2.2. Valves, Reservoirs and Tanks

A valve is a control device in a WDN that is used to vary the flow rate and/or pressure by closing and opening the stem. Head loss equation for a valve is given by

$$\Delta h_v = \frac{Q^2 G_L}{\left(C_v \frac{e^{ln\tau V}}{\tau}\right)^2} \tag{4}$$

where Δh_v is the head loss across the valve for a flow rate Q, C_v is the valve coefficient when the valve is 100% open, τ is the valve rangeability, V is the fraction of valve opening and G_L is the specific gravity of the fluid.

Tanks are storage units in WDNs and are associated with a minimum and maximum capacity. Quasi-steady state approximation is used here, wherein water level in all reservoirs and tanks are assumed to be constant in each time period and are updated at the end of the period. Mass balance expression for a reservoir/tank and physical storage limits of a tank are

$$H_z(k+1) = H_z(k) + \frac{\Delta t}{A_z}\left(Q'_{\text{in}}(k) - Q'_{\text{out}}(k)\right), \quad z = r \text{ or } t \tag{5}$$

$$0 \le H_t(k) \le H_{t\max} \tag{6}$$

where $H_r(k)$ and $H_t(k)$ are liquid levels in reservoir and tank at the end of time period k, A_r and A_t are cross sectional areas of reservoir and tank, $Q'_{\text{in}}(k)$ and $Q'_{\text{out}}(k)$ are sum of steady state rate of inflows to and outflows from the reservoir/tank respectively, Δt is the sampling time and $H_{t\max}$ represents maximum storage height.

3. Control Problem Description

Traditionally, demand outflows are the controlled variables and control can be effected by manipulations of stem positions of continuous control valves. Continuous valves provide better controllability of flow rate and/or pressure in WDNs than on-off valves. Generally, WDNs are non-square systems with one or more demand outflows being controlled by a single valve. The constraints to be satisfied represent the physical limitations of the system (limitation on the storage capacity of the tanks as in Eq. 6) and manipulated variables (valve opening in percentage can be from 0% to 100%). A suitable demand set point profile can be chosen to capture the temporal and spatial variations in the water usage pattern. To conserve water, the amount of water supplied should be just enough to meet the consumers' demand as over supply may lead to wastage of water.

3.1. Control strategy

Kumar (2008) proposed the use of MPC strategy for optimal operation of directly pumped WDNs. Control moves were calculated by minimizing the instantaneous deviation of demand outflow from the desired flow rate. However, storage facilities such as tanks or sumps, that are usually available at the demand points, were not accounted for. If it is not possible to meet peak demand requirements, water can be stored in these buffer tanks during the preceding periods and can be used to meet peak demand requirements. Thus, the use of buffer tanks allows intermittent supply and it is not necessary to meet the instantaneous demand rate. Rather, it is sufficient to schedule the supply such that the average daily requirement is met. However, in water sufficient situations, it is important not to overfill the tanks in order to conserve water. Hence, a common control strategy has to be devised which can address both these situations. The withdrawal rate from a tank is typically unknown. In the present work, it is assumed to be limited by either the amount of water in the tank or the actual demand rate, whichever is lower.

$$Q'_{\text{out}_i}(k) = \min\left(d_i^{sp}(k), \frac{H_t(k)\times A_t}{\Delta t} + Q'_{\text{in}_i}(k)\right), \quad i = 1, ..., N_d \tag{7}$$

where $d_i^{sp}(k)$ and $Q'_{\text{out}_i}(k)$ are demand set-point and the amount of water withdrawn from the tank, respectively. $Q'_{\text{in}_i}(k)$ is the flow rate into the tank and is equal to the outflow rate from the demand node to which it is linked. At any instant k, the assumed demand set profile may not match the consumers' actual consumption of water from the tanks and the cumulative deviation, $\Delta d_i(k)$ can be calculated as:

$$\Delta d_i(k) = \Delta d_i(k-1) + Q'_{\text{in}_i}(k) - (H_i(k) - H_i(k-1))A_t/\Delta_t - d_i^{sp}(k) \tag{8}$$

The second term in Eq. 8 is the actual withdrawal rate of water inferred from the liquid levels in the tank at the beginning and end of a time period. The control objective chosen in the present work is to minimize the sum square of cumulative deviations. This will try to ensure that the amount of water supplied closely matches the required amount of water over the horizon of interest. In addition, to prevent wastage of water when it is available in excess, water level in storage tank at the end of horizon is also simultaneously minimized. Hence, the control objective chosen is to minimize a weighted sum of the two terms.

3.2. MPC Formulation

MPC is an advanced control scheme that uses a model of the system to be controlled to predict its behaviour over a finite time horizon in the future (Maciejowski, 2002). The process in the basic scheme of MPC shown in figure 1, is a simulator that uses the pressure

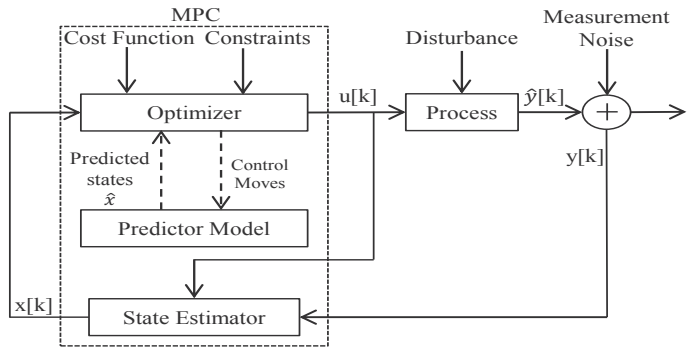

Figure 1. Basic MPC scheme

driven model to simulate the working of WDN. State estimator developed by Kumar et al. (2008) is used to estimate the current states (flow rate, pressure and outflow rate) from the corrupted measurements. The predictor model (also called extended period simulator) requires an explicit model for predicting the process output for N_p (prediction horizon) time steps ahead given N_c (control horizon) future control moves. The optimizer determines the optimal future control moves which minimizes the cost function while taking into account the constraints. Control moves for the current time period is implemented and the procedure is repeated for the next time period, based on the new set of measurements.

$$\min_{u_k,\ldots,u_{k+N_p-1}} \quad J = \sum_{i=1}^{N_d}\sum_{j=1}^{N_p} H_{t_i}^2(k+j) + \Delta d_i^2(k+j) \tag{9}$$

$$0 < u_k < 1 \tag{10}$$

$$p_j \geq p_{\min}, \quad j \in \text{demand nodes} \tag{11}$$

where u_k is the fractional control valve position at k^{th} instant, N_p is the prediction horizon, N_d is the total number of demand nodes in the network, p_j is the pressure at node j and $p_{\min}$ is the minimum pressure to be maintained.

4. Demonstration

The use of MPC strategy for online control of WDNs is tested on a sample network shown in figure 2. Elevation of all nodes is taken as zero and the source pressure is considered as 30 m of water and a minimum gauge pressure requirement of 2 m of water is imposed at the demand nodes. Cross sectional area of the storage tanks at nodes 5 and 11 are assumed to be 6 m^2 and 8 m^2 respectively, and maximum height of these tanks are taken to be 3 m. Initial water level in both tanks is assumed to be 0.1 m. The two control valves have a

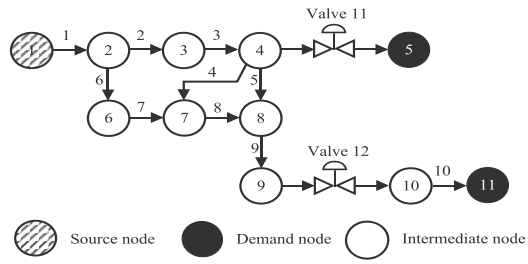

Figure 2. Schematic of the WDN used in the demonstration of MPC strategy

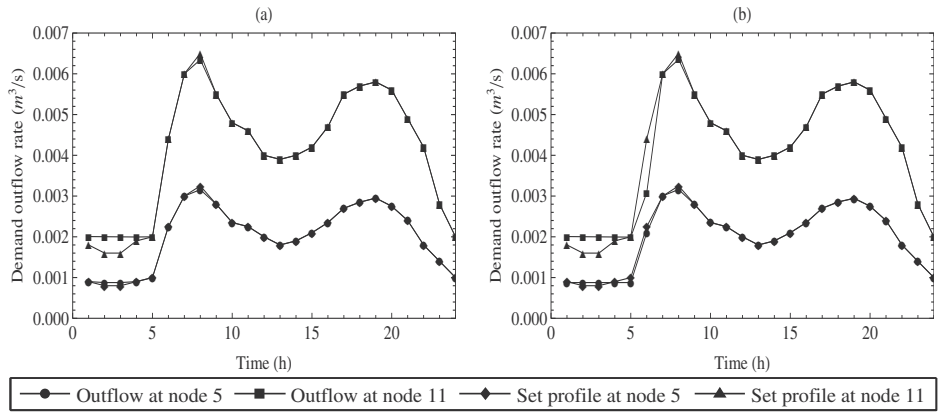

Figure 3. (a) Demand outflow profile without storage tank and (b) with storage tank

rangeability of 50 and the valve coefficient, C_v, of the valves 11 and 12 are 50 and 100 respectively. Pressure at nodes 1, 4 and 8, flow rate in pipe 1 and water level in the two tanks are measured on an hourly basis. The case when there is sufficient water to meet the need of customers is studied. MPC is applied with $N_p = 1$ and $N_c = 1$. The outflow rates at the two demand points obtained with the objective function used by Kumar (2008) without taking into account the storage tanks available at these points, are shown in 3(a). It is observed that the outflow rate matches the demand rate for most time periods, except the oversupply in the first few periods (to satisfy the pressure constraint at demand nodes). The total outflow during the 24 h period exceeds the requirement at demand node 11 by 0.97%. On the other hand, if storage facilities at the demand points and the control objective given by Eq. 9 are considered, then the solution obtained is shown in 3(b). It is observed that the initial oversupply is compensated by undersupply during the periods 5 to 8, such that the integral amount of water supplied during the 24 h period matches with the requirement. Both the tanks were empty at the end of 24 h period. In water deficient case, MPC scheme allocates water so as to meet the requirement over the 24 h period with minimal percentage undersupply. However, the results are not reported here in the interest of space.

5. Conclusions

In this work, MPC scheme was used for generating control strategies that operate WDNs with buffer tanks at demand nodes, to meet the performance goals. Sustainable operation of WDNs using a MPC control scheme was demonstrated with a sample WDN, resulting in water savings.

Multi-fidelity models for model predictive control

Shiva Kameswaran,[a] Niranjan Subrahmanya,[a]

[a]*ExxonMobil Research and Engineering, 1545 US22E, Annandale, 08807, USA*

Abstract

Model predictive control (MPC) is based on repeated solution of finite horizon dynamic optimization problems, where only the control decisions close to the start of the time horizon are of interest. This observation suggests the potential use of multi-fidelity models with models of reduced complexity and fidelity being used for predictions away from the current time instant. We explore this idea through theoretical analysis and simulations. We attempt to quantify the effect of (bounded) error in computing future states and controls on current control actions. The assumption of bounded error covers a number of potential approaches based on model and solution approximation techniques. One of these approaches, using reduced order models, is illustrated using a simulated process. We provide comparisons with conventional MPC in terms of the overall quality of the control as well as the computational complexity and demonstrate that MPC based on multi-fidelity models performs better than MPC based only on reduced order models.

Keywords: multi-fidelity models, model reduction, model predictive control

1. Introduction

Recent advances in computing have enabled use of high-fidelity dynamic models in technologies like model predictive control (MPC) and real-time optimization. The challenges in implementing these technologies for real-world processes are (a) computational cost associated with calculating optimal set points and controls (b) ensuring that controls are robust and execution prompt, and (c) explaining non-intuitive control actions to engineers. Such technologies employ optimization to make decisions over a prediction horizon. The prediction window is important for proactive decision-making based on understanding of the system's capabilities and stability considerations.

MPC is based on repeated solution of finite-time optimal control problems, where only the control decisions close to the start of the time horizon are of interest. This observation opens the door for approximation strategies such as ADP [4] and model reduction that attempt to capture the effects of states and controls that are farther along the prediction horizon on objective function, constraints, dynamics and stability. We explore the possibility of reducing model complexity as we move away from the start of the prediction horizon. This reduces the computational burden of carrying model detail well into the prediction horizon. This reduced complexity would improve computational robustness and allow frequent economically responsive optimization moves. In addition it becomes easier to navigate the reduced models to provide clearer interpretations of the control moves. Using such reduced order models (ROMs) farther in the prediction horizon can also facilitate computation of "cost-to-go" surrogates in methods that use reinforcement learning in MPC. While a great deal of the computational load in conventional linear MPC can be reduced through offline calculations (parametric programming), such methodologies only work for small-scale linear systems. There is also a vast body of literature on using ROMs in the context of MPC. Refer to [2] and the references therein for information on using a single ROM for MPC.

2. Analysis of the effect of using multi-fidelity models in optimal control

We begin our analysis by considering an unconstrained optimal control problem of the form shown below. Here *z(t)* are the states, *u(t)* are the controls. The objective is to minimize a scalar function of the states at the end of the time period $t \in [t_0, t_f]$. We assume that all the functions involved are sufficiently smooth and we continue to use the assumptions in [3].

$$\min_{z(t),u(t)} \varphi\left(z(t_f)\right) \tag{1a}$$

$$\frac{d}{dt}z(t) = f(z(t), u(t)); z(t_0) = z_0 \tag{1b}$$

The direct simultaneous approach [3] using Radau collocation and a uniform temporal mesh size h is used to solve the optimal control problem. We use the analytical setting in [3] to show that bounded perturbations to the rhs of the differential equation over $t \in [\tau, t_f]; t_0 < \tau$ result in bounded control moves. These perturbations to the rhs are assumed to be due to model reduction errors. While the errors due to model reduction can be well characterized [1] and have a definite structure, our analysis assumes this error to be bounded. The structure of the error is key for precise understanding of its impact on the controls and will be the subject of future research.

Let the KKT conditions for the discretized problem be written as $\emptyset(w) = -he$, where e is the error in the rhs of the state equation, and w collectively represents discretized states, controls and Lagrange multipliers. Refer to [3] for a detailed description of the structure and the components of $\emptyset$. The vector e has nonzero entries only for state collocation equations over temporal regions where a ROM is used ($t \in [\tau, t_f]; t_0 < \tau$). This nonzero sub-vector of e will be referred to as e_{state}. The true solution to (1), when discretized using same temporal mesh as in the simultaneous approach, results in an error residual r that satisfies $\emptyset(w^*) = r$. Using the mean value theorem,

$$\emptyset(w^*) - \emptyset(w) = J(w^* - w) = r + he \tag{2}$$

$$(w^* - w) = (\tilde{w} - w) + (w^* - \tilde{w}) = J^{-1}r + hJ^{-1}e \tag{3}$$

where $J = \int_0^1 \emptyset'(\delta w^* + (1-\delta)w)d\delta$ has the same symbolic form and structure as the KKT matrix of the discretized NLP, and $\tilde{w}$ satisfies $\emptyset(\tilde{w}) = 0$. In [3] it was shown that $\|w^* - \tilde{w}\|_\infty \sim \|J^{-1}r\|_\infty = O(h^K)$, where K is the number of collocation points. Consequently $\Delta w = (\tilde{w} - w)$ inherits the order property of $hJ^{-1}e$. It is important to note that the size of the vectors and matrices in (2) increase with *1/h*.

The similarity of J to the KKT matrix allows us to perform a range-and-null-space decomposition [3]. The constraint Jacobian matrix $\hat{A}$ is of the form $(\hat{C} \quad N)$ where N represents the derivatives wrt to the discretized controls and $\hat{C}$ includes derivatives wrt to the discretized states. Let Y and Z be a pair of range and null space matrices for $\hat{A}$ defined as $Y^T = (I\ 0)$ and $Z^T = (-N^T\hat{C}^{-T}\ \ I)$. It follows from [3] that error in the control variables (part of Δw corresponding to discretized controls) arising from errors in the rhs of the state differential equations is given by:

$$\Delta w_{cont} = -h(Z^T HZ)^{-1}Z^T HY\hat{C}^{-1}\begin{pmatrix} 0 \\ e_{state} \end{pmatrix} \tag{4}$$

The term $\hat{C}^{-1}h\begin{pmatrix} 0 \\ e_{state} \end{pmatrix}$ has the effect of integrating the error in the state equations forward in time. The effect of this error accumulation on the state related parts of the

objective function are partly represented by $HY\hat{C}^{-1}\begin{pmatrix}0\\ e_{state}\end{pmatrix}$. Z^T serves the role of a backward integrator where the consequence (objective fn) of all the accumulated error is communicated to the controls at various point in time. It has been shown in [3] that:

$$\|Z^T\|_\infty = O(1);\ \|Y\|_\infty = O(1);\ \|H\|_\infty = O(h);\ \|C^{-1}\|_\infty = O\left(\frac{1}{h}\right)$$

As in [3] we assume that $\|(Z^THZ)^{-1}\|_\infty = O\left(\frac{1}{h}\right)$. Given that e_{state} is *O(1)*, it follows from the above matrix norms and (4) that $\|\Delta w_{cont}\|_\infty = O(1)$. This result implies that if there is a bounded error that is added to the rhs of (1b) and the resulting problem is solved using the direct simultaneous approach then the norm of the difference between the optimal controls for the problems with and without the error term is bounded. We have not exploited the special structure of the error vector. The effect of several types of approximations can be examined using this framework and they include: model reduction error, inexact solution of state equations, and coarser / varying discretization error. All these three types of approximations can be applied as we move away from the start of the prediction horizon. The next section presents results based on an approximation that uses a ROM beyond a transition point in the prediction horizon.

3. Example

In this section, we consider a 10th order plant given by, $\dot{x} = A_p x + B_p u$

$$A_p = \begin{bmatrix}
-0.21 & 0.08 & 0.04 & -0.05 & -0.07 & -0.17 & -0.12 & 0.06 & -0.00 & -0.06\\
0.09 & -0.09 & -0.03 & 0.04 & -0.03 & 0.06 & 0.02 & 0.01 & 0.06 & 0.07\\
-0.14 & 0.04 & -0.22 & 0.02 & -0.02 & 0.01 & -0.14 & 0.03 & -0.04 & -0.02\\
0.14 & -0.04 & 0.07 & -0.25 & 0.02 & 0.01 & 0.07 & 0.02 & 0.07 & -0.00\\
0.01 & -0.07 & 0.05 & -0.03 & -0.13 & -0.05 & -0.00 & 0.04 & 0.02 & -0.01\\
0.07 & -0.04 & 0.17 & -0.09 & -0.03 & -0.22 & 0.08 & 0.10 & 0.04 & -0.02\\
-0.07 & -0.00 & 0.04 & -0.12 & -0.07 & -0.12 & -0.23 & 0.08 & -0.02 & -0.05\\
-0.05 & 0.06 & -0.04 & 0.06 & 0.03 & 0.10 & -0.01 & -0.06 & -0.03 & -0.02\\
-0.03 & 0.07 & 0.01 & 0.00 & -0.02 & -0.05 & -0.06 & 0.01 & -0.13 & -0.02\\
0.02 & 0.03 & 0.06 & -0.06 & -0.02 & -0.05 & 0.01 & -0.00 & 0.01 & -0.15
\end{bmatrix}$$

$$B_p = \begin{bmatrix}
-0.03 & 0.02 & 0.24 & 0.00 & -0.46 & 0.15 & 0.56 & -0.52 & -0.23 & 0.27\\
0.01 & -0.14 & 0.44 & -0.15 & 0.49 & -0.52 & -0.11 & -0.40 & 0.09 & 0.29\\
-0.55 & -0.15 & -0.38 & -0.09 & 0.08 & 0.24 & -0.03 & -0.06 & 0.39 & 0.55
\end{bmatrix}^T$$

The plant has 6 stable real poles, 2 stable complex poles and 2 unstable poles. We consider the problem of stabilizing all the states of the plant. The inputs are constrainted to lie within the interval [-1.5 1.5]. We consider 3 schemes for comparison.

1. MPC with the full model over the entire prediction horizon (Full model)
2. MPC with a reduced model over the entire prediction horizon (Reduced model)
3. MPC with the full model at the beginning and a ROM beyond a preset transition point (Multi-fidelity model)

For the sake of simplicity proper orthogonal decomposition [1] is used for model reduction. We vary the number of states in the ROM and report the tradeoff in terms of control accuracy and computational complexity. For multi-fidelity MPC, we also vary the fraction of the prediction horizon at which the transition to a reduced model is made (t_r). Control accuracy is measured using the frobenius norm of the difference between control and state values obtained using approximate techniques (reduced and multi-fidelity) to that obtained using the full model. The reported accuracies are normalized using the frobenius norm of the solutions from the full model and are denoted by NE_u (for normalized control error) and NE_x (for normalized state error). We consider only the initial part of the prediction horizon for computing the accuracies as this is the time-

frame that is of interest for implementation in a moving horizon implementation. In this example, we consider a prediction horizon of 15 minutes and assume that the interval between successive optimization runs is 15seconds. Therefore, the errors are measured during this 15 second interval only. The computational complexity is reported in terms of the number of optimization variables, which is used as a proxy for the true computational cost, but should suffice to demonstrate the basic idea. Let n_x be the number of states in the full model, n_r be the number of states in the reduced model, n_i be the number of inputs, N_1 be the number of elements before the transition to reduced model, N_2 be the number of elements after the transition and n_c be the number of collocation points in each element. The number of optimization variables (N_{opt}) may then be calculated as $(N_1+ N_2)* n_c *(n_x + n_i)$ for the full model, $(N_1+ N_2)* n_c *(n_r + n_i)$ for the reduced model and $N_1* n_c *(n_x + n_i) + N_2* n_c *(n_r + n_i)$ for the multi-fidelity model. In the simulations, $N_1+ N_2 = 400$, $n_c = 2$ and $n_i = 3$. The results are summarized in Table 1, Table 2 and Figure 1.For each parameter setting, simulations were run with 10 randomly chosen initial states and averages values of the error were used.

Table 1. Results for MPC based only on ROM

n_r	1	2	3	4	5	6	7	8	9	10
NE_u	0.95	0.79	0.71	0.38	0.35	0.27	0.15	0.15	0.06	0
NE_x	0.26	0.21	0.18	0.09	0.08	0.07	0.04	0.04	0.02	0
N_{opt}	3200	4000	4800	5600	6400	7200	8000	8800	9600	10400

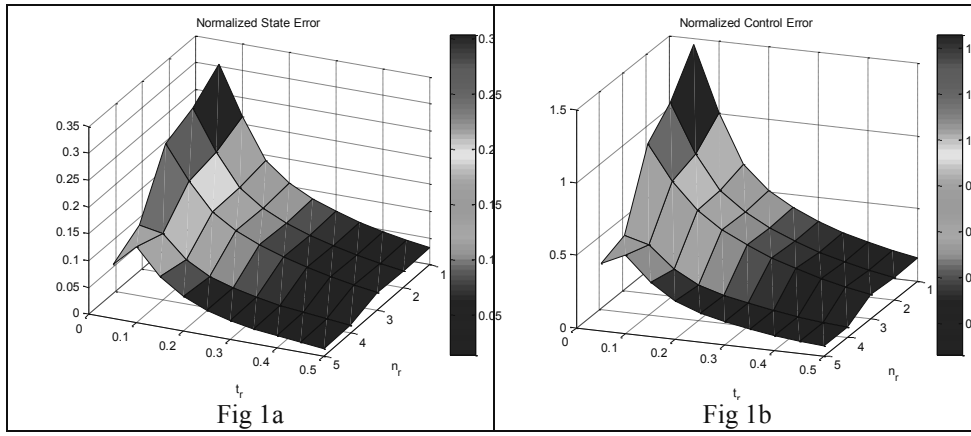

Fig 1a Fig 1b

Figure 1. a) normalized state error versus the number of reduced states and fraction of horizon at which the transition to reduced model is made for multi-fidelity MPC b) The same plot for the normalized control error

Table 2. Selected results for MPC based on multi-fidelity models

n_r	1	1	2	1	1	1	2	4	4	5
t_r	0.10	0.20	0.25	0.35	0.45	0.50	0.50	0.40	0.50	0.50
NE_u	1.01	0.51	0.40	0.28	0.19	0.16	0.16	0.10	0.07	0.07
NE_x	0.22	0.11	0.08	0.06	0.04	0.03	0.03	0.02	0.01	0.01
N_{opt}	3920	4640	5600	5720	6440	6800	7200	7520	8000	8400

Table 2 provides a numerical representation of selected information from Figure 1. Comparing, the results from Table 1 and Table 2, it can be seen that for a given number of variables, or alternatively for a given computational budget, multi-fidelity MPC

outperforms pure reduced order MPC across a broad range. From Figure 1, it can be seen that choosing the right values for the order of the reduced model and the time to transition to the reduced model is important to get the best performance for a given budget. Finally Figure 2 shows a sample of the estimated "optimal" control for the 3 approaches compared in this section. An interesting observation is that the discontinuity in model fidelity significantly distorts the optimal trajectory around the transition region, but it approximates the true optimal trajectory much better at the beginning of the prediction horizon as compared to the reduced order MPC. This confirms the intuition presented in the introduction to this paper. The nature of the control input distortion at the point of transition needs further analysis as this is the main source of error for the multi-fidelity MPC and also the main constraint on moving the transition horizon to an earlier point to further reduce computational complexity.

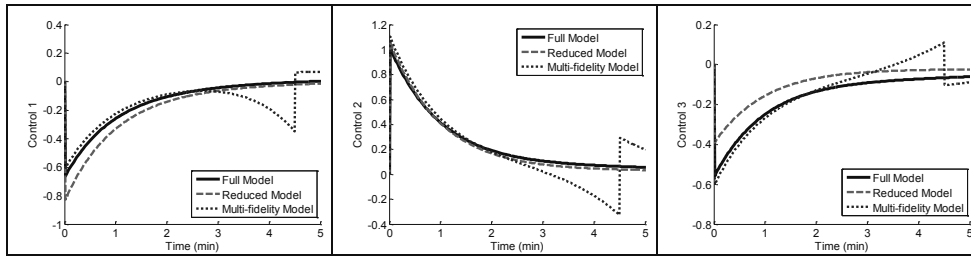

Figure 2. A comparison of "optimal" control trajectories computed by the 3 approaches. The ROM has 5 states (6400 variables). The multi-fidelity model has 3 states and transitions at 4.5 seconds (6480 variables).

4. Conclusion

In this paper we presented the idea of using accurate models near the beginning of a prediction horizon for MPC and then using models of reduced fidelity towards the end of the horizon. Theoretical analysis presented in section 2 indicates that the introduction of bounded error at later points in the control horizon will have a bounded perturbative effect on the computed control input at the beginning. Computational complexity can be traded for model error in multiple ways including using ROMs, inexact solutions and coarse discretizations. Further analysis that considers the exact structure of each of these errors is required to provide tighter bounds and guarantees for control input perturbation and will be the focus of future research. The simulation example presented in section 3 confirms the advantage of using multi-fidelity models over pure ROMs. It also emphasizes the need to use the right parameters to obtain the best approximation for a given computational budget. An interesting observation form the simulations is the fact that the difference between an approximate and optimal control inputs tends to be the highest near the point of transition from the high-fidelity model to the low-fidelity model. A better understanding and characterization of this phenomenon will be the focus of future research as well.

Abstract

This paper presents a frequency domain based approach to tune the penalty weights in the model predictive control (MPC) formulation. The two-step tuning method involves the design of a favourite controller taking into account the model-plant mismatch followed by the controller matching. We implement this approach on a SISO example.

Keywords: model predictive control, tuning, robust performance, inverse optimality

1. Introduction and Preliminaries

MPC is an advanced control methodology that has been widely adopted in industry as an effective tool to drive and maintain a plant at a specified operating condition. The performance of MPC highly depends on the model accuracy and the tuning of the system. The tuning problem in MPC is the selection of weighting matrices in such a way that the resulting closed loop behaviour is a good trade-off between the performance and the robustness given the specific characteristics of the process and the model's accuracy.

There have been several attempts to achieve a systematic tuning guideline for selecting the right set of MPC weighting matrices. In D.J.Chmielewski and A.M.Manthanwar (2004) it was proposed to minimize the variance of the controlled output by making use of both the solution of the minimum variance covariance constrained control and the inverse optimality problem. Lee and Yu (1993) proposed tuning for nominal performance first and hereafter to robustify the system by evaluation of the sensitivity and complementary sensitivity function. In Rowe and J.Maciejowski (2000) it was shown that for a process in which the model uncertainty is due to normalized coprime factor perturbations, $\mathscr{H}_\infty$ loop shaping can be utilized to determine the weighting matrices of the MPC.

This paper is organized as follow. First, we introduce preliminary information below. In Section 2, the frequency domain interpretation of MPC is presented. Section 3 explains the proposed MPC tuning method and presents the illustration on a SISO system with uncertainty description. In Section 4 conclusions are given.

We assume the system is represented by the difference equations

$$x(k+1) = Ax(k) + B_1 w_p(k) + B_2 u(k) \tag{1a}$$
$$z(k) = C_1 x(k) + D_{12} u(k) \tag{1b}$$

where (A, B_2) is controllable and (A, C_1) is detectable. $x \in \mathbb{R}^n, u \in \mathbb{R}^m, w_p \in \mathbb{R}^n$ are states, inputs and unmeasured disturbances modeled as a Gaussian white noise of unit intensity respectively. We also assume that disturbance energy distribution has low pass characteristics.

$$E\left[w_p(k)\right] = 0, \qquad E\left[w_p(k+\tau)\, w_p^T(k)\right] = I\delta(\tau)$$

*l.ozkan@tue.nl

where $\delta(\tau)$ represents the Dirac function. The outputs z is constructed from the weighted input signal $z = \begin{bmatrix} \tilde{u} \\ z_p \end{bmatrix}$. The variance of z_p due to w_p is expressed as

$$\begin{aligned} \sigma^2(z_p(k)) &= E\left[z_p^2(k)\right] - (E[z_p(k)])^2 = E\left[z_p^2(k)\right] \\ &= \frac{1}{2\pi}\int_{-\pi}^{\pi} \text{Trace}\left[T_{z_p w_p}\left(e^{j\omega_n}\right) T_{z_p w_p}^*\left(e^{j\omega_n}\right)\right] d\omega_n = \|T_{z_p w_p}\|_2^2 \quad \text{(Parseval)} \end{aligned}$$

where $T_{z_p w_p}$ defines the transfer function from w_p to z_p and $\omega_n = 2\pi\omega T_s$ is the normalized frequency. We consider an MPC controller solving the finite horizon control problem

$$\mathscr{V}(x(k)) = \min_{\mathscr{U}(k)} \sum_{i=0}^{N-1} x(i|k)^T Q x(i|k) + u(i|k)^T R u(i|k) + x(N|k)^T X x(N|k) \tag{2a}$$

$$s.t.$$

$$x(i+1|k) = Ax(i|k) + B_2 u(i|k), \qquad i \geq 0 \tag{2b}$$

$$Hx(i+1|k) \leq h, \quad Du(i|k) \leq d \qquad i = 0, \ldots N-1 \tag{2c}$$

$$u(i|k) = Kx(i|k), \qquad i \geq N \tag{2d}$$

$$x(0|k) = x(k) \tag{2e}$$

where $\mathscr{V}(x(k))$ is the cost function, $\mathscr{U}(k) = [u(0|k) \ldots u(N-1|k)]^T \in \mathbb{R}^{Nm}$ is the vector to be optimized. The matrices $Q \in \mathbb{R}^{n \times n}$ and $R \in \mathbb{R}^{m \times m}$ satisfy the conditions $Q = Q^T \geq 0$, $R = R^T > 0$ and represent the state and input weight respectively. The integer N denotes the MPC horizon and $X \in \mathbb{R}^{n_x \times n_x}$ is the terminal weight. Equation (2c) defines the state and input constraints. The auxiliary controller, equation (2d), is chosen as the solution of the infinite horizon LQR problem with weights Q and R and X is the corresponding solution of the discrete algebraic Riccati equation

$$K = -\left(R + B_2^T X B_2\right)^{-1} B_2^T X A \tag{3a}$$

$$X = Q + K^T R K + (A + B_2 K)^T X (A + B_2 K) \tag{3b}$$

With this choice of K and X, the MPC controller corresponds to the constrained linear quadratic regulator introduced in Scokaert and Rawlings (1998). Assuming that the process operates away from its constraint boundary, the MPC control law equals to $u(k) = Kx(k)$.

2. Frequency Domain Interpretation of MPC Tuning

In this section, we discuss the frequency domain analysis of MPC controllers as we change the weighting matrices Q and R in the objective function. The result of this analysis in the case of plant-model mismatch is the main motivation for the proposed tuning method. For this analysis, we interpret the cost function in (2) as a measure of the output energy of the process under control (Zhou et al. (1996)). We, therefore, choose the weights Q and R as $C_1^T C_1$, $R = D_{12}^T D_{12}$ respectively where we assume that the model of the process under control is constructed such that $C_1^T D_{12} = 0$ and $D_{12}^T D_{12} = \rho I$. The

squared output energy of the process under control due to w_p is then expressed as

$$\begin{aligned}\|z(k)\|_2^2 &= \sum_{k=0}^{\infty} x(k)^T C_1^T C_1 x(k) + u(k)^T D_{12}^T D_{12} u(k) = \|z_p(k)\|_2^2 + \rho\|u(k)\|_2^2 \\ &= \frac{1}{2\pi}\int_{-\pi}^{\pi}\left(\mathrm{tr}\left[T_{z_p w_p}^*\left(e^{j\omega_n}\right) T_{z_p w_p}\left(e^{j\omega_n}\right)\right] + \rho\,\mathrm{tr}\left[T_{uw_p}^*\left(e^{j\omega_n}\right) T_{uw_p}\left(e^{j\omega_n}\right)\right]\right) d\omega_n \\ &= \|T_{z_p w_p}\left(e^{j\omega_n}\right)\|_2^2 + \rho\|T_{uw_p}\left(e^{j\omega_n}\right)\|_2^2\end{aligned}$$

By the choice of ρ, the trade-off between performance and the robustness in the frequency domain can be demonstrated. For example, for high values of ρ, the bandwidth of the closed loop system is zero and no control is applied. Incrementally decreasing ρ, the bandwidth for which the disturbance is rejected increases, hence the output variance decreases. In case of plant-model mismatch, the decrease in the output variance is achieved up to a certain bandwidth. Decreasing ρ further will result in an increase in the output variance due to model-plant mismatch becoming significant at this bandwidth. In figure 1(a) this observation is demonstrated using an SISO example with a plant-model mismatch.

3. MPC Tuning Method

The proposed tuning method involves two steps. First, a favourite controller is designed using $\mathscr{H}_\infty$ controller synthesis. Then, a solution to the problem of inverse optimality is used to determine the MPC weighting matrices Q and R.

3.1. The favourite controller

The general control configuration used for the synthesis of the favourite controller is shown in figure 1(b). The model P, is constructed from the blocks G_n, W_u and W_p representing a nominal description of the process under control, a bi-proper weight function describing the uncertainty of the nominal model and a bi-proper performance weight function respectively. The state vectors of the three individual blocks are assumed to be available for control and are stacked as the vector x. P can be described by the difference equations (1) and is used as the internal model of the MPC. The block $\triangle$ and K_{fv} represent the norm bounded perturbation matrix and the favourite controller respectively. K_{fv} satisfies the robust performance theorem 3.1.

Theorem: Assume that the plant is internally stable and is constructed by the inclusion of K_{fv} in the generalized plant P, then

$$\text{Robust Performance} \quad \leftrightarrow \quad \|W_p T_{\triangle z_p w_p}\|_\infty < 1, \qquad \forall\|\triangle\|_\infty \le 1$$

where $T_{\triangle z_p, w_p}$ represents the set of perturbed transfer function from w_p to z_p. Having found a K_{fv} that satisfies the theorem above, it follows that $\bar{\sigma}\left(T_{\triangle z_p, w_p}\right) < \bar{\sigma}\left(W_p^{-1}\right), \forall\omega_n$ (Skogestad and Postlethwaite (2005)). To synthesize K_{fv}, the following procedure is proposed. W_p is parameterized as

$$W_p^{-1}\left(e^{j\omega_n}\right) = \alpha\|T_{z_p w_p}(1)\|_\infty W_{hp}\left(e^{j\omega_n}\right) \tag{5}$$

where $W_{hp}\left(e^{j\omega_n}\right)$ is a first order stable high-pass filter characterized by $W_{hp}(1) = \beta$, $|W_{hp}\left(e^{j\omega_k}\right)| = 1$ and $W_{hp}(e^{j\pi}) = 1$. The controller designer first has to determine the amount of disturbance rejection by a combination of the parameters α and β. ω_κ has to

be determined such that disturbance rejection is only required for the frequencies where model uncertainty is insignificant. Subsequently, an iterative scheme is proposed to maximize the attained robust performance.

- Construct the model P, define A, B_1, B_2, C_1 and D_{12} and check the condition for the favourite controller to exists; find $Y = Y^T > 0$ and M that satisfy

$$\begin{pmatrix} -Y & AY + B_2M & B_1 & 0 \\ YA^T + M^TB_2 & -Y & 0 & YC_1^T + M^TD_{12}^T \\ B_1^T & 0 & -I & 0 \\ 0 & C_1Y + D_{12}M & 0 & -I \end{pmatrix} < 0 \tag{6}$$

- If a feasible Y and M are found, $K_{fv} = MY^{-1}, \omega_\kappa = \omega_\kappa + \varepsilon$. Else quit iterations.

The LMI condition (6) can be found in Gahinet and Apkarian (1993) and ε is user defined.

3.2. Inverse Optimality

In this section, we consider how to determine the weights Q, R and N in the MPC cost function such that K_{fv}, is optimal. A control law for which such Q, R and N can be found is called inverse optimal. The following theorem states the condition for inverse optimality.

Theorem: If there exists a matrix $X = X^T \geq 0$ and a matrix $R = R^T > 0$ that satisfy the constraints,

$$\left(A + B_2K_{fv}\right)^{-1} X \left(A + B_2K_{fv}\right) + K_{fv}^T R K_{fv} - X \leq 0 \tag{7a}$$

$$\left(R + B_2^T X B_2\right)^{-1} K_{fv} = -B_2^T XA \tag{7b}$$

then the control law $u(k) = K_{fv}x(k)$ is inverse optimal with respect to the cost function that is minimized by the MPC defined in section 1. The inverse optimal weights X and R can be found by the LMI problem (7) and Q can be found by (3b). The proof results from algebraic manipulations of (3).

Example: Consider the task of designing an MPC with the purpose to minimize the variance of the temperature in a swimming pool, z_p due to the unmeasured disturbance w_p. The nominal model G_n is described by the difference equations

$$G_n\left(e^{j\omega_n}\right) \begin{cases} x_n(k+1) &= 0.7788x_n(k) + w_p(k) + 0.04424\left(\triangle_{out}(k) + u(k)\right) \\ z_p(k) &= x_n(k) \end{cases}$$

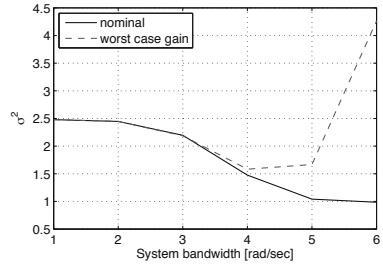
and the uncertainty weight, W_u is described by

$$W_u\left(e^{j\omega_n}\right) \begin{cases} x_u(k+1) &= 0.5626x_u(k) + 0.5u(k) \\ z_u(k) &= -0.8878x_u(k) + 1.016u(k) \end{cases}$$

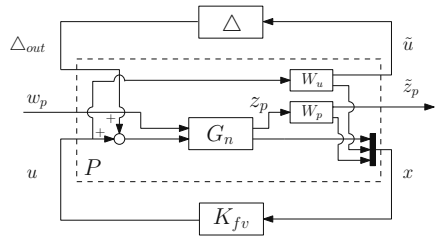
The parameters α, β and ω_κ to design the performance weight function are chosen as $\alpha = 1.3, \beta = 0.48$ and $\omega_\kappa = 0.5 rad/sec$.. K_{fv} resulting from the proposed iterative scheme with $\varepsilon = 0.01 rad/sec$ equals $K_{fv} = [-0.9233 \quad -1.0655 \quad -5.9393]$.

For this K_{fv} we find a feasible solution X and R from the LMI constraints expressed in theorem 3.2 and they are equal to $R = 2.7048 \cdot 10^{-4}$,

$$X = \begin{bmatrix} 1.4359 & -0.0589 & 0.4672 \\ -0.0589 & 0.1320 & 0.3654 \\ 0.4672 & 0.3654 & 3.4608 \end{bmatrix} \quad Q = \begin{bmatrix} 0.5763 & -0.0046 & 0.2222 \\ -0.0046 & 0.1282 & 0.3763 \\ 0.2222 & 0.3763 & 1.3325 \end{bmatrix}$$



(a) The variance of the nominal and worst case gain transfer



(b) The control configuration for MPC design

The variance of z_p when controlled by the MPC equals $\sigma^2(z_p) = 2.2$ obtained by a nominal simulation and $\sigma^2(z_p) = 2.25$ when simulated with worst case gain transfer from the set $T_{\triangle z_p w_p}$. The minor discrepancy between the two, 2.2 and 2.25, emphasizes the excellent robustness properties of the proposed method.

4. Conclusion

A frequency domain approach is presented to determine the set of weighting matrices Q and R in MPC formulation. An $\mathscr{H}_\infty$ control problem was constructed from the nominal model, a description of the model uncertainty and a performance weighting function. Subsequently, an iterative scheme was introduced to maximize the frequency region over which the desired rejection is achieved robustly. The static state feedback control law resulting from the scheme is denoted as the K_{fv}. An inverse optimality problem is formulated as an LMI to calculate the corresponding weighting matrices Q and R. A simple SISO example is used to demonstrate the tuning method which can be easily extended to a control problem of industrial relevance.

Control Strategy for Thermal Budget and Temperature Uniformity in Spike Rapid Thermal Processing Systems

Jyh-Cheng Jeng,* Wen-Chung Chen

Department of Chemical Engineering and Biotechnology, National Taipei University of Technology, Taipei 106, Taiwan

Abstract

Temperature control in the rapid thermal processing (RTP) system with spike-shaped temperature profile is a challenging task, and targeting perfect servo control is almost unachievable because of the high temperature ramp-up/down rate and significant nonlinearity of the process. This study presents a novel method of control system design to provide a precise thermal budget in the spike RTP system. A nonlinear control strategy is proposed based on modeling the RTP system as a nonlinear Wiener model. Further, multivariable control is considered to maintain the temperature uniformity within wafer. Simulation results demonstrate the effectiveness of the proposed control strategy, and provide guidelines for the design of the multivariable control configuration to achieve better wafer temperature uniformity.

Keywords: Rapid thermal processing; Thermal budget control; Nonlinear control; Wiener model; Multivariable control.

1. Introduction

Single wafer rapid thermal processing (RTP) has become one of the key technologies in semiconductor manufacturing due to its faster wafer processing with precise control of the thermal budget. The thermal budget is an important process issue derived from the duration and maximum of wafer temperature beyond a specific reference value, as shown in Fig. 1. As the dimension (line width) keeps shrinking, the demand of shallow junctions requires very tiny and precisely applied thermal energy. The spike RTP system is the way to maintain scaling requirements. As a result, a triangular-shaped set-point profile for wafer temperature is usually applied for thermal budget control.

Various control designs for RTP to follow the desired temperature trajectory have been proposed in the literature. However, achieving desired thermal budget by designing a tightened servo control system is difficult and complex in spike RTP system due to high set-point ramp-up/down rate. As an alternative, our previous work (Jeng and Lee, 2011) considered targeting the control performance on the indices for thermal budget, instead of set-point tracking. In this way, the thermal budget can be precisely controlled and the controller design is much simpler. Nevertheless, the previous work used a simple first-order model to represent the RTP system. In fact, the real RTP system is more accurately modeled as a nonlinear model. To solve this problem, this study uses a nonlinear Wiener model to represent the RTP system, and proposes a nonlinear control strategy based on extensions of the previous design method. In practice, the temperature uniformity within wafer during the heating/cooling process is also a very important specification. The RTP equipment has many lamps, and these lamps are usually clustered into several adjusting zones for wafer temperature control. This study

considers the multivariable control system to achieve good temperature uniformity within wafer. Moreover, the effects of allocation of clustered lamps and location of temperature measurements on the temperature uniformity are discussed.

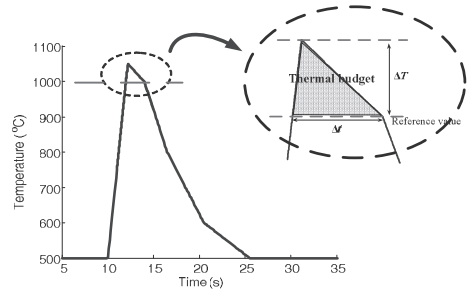

Figure 1. Thermal budget and temperature profile for the spike RTP system.

2. RTP System

A schematic diagram of the RTP system is shown in Fig. 2. In an RTP chamber, power is supplied to several rings of tungsten-halogen lamps, and energy is transferred through a quartz window onto a thin semiconductor wafer via direct or reflective paths. The wafer temperature is controlled by manipulating the lamp power sources.

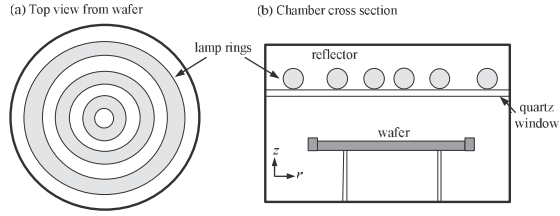

Figure 2. Schematic diagram of a RTP system: (a) top view (b) cross section.

Assume the wafer and the lamp rings are divided into several annual zones, n and m zones, respectively. Additionally, only temperatures in radius (r) direction are of interest by assuming symmetrical temperature distribution. A lumped physical model that describes the relationship between power from the jth lamp zone, P_j, and wafer temperature at the ith zone, T_i, can be formulated as follows: (Huang *et al.*, 2000)

$$\frac{dT_i}{dt} = \frac{-\sigma}{\rho C_p d}\left(\sum_{j=1}^{m}\varphi_{ij}\right)T_i^4 - \frac{h_{ci}}{\rho C_p d}\left(T_i - T_a\right) + \frac{1}{\rho C_p d}\sum_{j=1}^{m}\left(\varphi_{ij}P_j\right), \quad i = 1,\cdots,n \tag{1}$$

where ρ is the density, C_p is the heat capacity, σ is the Stefan-Boltzmann constant, d is the wafer thickness, h_{ci} is the convective heat transfer coefficient, T_a is the temperature of cooling gas, and φ_{ij} is given by

$$\varphi_{ij} = \frac{1}{\left(1-\varepsilon\right)/\varepsilon + \left(1/F_{i,j}\right)} \tag{2}$$

where ε is the emissivity and $F_{i,j}$ is the view factor from the wafer zone i to the lamp zone j. The view factor can be obtained as (Chao *et al.*, 2003)

$$F_{i,j} = \frac{1}{\pi}\int_{r_{L,j-1}}^{r_{L,j}}\int_0^{2\pi}\frac{h^2}{S_{ij}^4}r_L\,d\theta_{ij}\,dr_L \quad \text{with} \quad S_{ij}^2 = h^2 + {r_{w,i}}^2 + {r_L}^2 - 2r_{w,i}r_L\cos\theta_{ij} \tag{3}$$

where h is the distance between wafer and lamp; $r_{w,i}$ and $r_{L,j}$ are the radii of wafer zone i and lamp zone j, respectively. Equation (1) indicates that the RTP system is a nonlinear process in nature due to the radiative heat transfer (the T^4 term), and also a multivariable process. Table 1 gives the physical and system parameters used in this study.

Table 1. Parameters for RTP system

Parameter	Value	Parameter	Value
Wafer density	2330 kg/m^3	Distance between wafer and lamp	5 cm
Wafer thickness	0.0675 cm	Heat capacity (J/kg/K)	641+0.2473T
Emissivity	0.7	Stefan-Boltzmann constant	5.67×10^{-8} W/ m^2/K^4
Wafer radius	15 cm	Convective heat transfer coefficient	8.5 W/m^2/K
Lamp radius	30 cm	Temperature of cooling gas	27 ^{o}C

3. Thermal Budget Control

This study formulates the objective of thermal budget control as targeting the two thermal budget indices: time duration beyond the reference temperature, Δt, and the range between the maximum temperature and the reference value, ΔT, as shown in Fig. 1. Giving the ramp-up and ramp-down rates of set-point profile, k_1 and k_2, respectively, the controller parameters and the maximum of set-point profile are to be designed to meet these two control specifications.

3.1. Linear Model Based Design

Considering the single-input single-output (SISO) case (i.e., n=m=1), Jeng and Lee (2011) presented a design method for thermal budget control based on a first-order linearized RTP model, $K/(\tau s+1)$. The feedback controller used is a proportional-integral (PI) controller. The integral time is tuned by $\tau_I = \tau$. The controller gain K_C and the maximum of set-point profile $T_{\mathrm{sp,max}}$ are then determined to meet the specified thermal budget indices. The results are given as

$$K_C = \frac{\tau}{K}\frac{W\left(bC\exp\left(bA/B\right)/B\right)B - bA}{bB} \tag{4}$$

$$T_{\mathrm{sp,max}} = T_{ref} + \Delta T + k_2\frac{bB}{W\left(bC\exp\left(bA/B\right)/B\right)B - bA}\ln\left(\frac{k_1+k_2}{k_2}\right) \tag{5}$$

where T_{ref} is the reference temperature, $W(\bullet)$ is the Lambert W-function, and

$$\begin{aligned} &A = (k_1+k_2)(1-a);\quad B = \Delta T - k_2 b;\quad C = (k_1+k_2)e^{-a} \\ &a = 1-\left[k_2\ln\left((k_1+k_2)/k_2\right)\right]/k_1;\quad b = \Delta t - (\Delta T/k_1) \end{aligned} \tag{6}$$

3.2. Nonlinear and Multivariable Control Strategy

The heating/cooling process of RTP system is nonlinear, so that it is more accurately modeled as a nonlinear model. This study proposes using a nonlinear Wiener model to represent the RTP system for thermal budget control. In addition, this study considers multivariable control scheme to maintain better temperature uniformity within wafer.

3.2.1. Wiener Modeling for RTP System

The Wiener model, as shown in Fig. 3(a), has a linear dynamic subsystem, **G**, followed by a nonlinear static function, **F**. The input is lamp power, $\mathbf{P} = [P_1 \ \ldots \ P_m]^{\mathrm{T}}$, and the output is m wafer temperature measurements selected from n locations, $\mathbf{T} = [T_{m,1} \ \ldots \ T_{m,m}]^{\mathrm{T}}$. The physical model (1) indicates that the dynamic part of the PTP system is not coupled, and only the static part is interactive. Therefore, **G** is a diagonal matrix with element g_i, i=1,…,m; $\mathbf{F} = [f_1 \ldots f_m]^{\mathrm{T}}$ with $f_i = f_i(v_1, \ldots, v_m)$.

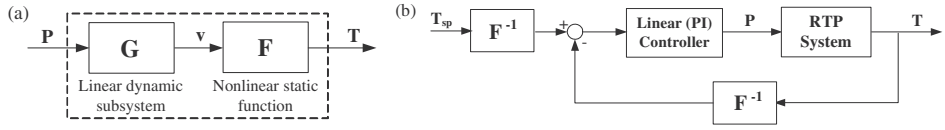

Figure 3. (a) Wiener model. (b) Control structure for RTP system based on Wiener model.

This study proposes a noniterative algorithm for the identification of Wiener model using the input-output data. The intermediate variable v_i, at time k, can be written as

$$v_i(k) = \sum_{l=0}^{L} h_i(l) P_i(k-l) \tag{7}$$

where $h_i(l)$ designates the finite impulse response model of the linear dynamics g_i. On the other hand, $v_i(k)$ can also be written in terms of the inverse function of the static nonlinearity, f_i^{-1}, described by expansion of a set of known basis function B_r as

$$v_i(k) = f_i^{-1}\left(T_{m,1}(k),\cdots,T_{m,m}(k)\right) = \sum_{r=1}^{R} c_{i,r} B_r\left(T_{m,1}(k),\cdots,T_{m,m}(k)\right) \tag{8}$$

where $c_{i,r}$'s are unknown coefficients to be determined. Because the gains of the linear dynamic subsystem and the nonlinear static function are actually not unique, it will be assumed here, without loss of generality, that $c_{i,1} = 1$. Equating the right-hand sides of (7) and (8), the following equation is obtained.

$$B_1\left(T_{m,1}(k),\cdots,T_{m,m}(k)\right) = \sum_{l=0}^{L} h_i(l) P_i(k-l) - \sum_{r=2}^{R} c_{i,r} B_r\left(T_{m,1}(k),\cdots,T_{m,m}(k)\right) \tag{9}$$

Equation (9) allows the estimation of model parameters, $h_i(l)$ and $c_{i,r}$, by the linear regression technique.

3.2.2. Wiener Model Based Design

The identified Wiener model is used to design a simple linearizing control system, as shown in Fig. 3(b), resulting in an equivalent linear control system. Because the linear dynamic subsystem is not coupled, the multivariable control design is now decomposed into m SISO design tasks. Therefore, the linear model-based thermal budget control approach can be directly applied to design the m linear controllers (PI controllers) for the linear dynamic subsystem, g_i, without considering the static nonlinearity.

4. Simulation Results

The process conditions are given as: $k_1 = 200\ ^{o}$C/sec, $k_2 = 50\ ^{o}$C/sec, and $T_{ref} = 1000\ ^{o}$C. The control targets are set as $\Delta t = 2$ sec and $\Delta T = 50\ ^{o}$C. From the linear model based design, controller parameters $\tau_{I,i} = \tau_i$, $K_{C,i} = 2.646\ \tau_i / K_i$, and $T_{\mathrm{sp,max}} = 1080.4\ ^{o}$C are resulted.

4.1. Multivariable Control: 2×2 Scheme

For the 2×2 control scheme, the lamps are clustered into two zones (with outer radius of $r_{L,1}$ and $r_{L,2} = 30$cm) to control the wafer temperature at two locations.

4.1.1. Effect of Allocation of Clustered Lamps

Assume the wafer is divided into 15 annual zones (n=15) with radius $r_{w,i} = i$ cm, and the temperatures at the 2nd and 15th zones ($r_{w,2}$ and $r_{w,15}$) are used for thermal budget control. Three cases for the allocation of clustered lamps are considered: $r_{L,1} = 10$cm, 15cm, and 20cm. Based on a steady operating point $T_{is} = 600\ ^{o}$C, the Wiener model is identified for each case using the simulated input-output data from (1). The control structure shown in Fig. 3(b) is applied for thermal budget control. Table 2 shows the percentage errors of Δt and ΔT ($E_{t,i}$(%) and $E_{T,i}$(%), respectively) resulting from the two controlled temperature profiles. To evaluate the temperature uniformity, the average of the absolute values of the error for all 15 temperatures and the standard deviation of the error for all 15 temperatures are also given in Table 2. The lamp allocation of $r_{L,1}$ = 20cm results in the best uniformity of thermal budget indices. This result can be attributed to more uniformly distributed view factors $F_{i,1}$ and $F_{i,2}$ on the wafer surface because the radius of the inner lamp zone is larger than the wafer radius.

4.1.2. Effect of Location of Temperature Measurement for Control

Using the lamp allocation of $r_{L,1} = 20$cm, various locations of temperature measurement are selected for control. The results are given in Table 3, where the results for SISO control are also given for comparison. The 2×2 control scheme shows improved

uniformity of thermal budget indices compared to SISO control scheme regardless of the locations of temperature measurement. Nevertheless, the specified thermal budget indices can be more accurately achieved when one of the temperature measurements for control is located at the most outer zone of wafer ($r_{w,15}$). The view factors at the most outer zone of wafer $F_{15,1}$ and $F_{15,2}$ are particularly lower and higher, respectively, than those at other zones, so that the dynamics of temperature at the most outer zone is quite different with those at other zones. Therefore, the temperature at the most outer zone must be directly controlled. On the other hand, the location of the other temperature measurement has no significant effect on the control performance.

Table 2. Results for 2×2 control with various allocations of lamps

Allocation	$E_{t,2}$	$E_{T,2}$	$E_{t,15}$	$E_{T,15}$	avg($\|E_{t,i}\|$)	std($E_{t,i}$)	avg($\|E_{T,i}\|$)	std($E_{T,i}$)
$r_{L,1}=10$cm	-2.0	8.99	-2.0	-0.05	8.72	6.66	28.95	19.31
$r_{L,1}=15$cm	-1.5	1.98	-2.0	6.72	3.03	2.36	11.83	8.81
$r_{L,1}=20$cm	-1.0	5.43	-2.0	2.28	1.13	0.32	4.79	0.86

4.2. Multivariable Control: 3×3 *Scheme*

The lamps are clustered into three zones to control the wafer temperature at three locations. According to the results in 2×2 control, the lamps are allocated as $r_{L,1}=20$cm, $r_{L,2}=25$cm, and $r_{L,3}=30$cm, and the locations of temperature measurement are $r_{w,5}$, $r_{w,10}$, and $r_{w,15}$. The results are given in Table 3. The uniformity of thermal budget indices is even better than that of 2×2 control scheme, especially for the ΔT index.

Table 3. Results for SISO, 2×2, and 3×3 control schemes

Location of measurement	avg($\|E_{t,i}\|$)	std($E_{t,i}$)	avg($\|E_{T,i}\|$)	std($E_{T,i}$)
2×2, $r_{w,2}$ and $r_{w,15}$	1.13	0.32	4.79	0.86
2×2, $r_{w,8}$ and $r_{w,15}$	1.23	0.33	4.87	0.81
2×2, $r_{w,5}$ and $r_{w,10}$	4.63	0.35	7.88	0.97
SISO, $r_{w,15}$	2.10	1.11	4.29	2.18
SISO, $r_{w,8}$	1.33	1.30	3.49	2.94
3×3, $r_{w,5}$, $r_{w,10}$, and $r_{w,15}$	0.37	0.30	5.04	0.25

5. Conclusions

This study proposes a nonlinear control strategy for thermal budget in the spike RTP based on Wiener modeling the RTP system. Furthermore, multivariable control is considered to maintain the wafer temperature uniformity. Simulation results have confirmed the effectiveness of the proposed control strategy, and revealed two guidelines for the design of the multivariable control configuration to achieve better wafer temperature uniformity: (1) the radius of the most inner lamp zone must be allocated larger than the wafer radius; (2) the wafer temperature at the most outer zone must be measured for feedback control.

Systematic Formalization of Control Requirements using Hierarchical Cause-Effect Charts[1]

Stephan Fischer, Christian Sonntag, Sebastian Engell

Process Dynamics and Operations Group, Department of Biochemical and Chemical Engineering, TU Dortmund, 44221 Dortmund, Germany

Abstract

In this paper, a hierarchically structured formalism, the *Hierarchical Cause-Effect Charts* (*HCEC*), is introduced to iteratively refine and formalize complex control requirements of industrial systems, resulting in a hierarchical tree structure of small and transparent cause-effect matrices that can be translated into Boolean formulae algorithmically. These formulae are used as input for a supervisory control synthesis tool chain, resulting in a logic controller that is correct by design. The formalization methodology is supported by a graphical software tool.

Keywords: Supervisory Control Synthesis, Cause-Effect-Matrix, Logic Control

1. Introduction

The safe operation of chemical plants requires large amounts of control logic. *Cause-Effect Matrices (CEM)* and similar formalisms have become very popular in this domain to specify control requirements in an intuitive fashion (e.g. Martinez & Enkerud (2005), Russo & Turk (2007), and Fischer & Lohmann (2009)). In addition, many *CEM* formalisms allow the algorithmic generation of control code. A major drawback of these formalisms is that the matrices become very large (up to thousands of rows and columns) and intransparent in realistic application scenarios. Thus, the validation of *CEM* of industrial-scale systems is a challenging and tedious task. A formalized representation of the specification is required for analysis and validation of the resulting logic by means of formal methods.

In this contribution, we present a hierarchically structured formalism, *Hierarchical Cause-Effect Charts* (*HCEC*), for the iterative refinement and formalization of the requirements of a control system, resulting in a hierarchical tree structure of small and well-arranged cause-effect matrices that can be translated into Boolean formulae algorithmically. These formulae are used as input for a supervisory control synthesis tool chain described in Theunissen et al. (2009), resulting in a logic controller that is correct by design. The formalization methodology is supported by a software tool that is implemented as an extension of the *DC/FT* software (see Fischer et al. (2011)) that supports the refinement of informal specifications into *Sequential Function Chart* (*SFC*) control programs.

1.1. Illustrative Example

To illustrate the formalization methodology, the example process shown in Fig. 1 is considered. The plant consists of three tanks (T1-T3) that are connected via pipes. The flow to and from the tanks is controlled by valves (represented by Boolean variables [1: open, 0: closed]). The levels in T1 and T2 are measured by two independent

[1] The research reported in this paper was (partly) funded by the European FP7 project MULTIFORM, contract number INFSO-ICT-224249, http://www.ict-multiform.eu. This support is very gratefully acknowledged.

measurements (one continuous sensor and two discrete sensors for each tank). T3 is equipped with two quality sensors, a temperature sensor, a pressure sensor, and two discrete level sensors.

For the safe operation of the plant, the following control requirements have to be implemented in the controller:

1. An overflow of the tanks must be avoided. The inflow to the tanks has to be stopped if one of the level measurements indicates the risk of an overflow.

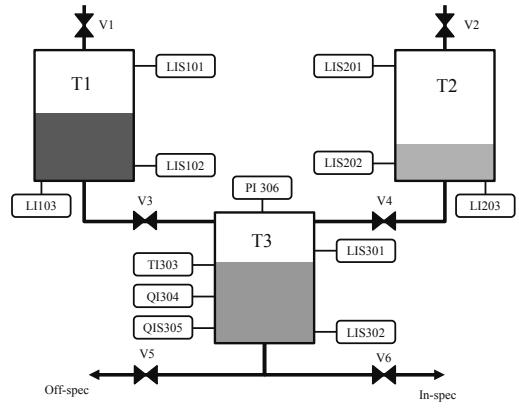

Figure 1: Example process

2. The production has to be stopped if either the pressure or the temperature in T3 reaches predefined (upper) thresholds. In both cases, T3 should be emptied via V5.
3. In addition, the following combinations of opened valves have to be avoided since the resulting (direct) material flows are undesired: V1 and V3, V2 and V4, V3 and V4, V3 and V5, V3 and V6, V4 and V5, and V4 and V6.
4. It has to be ensured that only in-spec product is transported to the downstream processing units (not shown). The valve V6 must not be opened if the quality is insufficient. The quality is determined by two independent quality measurements (QI304 and QIS305).

The inputs of the controller are the measurements via the sensors (LIS101 - PI306), operator commands (OpenV5, OpenV6) and the settings of the valves (V1-V6), the latter of which are considered to be both, input and output variables. The outputs of the controller are the settings sent to the valves (V1-V6) and two alarm variables (alarm, stop).

1.2. Supervisory Control Synthesis

The synthesis of a supervisory controller as reported in Theunissen et al. (2009) requires an automata model of the plant and a formal specification of the control requirements by a set of Boolean formulae specifying the control requirements. In this contribution, we consider the plant model as given while we focus on structuring and specifying the control requirements using the hierarchical *HCEC* formalism. The specification is then automatically translated into Boolean formulae as described in the following sections.

2. The Formalization Procedure

2.1. Cause-Effect Matrices (CEM)

The *Cause-Effect Matrix* (*CEM*) formalism is used for the specification and (partly for the) implementation of safety-related logic controllers but is not limited to this domain. An advantage of *CEM*-based formalisms is that a large amount of information can be visualized in a clearly arranged and intuitive data structure. However, neither the syntax nor the semantics of the *CEM* have been standardized yet so that different forms of *CEM* exist. The different *CEM* implementations range from very simple forms that only represent connections of sensors and actuators to complex forms that can represent more advanced control logic. All *CEM* formalisms share the basic structure that consists of four quadrants (see Tab. 1). The top-right quadrant contains the definitions of the *effects* (i.e. the actions in the control requirements), the

top-left quadrant holds information of the matrix such as author, date, name, project, etc., the bottom-left quadrant contains the definitions of the *causes* (inputs to the logic controller or internal variables), and the bottom-right quadrant defines the connections of causes and effects.

Table 1: Cause-Effect Matrix (*Quality Control* example, see Fig. 2)

Quality Control - Empty tank T3 via V5 in case of an error - Ensure product quality before opening V6		Stop	V5	V6
		Stop reaction	*Open V5*	*Open V6*
Inputs	**Comments**	OR	OR	AND
TI303 ≥ 200	*Temperature too high*	+	+	
PI306 ≥ 3.50	*Pressure too high*	+	+	
QIS305 AND QI304 ≥ 100	*Quality sufficient*			o
OpenV6	*Command to open V6*			o

The *CEM* definition here utilized for the formalization of the control requirements is defined as follows: Each cause consists of one or more inputs (plant states or events) and a logical function (AND, OR, or XOR) defining the connection of inputs in case of multiple inputs (e.g. QIS305 and QI304 in the third row in Tab. 1). The intersections define the connections of causes and effects. Each cell (= connection of one cause to one effect) can hold one of three qualifiers (+, -, o) defining if the cause is forcing (+), enabling (o) or blocking (-) the effect/event. If the cause forces the effect, the effect has to be activated whenever the cause is activated while enabling means that the effect can only be activated while the cause is activated. Blocking means that the effect must not be activated while the cause is activated. Each effect holds one output (action) that is enabled, forced, or blocked according to the connection specified in the intersections. Furthermore, effects hold a logical function defining how the intersections have to be interpreted (usually OR or AND). In addition, each cause and each effect holds a descriptive *comment* in natural language (see Tab. 1).

2.2. Hierarchical Cause-Effect Charts (HCEC)

In theory, it is possible to specify all requirements in one large matrix. However, the resulting matrix would be hardly comprehensible and maintainable (even in the case of simple requirements) so that a hierarchical approach should be utilized instead. To this end, this paper introduces the *Hierarchical Cause-Effect Charts* (*HCEC*) formalism (see Fig. 2) that introduces a hierarchical structure for *CE* matrices. It consists of a set of *causes* (inputs) on the left-hand side, a set of *effects* (outputs) on the right-hand side,

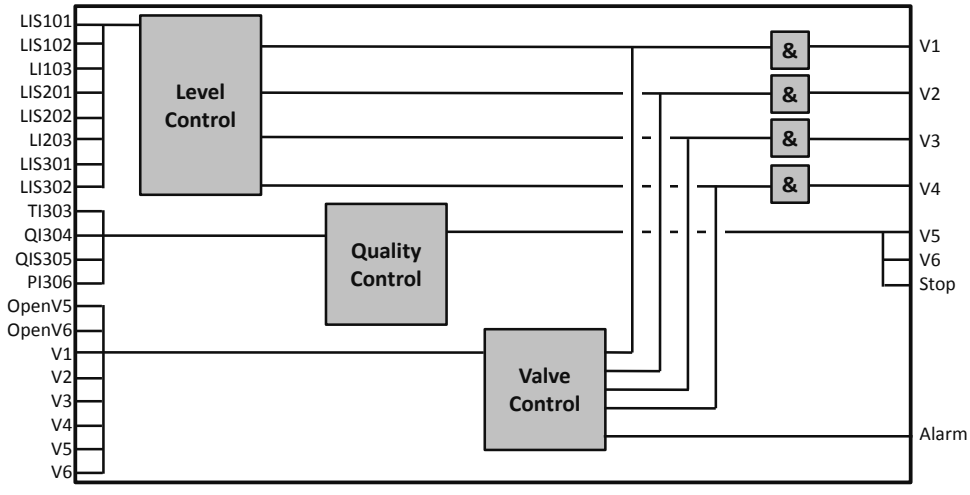

Figure 2: HCEC of the example process

and a set of *Function Blocks* that represent subsets of the control requirements. The requirements are grouped with respect to the process equipment involved, or in another appropriate way. Each of the function blocks is connected to sub-sets of causes and effects that are necessary to specify the behavior of this part of the system. The function blocks are either further refined using another *HCEC* sub-chart or by means of a *CEM*. The refinement ends if all requirements are formally defined by *CEM*.
In theory, it is possible to split the requirements into function blocks and finally CE matrices arbitrarily. However, in particular in safety-related control, requirements can usually be grouped according to the functional unit they belong to as this is highly recommended in relevant standards (see e.g. Brown (2000)).
For the example process, it was decided to group the requirements with respect to the required control tasks. Inputs to a module can be used in multiple embedded function blocks while in case of multiple function blocks accessing the value of the same output variable, an additional function block has to be introduced that specifies either the priority of one function block or how the signals are combined (e.g. for variable V1, see Fig. 2). For the example process, the set of causes consists of all sensor inputs from the plant and the current valve positions while the effects contain all actuator settings (see Fig. 2).

3. Formal Specification

3.1. Formalization of the Requirements for the Example
Initially, all outputs and inputs are assigned to the top-level *HCEC* block. During the hierarchical refinement of the control logic, three groups of interlocks are defined (*Level Control*, *Quality Control*, and *Valve Control*). Therefore, three function blocks are embedded into the top-level *HCEC* (see Fig. 2). The function block *Level Control* is further refined with another *HCEC* containing three function blocks (one for the level control of each tank). These low-level function blocks are refined by *CEM*s. For this relatively simple example, a refinement by means of *CEM*s is sufficient for *Valve Control* and *Quality Control*. The CEM of *Quality Control* is depicted in Tab. 1.

3.2. Translation of the Matrices into Boolean Formulae
The matrices are translated into a formal representation of the requirements that is suitable for the controller synthesis as follows:
Each "+" in the matrix denotes that the event should be forced when the condition is fulfilled. This can be expressed using the implication ("cause => effect"). The "-" denotes that the event is forbidden as long as one of the conditions is fulfilled. This can be expressed using a negated implication ("cause => ¬(effect)"). The third symbol, "o" denotes that the event is enabled only if the condition is true. This can be expressed by the implication ("effect => cause"). Since multiple "causes" can enable, force, or forbid a certain event/effect, the following rules apply:
1. All connections using the "-" are formulated as simple formulae ($a \Rightarrow \neg(b)$)
2. All connection using the "+" are combined using either "OR" or "AND". The utilized connector is specified in the matrix.
3. All connections using the "o" are formulated as simple formulae ($b \Rightarrow a$).

3.3. Formalized Requirements of the Example Process
After all requirements have been processed and the *HCEC* structure has been completed, the requirements are translated into Boolean formulae. As an example, the requirements implemented in the matrix shown in Tab. 1 are translated into the following four formulae:

$$(TI303 \geq 200) \vee (PI306 \geq 3.5) \Rightarrow Stop \quad (1)$$

$$(TI303 \geq 200) \vee (PI306 \geq 3.5) \Rightarrow V5 \quad (2)$$

$$V6 \Rightarrow QIS305 \wedge (QI304 \geq 100) \quad (3)$$

$$V6 \Rightarrow OpenV6 \quad (4)$$

These formulae in turn are used as inputs to the supervisory control synthesis tool chain, automatically resulting in a logic controller that fulfills the given specification. For details on controller synthesis we refer to Theunissen et al. (2009).

4. Conclusions

This paper introduces the new *Hierarchical Cause-Effect Charts* (*HCEC*) formalism for the structured representation of safety-related control logic. This formalism is embedded into an automated tool chain for algorithmic logic controller design that starts with an informal, natural-language description of the control requirements. The formalization benefits from the hierarchy which supports the design by breaking down the complexity of the system into CE matrices of manageable size that involve only small subsets of states and events of the controlled system and facilitates changes in the controller specification i.e. in the context of incremental system design or customization purposes. For the example process, the requirements are split into six matrices arranged in three levels of hierarchy with not more than seven rows and five columns each where one single matrix would consist of about 30 rows (inputs and their combinations) and a minimum of ten columns.

A formal representation of the control requirements as Boolean formulae is generated automatically from the final HCEC structure and is used as the input to the supervisory controller synthesis methodology which guarantees the correctness of the controller (according to the requirements). The HCEC formalism is generic and allows the application to other CEM formalisms used for e.g. test-case and/or code generation or as basis for formal verification. Future work will focus on this area.

Abstract

The aim of this work is to apply the self-optimizing control technique (Skogestad, 2000) in order to ascertain the plantwide control structure for a hydrodesulfurization HDS plant of a petroleum refinery with regards to hydrogen consumption optimization. The resulting control structure for the HDS plant is simple, robust to uncertainty, easy to implement (feedback control) and assures the global optimum in most cases, although an upper RTO layer will be needed to guarantee the operation in the adequate region, with non frequent updates. Only in one uncommon scenario a trade-off arises regarding the unconstrained degrees of freedom, and self-optimizing control variables must be looked for. Potential application to global refinery H_2 network is also discussed.

Keywords: self-optimizing control, hydrogen optimization, hydrodesulfurization plant.

1. Introduction

Hydrogen is an expensive utility used in many operations that is gaining increasing importance in the economic balance of a refinery. In this framework, a project oriented towards the optimal management of the real-time operation of a refinery H_2 network is being undertaken in collaboration with the Petronor refinery (Vizcaya, Spain) of the Repsol group (Sarabia et al., 2009), in order to minimize H_2 production costs.

H_2 is distributed by means of a network from the producer plants to the consumer plants. Make-up H_2 to each consumer plant can be provided from different production lines, corresponding to different producer plants as well as consumer plants outlets. Accumulation of H_2 is not possible; as a deficit of H_2 is very damaging for catalyst active life, being catalysts very expensive, then always H_2 production must exceed consumption in operation. Because H_2 is expensive to produce, minimization of H_2 production has a great potential for economic profit. Furthermore, in scenarios where H_2 production is bottleneck for the refinery fuel processing capacity, the potential for profit increase is even higher. Minimization of H_2 production cost is mainly achieved by means of: a) a better H_2 redistribution at the network scale, trying to reuse as much as possible the low purity H_2 from the consumer plants outlets; b) minimization of losses to fuel gas, as a consequence of a better fitting of H_2 production to H_2 consumption in operation, while guaranteeing certain excess for pressure control purposes.

Determining a good plantwide control structure, in this case for an H_2 consumer diesel hydrodesulfurization HDS plant, is an issue of great practical importance to achieve optimal operation. Skogestad's procedure looks for a control strategy which can be

implemented in practice in a robust and simple manner. In the first place, active constraints are controlled, and then, for the remaining unconstrained economic degrees of freedom, self-optimizing variables are looked for. Self-optimizing control (Skogestad, 2000) is when close-to-optimal economic operation is obtained with a constant set-point policy. In this way it is avoided, or at least reduced, the need for an upper optimization RTO layer, being feedback control still the easiest way to implement a control strategy in industrial practice (Skogestad, 2004). Self-optimizing control design has been applied successfully to many processes (e.g. Araujo, Govatsmark and Skogestad, 2007; Lid and Skogestad, 2008).

2. Hydrodesulfurization plant description

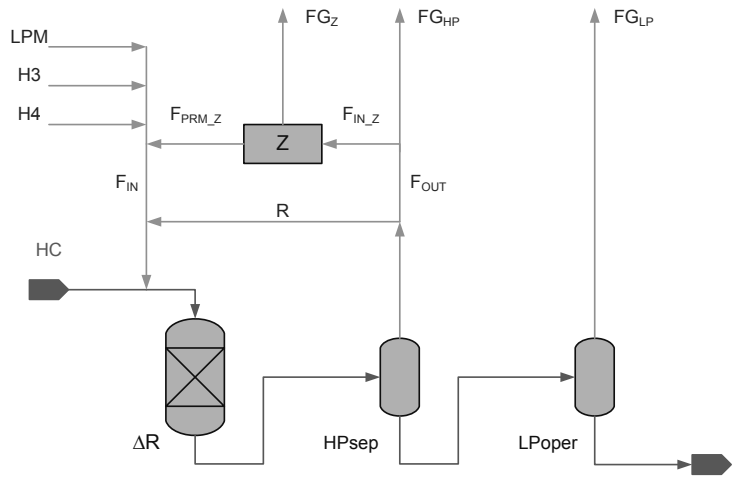

Figure 1. General H_2 consumer plant structure, with membranes unit for H_2 recovery.

A process flow diagram for the HDS plant is shown in Fig.1. Desulfurization reactions take place in fixed bed catalytic reactors (ΔR) where a minimum ratio H_2/hydrocarbon must be ensured for catalyst maintenance reasons. Reactors are fed with a blend of fuels of different qualities. The hydrocarbon (HC) feed is mixed with the recycled H_2 stream (R) and with make-up H_2 from the network. Two make-up streams (*H4*, *H3*) correspond to high purity inlets from producer plants, while the other (*LPM*) corresponds to the low purity line constituted from other plants outlets and excess. After being separated in a high pressure separation drum (*HPsep*), non reacted H_2 is partially recycled (R), partially purified and recycled in membranes Z (F_{PRM_Z}), and partially purged and burnt as fuel gas (FG_Z, FG_{HP}). Downstream of *HPsep*, several distillation columns at low pressure (*LPoper*) enable the complete separation of light gases from the desulfurized diesel stream. Light gases from low pressure separation processes (*LPoper*) are directed to fuel gas (FG_{LP}), since H_2 purity is not high enough for its recovery to be profitable. A HDS plant simplified model is available from previous work (Sayalero et al., 2010).

3. Self-optimizing control structure

The systematic procedure for plantwide control (Skogestad, 2004) will be applied to determine the self-optimizing control structure, following the steps in the top-down economic steady-state analysis.

3.1. Degrees of freedom analysis

A total of 5 degrees of freedom are available for economic optimization based on the process model. The following are natural manipulated variables (u) in operation: H_2 make-up flow rates from production plants F_{H3}, F_{H4}, membranes inlet flow rate F_{IN_Z}, membranes purge ratioed to the inlet F_{FG_Z}/F_{IN_Z}, purge to fuel gas from the high pressure recycle F_{FG_HP}. Other process variables are not truly degrees of freedom regarding H_2 optimization; that is the case for: a) pressure in separators, controlled at a fixed value according to compression ratios and security valves design; b) temperature in separators, regulated at minimum possible value by means of air exchangers, thus enabling the best relative separation of H_2 from light ends; c) quench flows between beds in the catalytic reactors, whose purpose is to maintain proper temperature gradients and to avoid high temperatures; d) reactor inlet temperature, which will always be active constraint at the minimum value enabling to achieve the sulfur specification in product.

3.2. Definition of optimal operation: cost and constraints

Only H_2 material cost is considered, as energy cost is in general an order of magnitude lower. Due to H_2 recycle flow being much greater than H_2 make-up flow, the H_2/hydrocarbon minimum ratio constraint (F_{H2}/F_{HC} > min) at reactor inlet is attained by means of recycle compressor's capacity (at minimum feasible, to minimize energy cost), and is thus decoupled from the H_2 optimization problem. Membranes operating costs can be disregarded as only low pressure steam is needed. Fuel gas value of purge streams is not considered (p_{fuel}) as this term will compete with minimization of the LPM make-up H_2 flowrate, being LPM H_2 price already a fictitious one. As a consequence, only make-up H_2 cost will be considered:

$$\min_u J = p_{H4} \cdot F_{H4} + p_{H3} \cdot F_{H3} + p_{LPM} \cdot F_{LPM} \qquad \text{(Eqn. 1.)}$$

Constraints to fulfill are the following: a) recycle H_2 purity between minimum to prevent deposition of coke over catalyst particles ensuring enough H_2 excess, and maximum to avoid surge of centrifugal compressor: min < y_{REC} < max; b) membranes operating range: min < F_{FG_Z}/F_{IN_Z} < max, and membranes capacity: min < F_{IN_Z} < max; c) producer plants capacity and LPM availability: min < F_{H3} < max, min < F_{H4} < max, 0 < F_{LPM} < max; d) compressors [reciprocating/centrifugal] capacity: min < F_C < max.

3.3. Identification of important disturbances

Regarding the plant state, disturbances in hydrocarbon feed influence: gas separated in the low pressure operations F_{FG_LP}, $y_{FG\_LP}^{H2}$, determined under pressure control according to inventory regulation; hydrogen consumption ΔR_{H2} and light ends generation ΔR_L in the reactor. Regarding different future scenarios, there are several disturbances that deserve being considered, namely: H_2 purity of certain make-up streams y_{LPM}^{H2}, y_{H3}^{H2}, and make-up availability from the low purity line F_{LPM}.

3.4. Regions of active constraints (modes of operation)

To identify the different regions of active constraints, optimization with respect to the available degrees of freedom is performed for the different operating points (19) selected corresponding to historical process conditions, for 6 case studies corresponding to different disturbances in utilities; in total 114 case studies. The model is implemented in EcosimPro® modelling and simulation environment and optimizations are performed with a NAG® SQP solver linked with EcosimPro®. In increasing order of H_2 requirements, the regions of active constraints are the following:

- **A.** Recycle H_2 purity (y_{REC}^{H2} = min) controlled with F_{IN_Z}. Manipulated variables active: F_{FG_Z}/F_{IN_Z} = min, F_{FG_HP} = 0, F_{H3} = 0, F_{H4} = 0.

The purge of H_2 is minimum (F_{FG_Z}/F_{IN_Z} = lower bound), and as a result both make-up H_2 flow and H_2 losses in the purge are also minimum.

- **B.** Recycle H_2 purity (y_{REC}^{H2} = min) controlled with F_{FG_Z}/F_{IN_Z}. Manipulated variables active: F_{IN_Z} = max, $F_{FG\_HP} = 0$, $F_{H3} = 0$, $F_{H4} = 0$.
  When H_2 requirements increase with respect to previous **A**, H_2 purge (F_{FG_Z}/F_{IN_Z}) is not at the lower bound because the membranes capacity upper bound is reached. Higher purge implies higher permeate purity, but also higher make-up H_2 flow rate.
- **C.** Recycle H_2 purity (y_{REC}^{H2} = min) controlled with F_{FG_HP}. Manipulated variables active: F_{IN_Z} = max, F_{FG_Z}/F_{IN_Z} = max, $F_{H3} = 0$, $F_{H4} = 0$.
  When H_2 requirements increase with respect to **B**, and membranes are saturated.
- **D.** Trade-off between ratio purged in membranes and HPM H_2 make-up (F_{H4}, F_{FG_Z}/F_{IN_Z}). Recycle H_2 purity controlled (y_{REC}^{H2} = min). Manipulated variables active: F_{IN_Z} = max, $F_{FG\_HP} = 0$, $F_{H3} = 0$. Case rather infrequent.
  When make-up H_2 from a producer plant (HPM H_2) is needed due to LPM H_2 shortage (small purity of 0.67 %1mol for example but not small F_{LPM} availability). The optimum is quite flat with respect to F_{FG_Z}/F_{IN_Z}, so a value can be fixed while using F_{H4} to control y_{REC}^{H2}, being $F_{FG\_Z}/F_{IN\_Z} = 0.33$ the most common by far (self-optimizing variable). According to the experiments carried out, the optimal ratio varies between 0.27-0.36, so 600 Nm^3 H_2/h is the difference for F_{IN_Z} = max, and the maximum loss in HPM H_2 is 300 Nm^3/h provided 0.33 is fixed. Cases B and D can be easily distinguished; if an increase in F_{LPM} (by allowing an increase in F_{FG_Z}/F_{IN_Z}) does not lead to an increase in y_{REC}^{H2}, then HPM H_2 will be needed. This occurs when $y_{LPM}^{H2} < y_{REC}^{H2}$. Direct purge F_{FG_HP} will be needed if membranes get saturated, besides HPM H_2.
- **E.** When the maximum make-up compressor's capacity is binding constraint besides y_{REC}^{H2} (y_{REC}^{H2} = min, F_{C1} = max), controlled with F_{FG_HP} and F_{H4}. Manipulated variables active: F_{IN_Z} = max, F_{FG_Z}/F_{IN_Z} = max, $F_{H3} = 0$.
  This situation is common in cases where $y_{LPM}^{H2} > y_{REC}^{H2}$, but only slightly greater. As a high flow F_{LPM} is needed, make-up compressor capacity gets saturated. As usual, membranes capacity is fully employed before HPM H_2 is used.
  F. When the maximum LPM H_2 availability is active constraint, besides y_{REC}^{H2} (y_{REC}^{H2} = min, F_{LPM} = max). Manipulated variables active: either F_{FG_Z}/F_{IN_Z} = min, $F_{FG\_HP} = 0$, $F_{H4} = 0$ (control with F_{IN_Z}, F_{H3}); F_{FG_Z}/F_{IN_Z} = min, $F_{FG\_HP} = 0$, $F_{H3} = 0$ (control with F_{IN_Z}, F_{H4}); F_{IN_Z} = max, F_{FG_Z}/F_{IN_Z} = min, $F_{FG\_HP} = 0$ (control with F_{H3}, F_{H4}); or F_{IN_Z} = max, $F_{FG\_HP} = 0$, $F_{H3} = 0$ (control with F_{FG_Z}/F_{IN_Z}, F_{H4}).
  Both membranes and HPM H_2 make-up are needed. With increasing H_2 demand, first F_{IN_Z} is manipulated, then F_{FG_Z}/F_{IN_Z}. Between the two HPM H_2, F_{H3} and F_{H4}, which one is used depends mainly on their respective prices and purities (very constant), but also on plant state, although no trade-off arises. An upper RTO layer will be required to know whether to use F_{H3} or F_{H4}, with very low frequent updates.

4. Discussion

Self-optimizing control is a robust technique not sensitive to uncertainty when compared with RTO (Skogestad, 2000). As i) disturbances: H_2 consumption, light gases inlet and generation, and gases solubility in hydrocarbons, are difficult to estimate accurately, and ii) gas flow measurements need to be compensated with molecular weight in operation, where the stream molecular weight is quite sensitive to light gases composition due to the low value of H_2 molecular weight (2.016 g/mol), a self-optimizing control approach can be advantageous and preferred compared to RTO.

Other major advantage is that the self-optimizing approach considered is reliable regardless of model mismatch: although model validation is not perfect quantitatively (errors up to 10% in the prediction of H_2 consumption rate), the analysis performed regarding regions of active constraints is correct.
The resulting control structure for the HDS plant is simple, easy to implement (feedback control with programmed logic) and assures the global optimum in most cases, although an upper RTO layer will be needed to guarantee the operation in the adequate region, with non frequent updates. Only in one scenario, rather uncommon, a trade-off arises regarding the unconstrained degrees of freedom, and self-optimizing control variables must be looked for to assure close to optimal operation avoiding more complex on-line optimization techniques. Main drawbacks are related to plant automation level, which needs to be high to implement this technology; in particular the membranes unit can't be operated manually. Transport delay due to reactor and dynamic effects due to separators are not negligible, therefore a MPC approach with an economic objective function could be justified, especially when the high number of regions of active constraints is taken into account, due to its potential to easily handle constraints.

4.1. Hydrogen optimal management at refinery network scale

A further step is being considered regarding the potential application of self-optimizing control design to on-line optimization of the global H_2 network operation. Although the structure at network scale is much more complex, the number of combinations allowed is usually small. Considering where it is more efficient to employ HPM H_2, and looking for self-optimizing variables when needed, consumer plants optimization with regards to H_2 consumption could be decoupled from the whole network, being the problem at network scale simplified, and thus reducing the loss between RTO executions.

Abstract

This paper presents the application of reconfigurable control strategy to a multivariable neutralization process under several fault scenarios. The combined control strategy is integrated to a reconfiguration block that uses the available signals from the remaining sensors and actuators to reconstruct a signal useful to the nominal controller leading to a stable closed-loop behavior even in the presence of faults. Simulations results show that, although the overall system performance can be compromised, the reconfigurable control strategy leads to a system that is still able to operate within acceptable performance in the studied fault scenarios.

Keywords: fault tolerant control, neutralization, reconfigurable control

1. Introduction

Modern control design aims not only to stabilize processes in normal operating conditions, but also to control them successfully in abnormal situations. In this sense, fault tolerant control (FTC) systems include taking online corrective actions to mitigate fault effects preventing plant shutdown and off-specification production. The main objective is to make the system closed-loop stable under a fault situation while accepting a reduced performance in the overall process (Blanke et al., 2001).

Reconfigurable control is a type of active fault tolerant system where the fault-handling is carried out by changing the parameters of a nominal controller, switching it, or broadly restructuring the control loop to deal with different dynamics imposed by faults. Control reconfiguration differs from the passive fault tolerant systems, where the failure modes are accounted in the design stage ensuring the control system to work under several fault scenarios considered in advance (Jiang, 2005).

This work considers the problem of achieving a fault tolerant control loop by means of a reconfigurable control based on the use of virtual instrumentation (Steffen, 2005; Richter, 2011). In order to recover closed-loop stability in the presence of actuator/sensor losses, the reconfiguration strategy uses a signal composed by the difference between nominal and faulty plant dynamics. Instead of switching the nominal controller to one designed for a specific fault, a control reconfiguration block hides the fault from the nominal controller keeping it active during the fault period. Hence, the available signals from the remaining sensors and actuators are used to reconstruct a signal useful to the nominal controller bypassing the faulty instrumentation (Richter and Lunze, 2010).

*thiagocosta@feq.unicamp.br

The studied method is used to design a FTC system applied to a multivariable neutralization process under several fault scenarios. Simulations results show that, although the overall system performance can be compromised, the reconfigurable control strategy leads to a system that is still able to operate within acceptable performance in the studied fault scenarios.

2. Neutralization Process

The studied neutralization process (Figure 1) is characterized by a continuous stirred tank reactor (CSTR) supplied by a strong acid (HNO_3) and a strong base (NaOH) lines, in addition to a third line composed by a buffering component ($NaHCO_3$). Each stream flow is locally manipulated by a dedicated slave controller that receives a reference signal from the multivariable controller output. The fault scenarios (FI and FII) considered are based on the loss of communication between master and slave controllers.

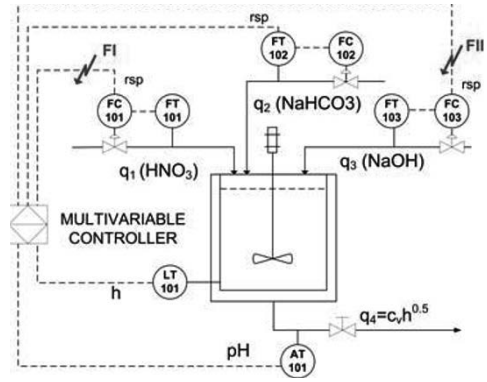

Figure 1. Neutralization process subject to faults in the signal path between master and slave controllers

The nominal plant model, without the presence of faults, is described by equations 1 – 3 and is considered as the reference model for the reconfiguration control design. It consists of three states: reactor level (h) and the invariant species concentrations W_a and W_b. Basically, system dynamics are just slightly nonlinear due to the bilinear combination between the invariant states with respect to the input flows.

$$\dot{h} = [q_1 + q_2 + q_3 - q_4]A^{-1} \tag{1}$$

$$\dot{W}_a = [(W_{a1} - W_a)q_1 + (W_{a2} - W_a)q_2 + (W_{a3} - W_a)q_3](Ah)^{-1} \tag{2}$$

$$\dot{W}_b = [(W_{b1} - W_b)q_1 + (W_{b2} - W_b)q_2 + (W_{b3} - W_b)q_3](Ah)^{-1} \tag{3}$$

The main nonlinearity is described by the static output model given by equation 4 which relates the output of the dynamic subsystem (invariants) to the system output, pH. The block oriented characteristics of the neutralization process are similar to a Wiener model. Hence, the design of the reconfiguration control based on linear techniques is considered feasible as the main process nonlinearity is located on the system static gain and not on its dynamics.

$$W_a + 10^{pH-14} - 10^{-pH} + W_b \frac{1 + 2 \times 10^{pH-pk_2}}{1 + 10^{pk_1-pH} + 10^{pH-pk_2}} = 0 \tag{4}$$

3. Control Reconfiguration Procedure

In this work, control reconfiguration operates on the use of virtual actuators as proposed in Steffen (2005). The idea builds on the use of state feedback applied to the deviation of the faulty plant from its nominal behavior represented by a new state denoted x_Δ. The reconfiguration block (Figure 2) is placed between the faulty plant and the nominal controller. The block receives the output of the faulty plant (y_p) and the output of the controller (u_c) correcting the signal sent to the nominal controller (y_c) and translating the signal from the controller to a signal (u_p) that will make use of the available actuators to handle the fault. The virtual actuator is based on two design parameters: M and N. Feedback gain M is used to stabilize the pair (A, B_f), where B_f denotes the faulty plant input matrix. The feedforward term $N = I$ is used to provide the reconfiguration block with autonomous behavior.

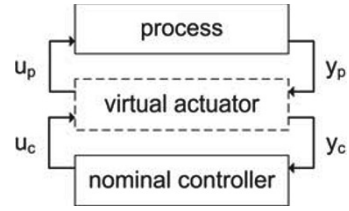

Figure 2. Reconfigurable control based on virtual actuator

$$\dot{x}_\Delta = \left(A - B_f M\right) x_\Delta + \left(B - B_f N\right) u_c; \;\; x_\Delta = x - x_f \text{ and } x_\Delta(0) = 0 \tag{5}$$

$$y_c = y_p + C x_\Delta; \; u_p = M x_\Delta + N u_c \tag{6}$$

The virtual actuator gain M is designed here by means of an optimization problem as in the design of a LQR (linear quadratic regulator). Given the system presented by equations 5 – 6 the virtual actuator is obtained by solving the following LMI (linear matrix inequality):

$$\min_P \operatorname{Tr}(P)$$

$$\text{s. t. } \begin{pmatrix} A^T P + PA + Q & PB_f \\ B_f^T P^T & R \end{pmatrix} > 0; \;\; P = P^T > 0 \tag{7}$$

4. Simulation Results

Two fault scenarios were investigated in order to demonstrate the efficacy of the studied control reconfiguration strategy: loss of communication between master and slave controllers in acid line (FI) and base line (FII). Which means that stream flow in the faulty line is fixed in steady state due to the inability of the actuator to respond. A linearized state-space model, derived from equations 1 – 3 was used for the nominal controller and the reconfiguration block design. Each fault is modeled by replacing the respective input matrix column elements to zero (actuator is bypassed). Parameters used in simulation are given in Henson and Seborg (1994). Nominal closed-loop behavior is shown in Figure 3.

Fault scenario I is presented in Figure 4. System output behaviour is shown in Figures 4(a) and 4(b) for both reconfigured (solid line) and non-reconfigured cases (thin line). Figures 4(c) to 4(e) shows the controller output (solid lines) and actual stream flow (dashed lines) in the faulty non-reconfigured case. The simulation shows that the nominal controller performance is degraded by the loss of the first actuator. Whereas, the reconfiguration block as shown in Figures 4(f) to 4(h) changes the nominal controller output (solid lines) to a signal meaningful for the faulty plant (actual stream flow – dashed lines) that uses

mainly the second input (buffer stream) to cope with the acid line loss. As in the first case, control reconfiguration after fault, FII (Figure 5), is able to recover the closed-loop system within acceptable performance based on buffer input (q_2) amplification. It is important to mention that in both situations a small offset is introduced due to the plant/model mismatch in the reconfigured case.

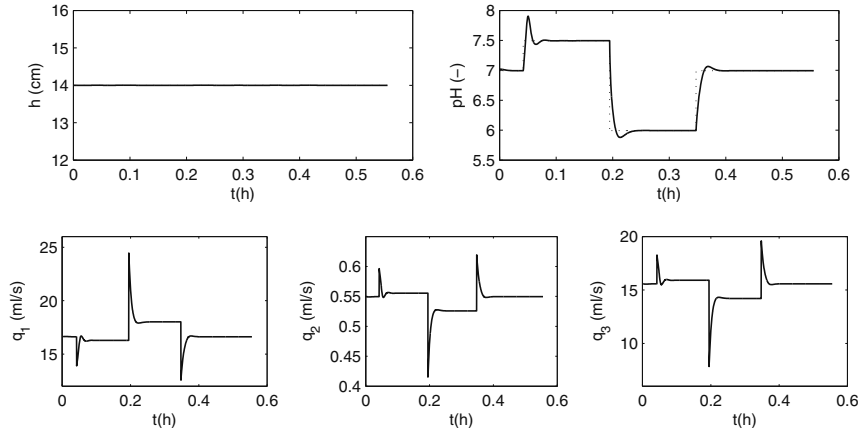

Figure 3. Closed-loop nominal behavior based on a LQR controller for the following initial conditions: $q_1 = 16.6ml/s$, $q_2 = 0.55ml/s$, $q_3 = 15.6ml/s$, $pH = 7.02$ *and* $h = 14.00cm$.

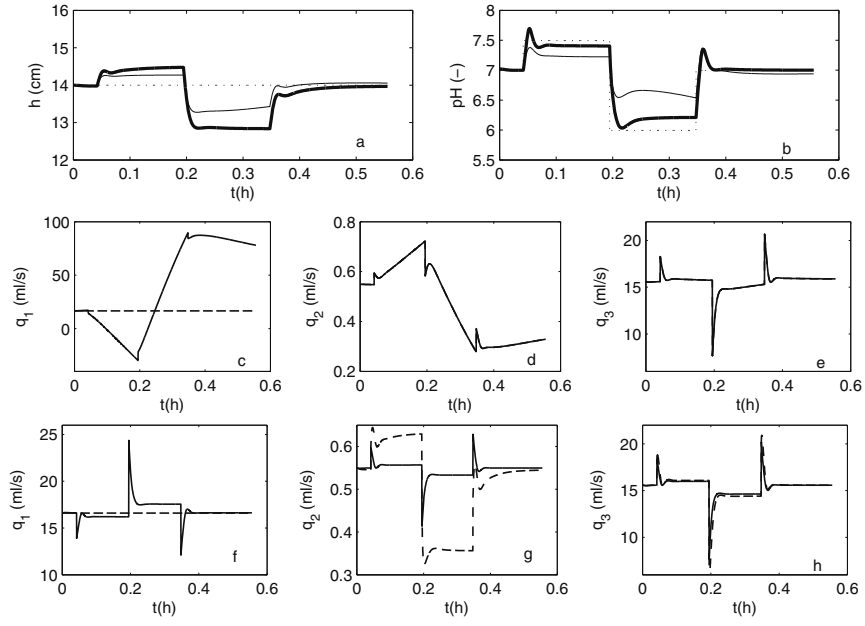

Figure 4. Fault Case I. Controlled variables (a) – (b): reconfigured (–) and non-reconfigured cases (–). Input variables for non-reconfigured (c–e) and reconfigured (f–h) cases: controller output (solid lines) and actual stream flow (dashed lines).

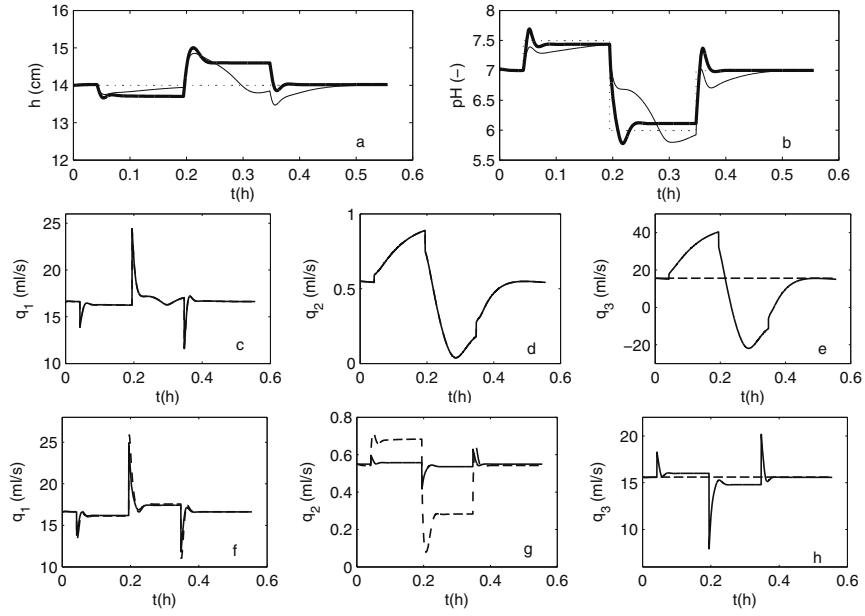

Figure 5. Fault Case II. Controlled variables (a) – (b): reconfigured (–) and non-reconfigured cases (–). Input variables for non-reconfigured (c–e) and reconfigured (f–h) cases: controller output (solid lines) and actual stream flow (dashed lines).

5. Conclusions

This paper addressed a reconfigurable stabilizing control based on the use of virtual actuators. The method applied in the control reconfiguration of a neutralization process subject to actuator losses proved feasible and efficient in the studied scenarios. Although the system overall performance has been compromised the reconfigurable control strategy led to a system within good performance/loss-recover operation as shown in the fault scenarios studied.

Robust IMC-PID Design for Optimal Closed-loop Response with Specified Gain and Phase Margins for SOPTD Systems

Keyu Li *

Department of Thermal Energy Engineering;China University of Petroleum, Beijing;Beijing, China

Abstract

A new internal model control (IMC) based robust PID tuning method for second order plus time delay (SOPTD) systems is developed to meet specified gain and phase margins (GPM). The exact open-loop amplitude ratio and phase change equations are derived based on frequency analysis. The tuning method based on IMC with constraints on GPM and closed-loop overshoot ratio is further given. The method is demonstrated in simulation examples and compared with previous work on this topic.

Keywords: Gain and phase margins, PID tuning, IMC

1. Introduction

Internal model control (IMC) Rivera et al. (1986) has been widely accepted by industry for PID tuning due to its simplicity to apply. For any model-based PID tuning algorithm like IMC, robustness plays an important role in PID design due to model mismatch. In practice, gain and phase margins serve as important indicators of system robustness, and the combination of IMC tuning and GPM has also been explored Ho et al. (2001); Kaya (2004); Chu et al. (2011). Previous work includes IMC-GPM tuning for PI controller and PID controller for FOPTD systems, but there is still no report on IMC based PID tuning for SOPTD systems with specified gain and phase margins.

In this work, the IMC tuning algorithm is used for SOPTD systems to meet specified gain and phase margins for the PID controller for the first time. Another contribution of this work is that the overshoot ratio is directly used in the controller design as the closed-loop performance criterion combined with GPM as the robustness criteria.

2. System Frequency Analysis

2.1. The Open-loop Frequency Analysis

The transfer function of a SOPTD process is given by

$$G_p(s) = \frac{K_p}{\tau^2 s^2 + 2\xi\tau s + 1} e^{-\theta s} \tag{1}$$

and the transfer function of the PID controller in parallel form is given by

$$G_c(s) = K_c(1 + \frac{1}{\tau_I s} + \tau_D s) \tag{2}$$

*likeyu@cup.edu.cn

Then the open-loop transfer function is given by

$$G_{ol}(s) = G_c(s)G_p(s) \tag{3}$$

$$= \frac{K_cK_p(\tau_I\tau_Ds^2+\tau_Is+1)e^{-\theta s}}{\tau_Is(\tau^2s^2+2\xi\tau s+1)} \tag{4}$$

With relatively simple mathematical manipulation, the frequency response amplitude ratio AR_{ol} and phase change ϕ_{ol} are explicitly given by

$$AR_{ol} = \frac{K_cK_p\sqrt{(1-\omega^2\tau_I\tau_D)^2+(\omega\tau_I)^2}}{\omega\tau_I\sqrt{(1-\omega^2\tau^2)^2+(2\omega\xi\tau)^2}} \tag{5}$$

$$\phi_{ol} = \begin{cases} \Lambda_1(\omega)-\omega\theta-\Lambda_2(\omega)+\frac{\pi}{2} & \text{if } \Lambda_1(\omega)<0, \Lambda_2(\omega)\geq 0 \\ \Lambda_1(\omega)-\omega\theta-\Lambda_2(\omega)-\frac{3\pi}{2} & \text{if } \Lambda_1(\omega)\geq 0, \Lambda_2(\omega)<0 \\ \Lambda_1(\omega)-\omega\theta-\Lambda_2(\omega)-\frac{\pi}{2} & \text{else} \end{cases} \tag{6}$$

where

$$\Lambda_1(\omega) = tan^{-1}\left(\frac{\omega\tau_I}{1-\omega^2\tau_I\tau_D}\right) \tag{7}$$

$$\Lambda_2(\omega) = tan^{-1}\left(\frac{2\omega\xi\tau}{1-\omega^2\tau^2}\right) \tag{8}$$

2.2. The Closed-loop Frequency Analysis

For open-loop system G_{ol}, the closed-loop transfer function is given by

$$G_{cl} = \frac{G_{ol}}{1+G_{ol}} \tag{9}$$

By simple mathematical manipulation, we have

$$AR_{cl} = \frac{1}{\sqrt{(\frac{1}{AR_{ol}}+cos\phi_{ol})^2+sin^2\phi_{ol}}} \tag{10}$$

Thus the overshoot ratio can be obtained by calculating the maximum amplitude ratio AR_{cl} from AR_{ol} and ϕ_{ol} in the entire frequency range $\omega\in(0,\infty)$.

3. IMC-PID Design Based on Gain and Phase Margins

From definition, the gain margin A and phase margin ϕ can be calculated from the following equations:

$$A = \frac{1}{|G_{ol}(j\omega_p)|} \tag{11}$$

$$\phi = \angle G_{ol}(j\omega_g)+\pi \tag{12}$$

where

$$|G_{ol}(j\omega_g)| = 1 \tag{13}$$

$$\angle G_{ol}(j\omega_p) = -\pi \tag{14}$$

Substituting Eq. 5 and 6 into 11-14, we have 4 equations

$$A = \frac{\omega_p \tau_I}{K_c K_p} \sqrt{\frac{(1-\omega_p^2\tau^2)^2 + (2\omega_p \xi \tau)^2}{(1-\omega_p^2 \tau_I \tau_D)^2 + \omega_p^2 \tau_I^2}} \tag{15}$$

$$\phi = \begin{cases} \Lambda_1(\omega_g) - \omega_g \theta - \Lambda_2(\omega_g) + \frac{3\pi}{2} & \text{if } \Lambda_1(\omega_g) < 0, \Lambda_2(\omega_g) \geq 0 \\ \Lambda_1(\omega_g) - \omega_g \theta - \Lambda_2(\omega_g) - \frac{\pi}{2} & \text{if } \Lambda_1(\omega_g) \geq 0, \Lambda_2(\omega_g) < 0 \\ \Lambda_1(\omega_g) - \omega_g \theta - \Lambda_2(\omega_g) + \frac{\pi}{2} & \text{else} \end{cases} \tag{16}$$

and

$$\frac{K_c K_p}{\omega_g \tau_I} \sqrt{\frac{(1-\omega_g^2 \tau_I \tau_D)^2 + \omega_g^2 \tau_I^2}{(1-\omega_g^2\tau^2)^2 + (2\omega_g \xi \tau)^2}} = 1 \tag{17}$$

$$\begin{cases} \Lambda_1(\omega_p) - \omega_p \theta - \Lambda_2(\omega_p) + \frac{3\pi}{2} & \text{if } \Lambda_1(\omega_p) < 0, \Lambda_2(\omega_p) \geq 0 \\ \Lambda_1(\omega_p) - \omega_p \theta - \Lambda_2(\omega_p) - \frac{\pi}{2} & \text{if } \Lambda_1(\omega_p) \geq 0, \Lambda_2(\omega_p) < 0 \\ \Lambda_1(\omega_p) - \omega_p \theta - \Lambda_2(\omega_p) + \frac{\pi}{2} & \text{else} \end{cases} = 0 \tag{18}$$

with 5 unknowns ω_g, ω_p, K_c, τ_i and τ_D for given gain margin A and phase margin ϕ, so we can not solve them directly. However, if we further apply the IMC-Mac tuning formula Panda et al. (2004), the tuning problem becomes 4 equations with 3 unknowns (τ_c, ω_g and ω_p), where τ_c is the tuning parameter for IMC. Then the tuning problem could be solved to meet the robustness criteria, but we also want the PID tuning to lead to required closed-loop performance, such as response time and overshoot ratio. Since τ_c is related to the closed-loop response time and the overshoot ratio could be calculated from Eq. 10, we formulate the tuning problem into an optimization problem

$$\min_{\tau_c, \omega_g, \omega_p} \tau_c \tag{19}$$

S.T.

$$A \geq A^* \tag{20}$$

$$\phi \geq \Phi^* \tag{21}$$

$$AR_{cl} \leq O^* \qquad \forall\, \omega \in [0, \infty) \tag{22}$$

where A^* and Φ^* are given gain margin and phase margin bounds respectively; O^* is the user-specified overshoot ratio.

4. Simulation Examples

4.1. Second-order System

The SOPTD example in Ho et al. (1997) is first considered and the plant model is given by

$$G_p(s) = \frac{1}{s^2 + s + 1} e^{-s} \tag{23}$$

For required gain margin $A^* = 3$ and phase margin $\phi^* = 60^\circ$, the closed-loop response results for step response and load disturbance from Ho and proposed method are shown in Fig. 1. Tuning parameters and some results are shown in Table. 1.

Table 1. PID tuning results for example 1 with different methods

Parameter	K_c	τ_I	τ_D	A	ϕ	A^*	ϕ^*	O^*	IAE
Proposed	0.5241	1.0964	0.9358	3.0145	64.6366	3	60	1.2	5.4328
Method from Ho	0.52	1	1	3.9	65	3	60	N/A	5.5765

Table 2. PID tuning results for example 2 with different methods

Parameter	K_c	τ_I	τ_D	A	ϕ	IAE	Settling Time
Proposed	0.6133	0.6309	1.0532	3.277	63.9684	3.3620	4.6883
Method from Ho	0.783	0.832	0.790	4.898	70	3.3664	8.8755
Method from Shen	0.92	1.075	0.775	3.273	46.6	3.1019	9.4844

From the results we can see that the proposed method leads to smaller overshoot and integrated absolute error (IAE) value.

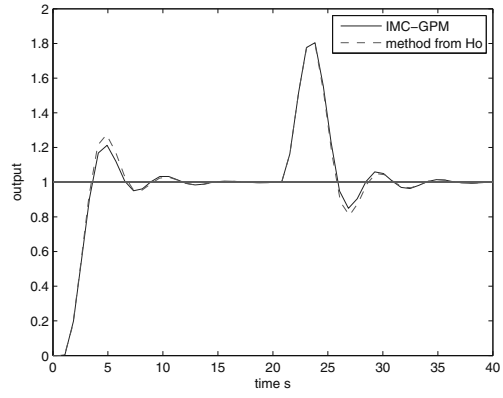

Figure 1. The Closed-loop Response from the SOPTD System

4.2. Higher Order System

Let's consider an example from Shen (2000), where Shen proposed a new PID tuning method for under-damped second order system based on dominant pole assignment. The system is given by

$$G(s) = \frac{18}{(s^2+s+2)(s+3)^2} \quad (24)$$

A step response experiment gives the model Shen (2000)

$$G_p(s) = \frac{1.52e^{-0.48s}}{s^2+0.9s+1.52} \quad (25)$$

The tuning method from Shen gives out a gain margin 3.273 and a phase margin 46.6°. Then we use the same values as the required gain and phase margin bounds, i.e. $A^* = 3.273$ and $\phi^* = 46.6°$, for proposed IMC-GPM method and Ho's method. The closed-loop responses from different methods are given in Fig. 2 and results are compared in Table 2.

From the results we can see that tuning method from Shen gives the best overall IAE, but more oscillations and the longest settling time. Our proposed method gives just slightly better IAE value than Ho's method, but far less oscillations and a much smaller settling time than the other two methods.

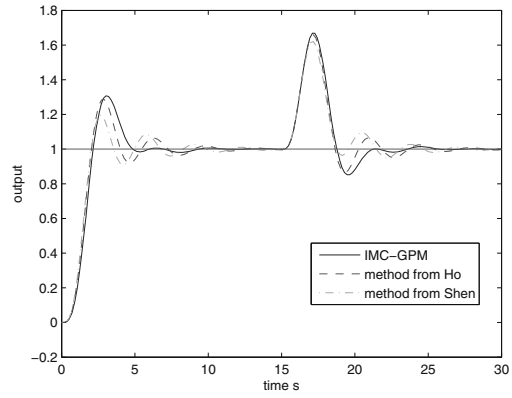

Figure 2. The Closed-loop Response from Higher Order System

5. Conclusion

The gain and phase margins are used as robustness criteria to tune the PID controller in the IMC framework. The closed-loop overshoot ratio is also explicitly used as a performance criterion by frequency analysis. The tuning algorithm is formulated as a nonlinear optimization problem to minimize the closed-loop response time τ_c, with constraints on gain margin, phase margin and overshoot ratio. The simulation results show that the new robust tuning method leads to better overall closed-loop performance (smaller IAE and settling time) than the existing GPM based PID tuning method. The proposed method also results in much smaller settling times and much less oscillations than the method based on pole assignment for examples in this paper.

A New Strategy of Locality Enhancement for Just-in-Time Learning Method

Qing Lin Su,[a] Manabu Kano,[b] Min-Sen Chiu[a]

Abstract

Just-in-Time Learning (JITL) method has recently received increasing attention, particularly its application to control and soft sensing. Unlike the conventional JITL methods, which construct a local model directly based on the relevant data selected from reference database, a novel strategy is proposed by considering the local model as a Taylor series of the global model expanded in the vicinity of a reference point. This reference point could be chosen as the most relevant data or the query data. A comparative study using a benchmark nonlinear CSTR process showed the efficiency of the proposed strategy by achieving better prediction than its conventional counterparts.

Keywords: Data-Based; Local Model; Just-in-Time Learning; Locality Enhancement

1. Introduction

Just-in-Time Learning (JITL) methodology approximates a nonlinear system with a set of local models valid in the relevant operating regimes (Atkeson et al., 1997; Bontempi et al., 1999). There are three steps, i.e., relevant data selection from database according to some similarity criterion, local model construction based on the relevant data, and model prediction using the local model and query data, associated with the JITL modeling. Recent developments include the combination of distance and angular metrics to characterize the similarity between query data and relevant data by Cheng and Chiu (2004), and the use of correlation measure proposed by Fujiwara et al. (2009). Recently, the supervised locality preserving projection was applied to the JITL modeling (Chen et al., 2011), which is capable of finding a projection vector from which both input variables and output variables can be used for similarity evaluation. However, previous local models are directly based on the relevant data. In this paper, a new strategy of locality enhancement by considering the local model as a Taylor series of the global model expanded around a reference point, which can be selected as the most relevant data or query data, is explored and applied to the JITL modeling.

2. Conventional Just-in-Time Learning Techniques

Suppose the relationship between the input $\mathbf{x} = [x_1, x_2, \ldots x_M]^T$ and output y is $y = f(\mathbf{x})$; and an available reference database given by $\boldsymbol{\psi} = [y_i, x_{i,1}, x_{i,2}, \ldots x_{i,M}]_{N\times(M+1)}$, where $i = 1, \cdots, N$, N is the number of sample data, and M is the number of input variables. In what follows, JITL method based on distance and angular metrics (Cheng and Chiu, 2004) is briefly reviewed.

When a query data $\mathbf{x}_q = [x_{q,1}, x_{q,2}, \ldots x_{q,M}]^T$ comes, the distance and angular metrics are calculated by Eqs. 1 and 2, respectively. The similarity index, S_i, between ith data in

the reference database and the query data is calculated by these two metrics as given in Eq. 3, with $0 \leq \gamma \leq 1$ as a tuning parameter.

$$d_i = \left\|\mathbf{x}_i - \mathbf{x}_q\right\|_2 \tag{1}$$

$$\cos(\theta_i) = \frac{\Delta\mathbf{x}_i^{\mathrm{T}}\Delta\mathbf{x}_q}{\|\Delta\mathbf{x}_i\|_2 \cdot \|\Delta\mathbf{x}_q\|_2}, \quad \Delta\mathbf{x}_i = \mathbf{x}_i - \mathbf{x}_{i-1} \tag{2}$$

$$S_i = \gamma\sqrt{\mathrm{e}^{-d_i^2}} + (1-\gamma)\cos(\theta_i) \tag{3}$$

After the selection of k ($k_{min} \leq k \leq k_{max}$) relevant sample data, linear or nonlinear regression model is trained accordingly, by which the prediction is made.

3. Locality-enhanced Just-in-Time Learning

It is worth to note that the aim of JITL methodology is to find a local model around the query data and make a prediction accordingly. Hereby, if the local model can be built directly at the query data, its prediction would theoretically be much more accurate than the conventional local model that is constructed directly based on the relevant dataset. In light of this, the strategy of locality enhancement by considering the Taylor series expanded at the reference point as the local model is explored in this study.

In reference to an arbitrary point, $(a_1, \cdots, a_M)$, the process model can be represented by the Taylor series as an infinite sum of terms with coefficients calculated by the corresponding derivative at this particular point as follows:

$$f(x_1, \ldots, x_M) = \sum_{n_1=0}^{\infty} \cdots \sum_{n_M=0}^{\infty} \frac{(x_1-a_1)^{n_1} \cdots (x_M-a_M)^{n_M}}{n_1! \cdots n_M!} \left(\frac{\partial^{n_1+\cdots+n_M} f}{\partial x_1^{n_1} \cdots \partial x_M^{n_M}}\right)(a_1, \cdots, a_M) \tag{4}$$

where n_i is the order of derivative with respect to x_i.

There are two possible choices for the reference point, the most relevant data, $\boldsymbol{\varphi}_n = [y_n, x_{n,1}, x_{n,2}, \ldots x_{n,\mathrm{M}}]^T$ or query data, $\boldsymbol{\varphi}_q = [y_q, x_{q,1}, x_{q,2}, \ldots x_{q,\mathrm{M}}]^T$. When the most relevant data is considered, the remaining relevant data could be normalized by Eqs. 5 and 6, whereas the corresponding local model is given by Eq. 7.

$$\tilde{y}_i = \frac{y_i - y_n}{y_n}, \quad i=2, \cdots, l_r \tag{5}$$

$$\tilde{x}_{i,j} = \frac{x_{i,j} - x_{n,j}}{x_{n,j}}, \quad j=1, \cdots, M \tag{6}$$

$$\tilde{y}_i = \sum_{n_1=0}^{\infty} \cdots \sum_{n_M=0}^{\infty} \frac{\tilde{x}_1^{\,n_1} \cdots \tilde{x}_M^{\,n_M}}{n_1! \cdots n_M!} \left(\frac{\partial^{n_1+\cdots+n_M} f}{\partial \tilde{x}_1^{n_1} \cdots \partial \tilde{x}_M^{n_M}}\right)(\tilde{\mathbf{x}} = \mathbf{0}),\ n_1 + \ldots + n_M \neq 0 \tag{7}$$

where l_r is the number of relevant data.

When query data is used as the reference point, the input variables could be normalized similarly using Eq. 6. As the output variable y_q is not available and therefore it is set equal to the predicted output, $\hat{y}_q$. The corresponding local model is represented by Eq. 8. Compare to Eq. 7, the local model in Eq. 8 has one more parameter, $\hat{y}_q$. As a result, the output prediction $\hat{y}_q$ is obtained while training the local model.

$$y_i = \hat{y}_q + \sum_{n_1=0}^{\infty} \cdots \sum_{n_M=0}^{\infty} \frac{\tilde{x}_1^{\,n_1} \cdots \tilde{x}_M^{\,n_M}}{n_1! \cdots n_M!} \left(\frac{\partial^{n_1+\cdots+n_M} f}{\partial \tilde{x}_1^{n_1} \cdots \partial \tilde{x}_M^{n_M}}\right)(\tilde{\mathbf{x}} = \mathbf{0}),\ n_1 + \ldots + n_M \neq 0 \tag{8}$$

For the purpose of comparison between traditional and the proposed locality-enhanced local models, a schematic illustration is provided in Fig. 1. As the proposed new strategy of locality enhancement can be readily applied to existing JITL methodologies. The JITL developed by Cheng and Chiu (2004) is used as the benchmark (JITL-OR), while the predictive performance of the resulting JITL methods taking into account of reference point chosen to be the nearest relevant data (JITL-RN) and query data (JITL-RQ), respectively, is compared in a case study presented in the next section.

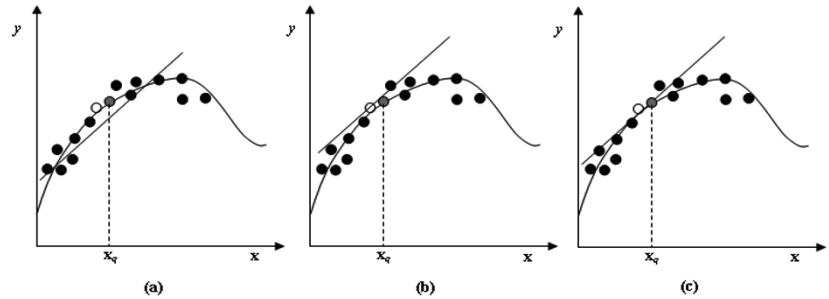

Fig. 1 Comparison of linear local model scheme: (a) JITL-OR; (b) JITL-RN; (c) JITL-RQ (● : relevant sample data; ○ : nearest relevant data; ● : query data)

4. Case Study: van de Vusse CSTR

To evaluate the proposed locality enhancement strategy, a nonlinear van de Vusse CSTR process is considered (Harris and Palazoğlu, 1998; Helbig et al., 2000). The reaction scheme is follows: $A \overset{k_1}{\rightarrow} B \overset{k_2}{\rightarrow} C$ and $2A \overset{k_3}{\rightarrow} D$. The reactor temperature T is controlled through a recirculating cooling medium in the jacket, where the medium temperature is manipulated through a heat flow Q_w. The feedstock of reactant A with concentration c_{A0} and temperature T_0 is introduced with flow rate F. The concentration of product B, c_B, is the process output which is influenced by the concentration of reactant A, c_A, and T, as well as the three process inputs, F, Q_w and c_{A0}. Five ARX local models are considered for one-step ahead prediction by the three JITL methods.

LM1 $c_B(k) = f\ [c_B(k\text{-}1), c_A(k\text{-}1), T(k\text{-}1), F(k\text{-}1), Q_w(k\text{-}1), c_{A0}(k\text{-}1)]$
LM2 $c_B(k) = f\ [c_B(k\text{-}1), c_B(k\text{-}2), T(k\text{-}1), F(k\text{-}1), Q_w(k\text{-}1), c_{A0}(k\text{-}1)]$
LM3 $c_B(k) = f\ [c_B(k\text{-}1), c_B(k\text{-}2), F(k\text{-}1), Q_w(k\text{-}1), c_{A0}(k\text{-}1)]$
LM4 $c_B(k) = f\ [c_B(k\text{-}1), T(k\text{-}1), F(k\text{-}1), Q_w(k\text{-}1), c_{A0}(k\text{-}1)]$
LM5 $c_B(k) = f\ [c_B(k\text{-}1), F(k\text{-}1), Q_w(k\text{-}1), c_{A0}(k\text{-}1)]$

To proceed to the JITL, a database containing 2000 sample data was generated by introducing random step changes in F, Q_w and c_{A0} within the ranges of ±50%, ±20%, and ±20% of their respective steady-state operating conditions, as shown in Fig. 2. The validation data was also generated in a similar fashion as shown in Fig. 3.

Each JITL method is fine tuned by choosing the parameters k_{min} and γ to give the best prediction accuracy. The results are summarized in Table 1, where RMSE represents the root mean square errors and Averaged-l_{opt} is the averaged number of relevant data selected during prediction. As k_{max} has least influence on JITL performance, k_{max} = 80 is used for all the JITL methods. It can be seen from the LM1, LM2 and LM4 cases that JITL-RN and JITL-RQ give better prediction than JITL-OR, while three JITL methods

give comparable prediction results for the LM3 and LM5 cases, where the temperature measurement is not included in the relevant data selection. Since temperature is an important variable affecting the reaction rate, advantages of the locality enhancement strategy may not be fully exploited when T is not considered in the relevant data selection. Representative prediction results using the LM2 local model are shown in Fig. 4. Furthermore, in case that relevant data are clustered near to the query data, like in LM1 and LM2 cases, fewer relevant data are utilized for the JITL with locality enhancement method, as indicated by a smaller averaged-l_{opt} in Table 1, implying that a stricter criterion on the linearity and locality around the query data, as shown in Fig. 1. Finally, as the essence of JITL-RN and JITL-RQ is similar to each other, their performance is comparable in all the tests. Based on the on-going discussions, it is evident that the proposed method indeed improves the performance of the original JITL method developed previously.

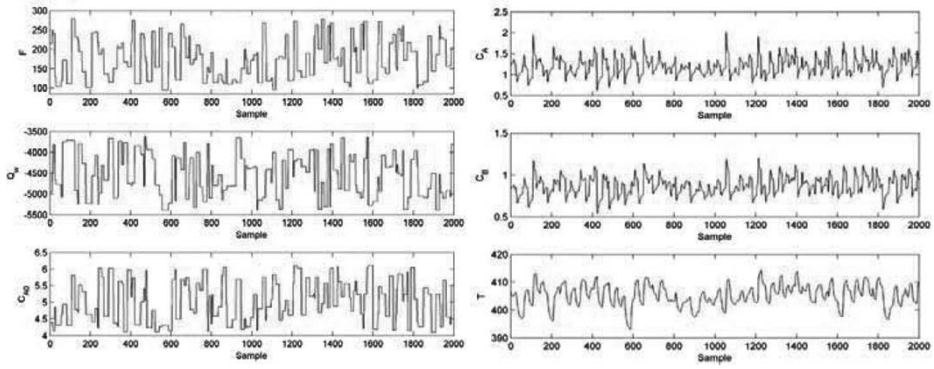

Fig. 2 Process data used to construct database for the JITL

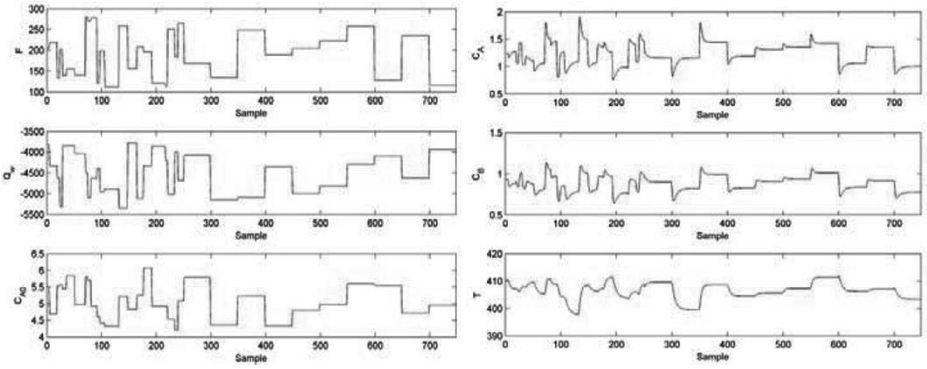

Fig. 3 Process data used for validation test

5. Conclusion

A locality-enhancement strategy for the JITL method is developed in the present study by considering the local model as a Taylor series of the global model expanded in the vicinity of the most relevant data or the query data, which focuses more on the query data rather than the whole relevant dataset. A comparative study using the van de Vusse CSTR process shows the efficacy of the proposed strategy by improving prediction accuracy compared with the conventional JITL method.

Hybrid Dynamic Modeling of 4-CBA Hydrogenation Fixed-Bed Catalytic Reactor of PTA Production Plant

Abbas Azarpour, Gholamreza Zahedi

Process Systems Engineering Centre (PROSPECT), Faculty of Chemical Engineering, Universiti Teknologi Malaysia, UTM Skudai, 81310 Johor Bahru, Johor, Malaysia

Abstract

In this paper, a dynamic hybrid model of 4-carboxybenzaldehyde (4-CBA) hydrogenation fixed-bed catalytic reactor of Purified Terephthalic Acid (PTA) production plant has been developed. At the first step, the deactivation model of the reaction system has been predicted by using artificial neural network (ANN) technique. Then, the deactivation model estimated by ANN as black box incorporated to first principle model (FPM) as white box. Therefore, the established hybrid model has been utilized to model the hydrogenation reactor of PTA plant. Finally, the simulated results have been compared with the industrial reactor data. It has been concluded that hybrid model is more precise than a FPM model.

Keywords: Terephthalic acid, hydrogenation, 4-carboxybenzaldehyde, hybrid modeling, deactivation.

1. Introduction

Purified terephthalic acid (PTA) is one of the most important chemicals as the major raw material to synthesize polyethylene terephthalate. Commercially, it is produced by the well-established process developed by the American Amoco Group. In this process, p-xylene (PX) is oxidized by air. The outlet main component of oxidation reactor which is called crude terephthalic acid (CTA) includes about 3000 ppm of 4-carboxybenzaldehyde (4-CBA) and 500 ppm of para-toluic acid (pta) as impurities. Since the amount of impurities is too high for polymerization, CTA is hydrogenated in a fixed-bed reactor (FBR) including carbon coated palladium (Pd/C) catalyst to convert the major impurity, 4-CBA, to pta. The final purified terephthalic acid contains less than 25 ppm of 4-CBA and 150 ppm of pta.

Several reports on modeling of fixed-bed reactors have been published with the aim of understanding the overall reactor performance and comparison of the predictions with experimental data among others (Goto & Smith, 1975; Levec & Smith, 1976; Herskowitz, 1985; Rajashekharam et al., 1998; Nijhuis et al., 2003; Bhaskar, 2004; Murali et al., 2007).

Shaogang et al. (2008) studied the mass transfer characteristics of the fixed-bed reactor for hydrorefining of terephthalic acid. They developed a steady state heterogeneous one-dimensional model of the reactor.

Hybrid model or gray box model (GBM)is a combination of first principle model (FPM) as white box and artificial neural network (ANN)as black box.

In this study, a hybrid model of the reactor performance consisting of FPM and the model predicting the deactivation behavior of the catalyst bed relied on ANN has been developed for the industrial fixed-bed reactor of PTA production plant. In hybrid model,

the catalytic hydrogenation reaction of 4-CBA in the three-phase reactor along with the deactivation of Pd/C catalyst implying the dynamic behavior of the system has been analyzed. A heterogeneous plug-flow model has been devised. This model is able to predict the trend of the Pd/C catalyst deactivation and components concentration distribution. Finally, the results of the dynamic model have been compared with the industrial data.

2. Hybrid Modeling of PTA Hydrogenation Reactor

In hydrogenation reactor, the feed is concurrently contacted with highly pressurized hydrogen from the top and they pass through a catalytic fixed-bed including Pd/C. Therefore, the main impurity of CTA naming 4-CBA is hydrogenated to pta.

2.1. First Principle Modeling

To develop a simplified dynamic model of the reactor for describing the hydrogenation reactions, it has been assumed that the reactor operates under unsteady state and isothermal conditions. Moreover, the chemical reactions take place on the surface of the catalyst particles. A plug flow behavior of gas and liquid phases in axial direction along the reactor has been developed. Generalized power law has been used to present the deactivation model in FPM (Bartholomew, 2001). This model is able to predict the concentration of the reaction components and the weakness of catalytic potentiality of Pd/C catalyst.

2.1.1. Reactions

Hydrogenation reaction of 4-CBA is a two-step process. At the first step, 4-CBA is hydrogenated to 4-hydroxymethylbenzoic acid (4-HMBA) which eventually converts to pta (Zhou et al., 2006). The following reactions show the mentioned steps:

$$C_8H_6O_3\,(4-CBA) \quad + \quad H_2 \xrightarrow{Pd/C} C_8H_8O_3(4-HMBA) \tag{1}$$

$$C_8H_8O_3\,(4-HMBA) + \quad H_2 \xrightarrow{Pd/C} C_8H_8O_2\,(pta) \; + \; H_2O \tag{2}$$

The kinetic rate equations of the reactions are following:

$$r_1 = k_{\circ_1} \exp\left(-\frac{E_1}{RT}\right) C_{4-CBA}^{0.96}\, C_{H2}^{0.24} \tag{3}$$

$$r_2 = k_{\circ_2} \exp\left(-\frac{E_2}{RT}\right) C_{4-HMBA}^{0.61}\, C_{H2}^{0.75} \tag{4}$$

where $k_{\circ_1}$ and $k_{\circ_2}$ are 0.04738 $\frac{m^{3.6}}{kmol^{0.2}.s.kg}$ and 0.15272 $\frac{m^{4.08}}{kmol^{0.36}.s.kg}$, respectively, and E_1 and E_2 are 16976.4 $\frac{kJ}{kmol}$ and 23438.6 $\frac{kJ}{kmol}$, correspondingly (Shaogang et al., 2008).

2.1.2 Mass Conservation

Mass balance for Hydrogen in gas phase is:

$$\varepsilon_g \frac{\partial C_{H_2,g}}{\partial t} = -u_g \frac{\partial C_{H_2,g}}{\partial z} - K_{H_2,gl} a_{gl} \left(\frac{P_{H_2}}{H_{H_2}} - C_{H_2,l}\right) \tag{5}$$

Mass balance for Hydrogen in liquid phase is:

$$\varepsilon_l \frac{\partial C_{H2,l}}{\partial t} = -u_l \frac{\partial C_{H2,l}}{\partial z} + K_{H_2,gl} a_{gl} \left(\frac{P_{H2}}{H_{H2}} - C_{H2,l} \right) - k_{H_{2,ls}} a_{ls} (C_{H2,l} - C^S_{H_2,s}) \quad (6)$$

Mass balances for other components are:

$$\varepsilon_l \frac{\partial C_{i,l}}{\partial t} = -u_l \frac{\partial C_{i,l}}{\partial z} - k_{i,ls} a_{ls} (C_{i,l} - C^S_{i,s}) \quad (7)$$

The components transported between liquid and solid phases are consumed or produced by the chemical reaction at the surface of the catalyst, according to the following differential equations:

$$\varepsilon_p (1 - \varepsilon_B) \frac{\partial C_{i,s}}{\partial t} = k_{i,ls} a_{ls} (C_{i,l} - C^S_{i,s}) \pm \sum_{j=1}^{2} r_j \eta_j \rho_B a \quad (8)$$

The following boundary and initial conditions have been considered to solve the model.

Initial Conditions:

For t = 0 at z = 0 $C_{i,g} = C^0_{i,g}$; i is hydrogen.

$C_{i,l} = C^0_{i,l}$; i are 4-CBA, 4-HMBA, pta.

$C_{i,s} = C^0_{i,s}$; i are 4-CBA, 4-HMBA, pta.

For t = 0 at z > 0 $C_{i,g} = C^{ss}_{i,g}$; i is hydrogen.

$C_{i,l} = C^{ss}_{i,l}$; i are 4-CBA, 4-HMBA, pta.

$C_{i,s} = C^{ss}_{i,s}$; i are 4-CBA, 4-HMBA, pta.

Boundary Conditions:

For t > 0 at z = 0 $C_{i,g} = C^0_{i,g}$; i is hydrogen.

$C_{i,l} = C^0_{i,l}$; i are 4-CBA, 4-HMBA, pta.

$C_{i,s} = C^0_{i,s}$; i are 4-CBA, 4-HMBA, pta.

a is the deactivation parameter of the system.

2.2 ANN Modeling

In this study, deactivation model has been derived by employing Artificial Neural Network. To train the network, Levenberg-Marquardt training algorithm was found to be suitable to estimate the deactivation parameter of the catalyst.

Time, and the concentrations of hydrogen, 4-CBA, 4-HMBA, and pta were the inputs of the ANN and the deactivation parameter was its output.

3. Hybrid Model

Hybrid or GBM model which is a combination of FPM and ANN was used to simulate the reactor. The hybrid model is able to predict the concentration values of the components and the deactivation trend of the catalyst.

4. Results and Discussions

Fig. 1 displays the profile of the concentration of reaction mixture components in the catalytic reactor. It can be realized that the concentration of pta increases continuously whilst the concentration of 4-CBA decreases along the bed. Moreover, concentration of 4-HMBA reaches at the maximum value and then reduces to the end of the bed.

Fig. 2 shows the reduction of hydrogen in solid phase through the bed. It can be figured out that the consumption of hydrogen is notable at the early parts of the bed.

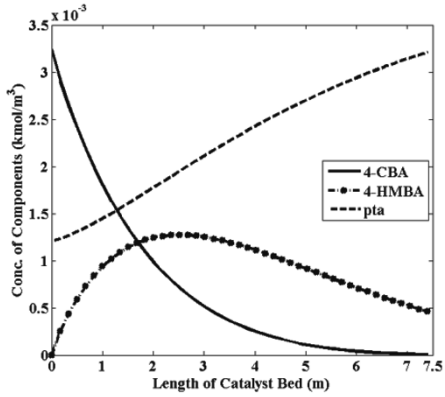

Fig. 1: Concentration profile of reaction components through the catalyst bed based on GBM.

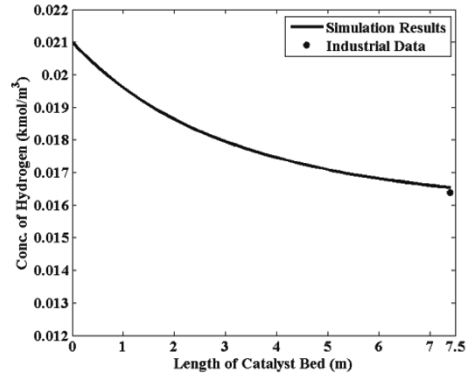

Fig. 2: Concentration profile of hydrogen through the catalyst bed based on GBM.

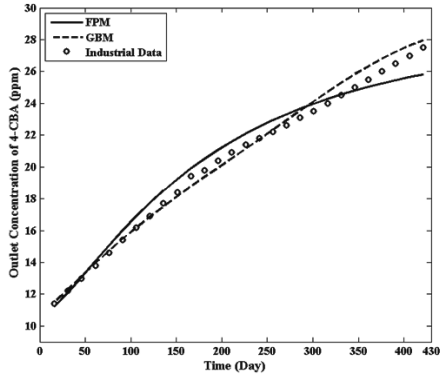

Fig. 3: Comparison of FPM and GBM with the industrial data based on the main impurity of PTA (4-CBA)

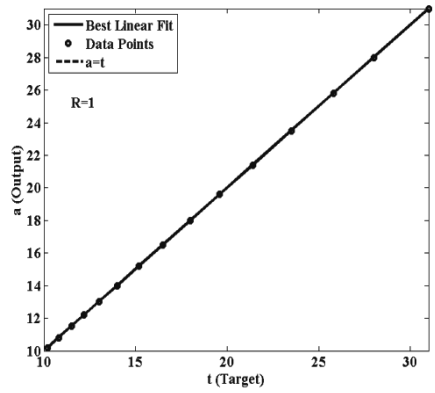

Fig. 4: ANN training regression for deactivation model

Fig. 3 compares the results of FPM with Hybrid model. It can be implied that the hybrid model is more precise than FPM.

Fig. 4 depicts the performance of the ANN which has been used for the deactivation model prediction. It is clear that the used network is very powerful to predict the required values of the deactivation model. To train the data, Levenberg-Marquardt algorithm has been employed with 70 neurons in the hidden layer.

5. Conclusion

In this paper, modeling of hydrogenation reactor of PTA plant has been carried out using gray box modeling technique. The gray box model incorporates both the ANN (black box) model and first principle (white box) model. To validate the devised gray box model, its prediction ability has been compared with the industrial reactor data. It has been concluded that the performance of gray box model is more precise than first principle model.

Abbreviations

C_i	concentration of component i (kmol/m^3)
E_j	activation energy of reaction j (kJ/kmol)
H	Henry's constant (barg.m^3/kmol)
$k_{\circ 1}$	frequency factor of reaction 1 (m$^{3.6}$/kmol$^{0.2}$.s.kg)
$k_{\circ 2}$	frequency factor of reaction 2 (m$^{4.08}$/kmol$^{0.36}$.s.kg)
$K_{i,gl}a_{gl}$	gas-liquid mass transfer coefficient of component i (1/s)
$K_{i,ls}a_{ls}$	liquid-solid mass transfer coefficient of component i (1/s)
P_i	partial pressure of component i (barg)
r_j	rate of reaction j (kmol/s.kg)
t	time (s)
T	temperature (K)
u_g , u_l	superficial velocity of gas and liquid (m/s)
Greek letters	
ε_B	bed void fraction (-)
ε_P	particle porosity (-)
ε_g	gas phase holdup (-)
ε_l	liquid phase holdup (-)
η_j	catalyst effectiveness factor (-)
ρ_B	bulk density (kg/m^3)

Integrated Model-Based Support for the Design of Complex Controlled Systems

Martin Hüfner, Stephan Fischer, Christian Sonntag, Sebastian Engell

Process Dynamics and Operations Group, Department of Biochemical and Chemical Engineering, Technische Universität Dortmund, 44221 Dortmund, Germany

Abstract

In the model-based design of industrial controlled processes, many design data artifacts are generated, such as a variety of models in different formalisms, design-related documentation, and design parameters. This leads to several challenges: The use of model-based tools in each stage often requires remodeling due to incompatibilities of the employed model formalisms. This is costly and error-prone and may result in inconsistencies. Inconsistencies within the design data set can also arise due to the complex interdependence of design artifacts, leading to design errors that are often only detected late in the design process or even after commissioning. This paper illustrates the use of a software-based *Design Framework* for model-based design that was developed recently within the European project *MULTIFORM* (*www.ict-multiform.eu*). The goal of the *Design Framework* is to reduce the design effort, and thus the cost, while improving the quality of the designed system by *consistently integrating* the artifacts and tools that arise in model-based design processes. The set of model-based tools that can be applied in each design stage is expanded by automated model transformations via the general model exchange format *CIF* (http://se.wtb.tue.nl/sewiki/cif). To ensure that design inconsistencies and errors are detected as early as possible (i.e. when it is relatively cheap to correct them), the framework provides structured data and model management capabilities as well as automated design consistency checking and design parameter propagation. The framework is illustrated using a challenging case study, the model-based design of a pipeless plant, which employs many of the capabilities of the framework.

Keywords: Model-based design, Design support, Model exchange, Tool integration, Pipeless plants, Design consistency.

1. Introduction

The model-based design of complex systems and their control systems offers many advantages over traditional design methodologies, because it leads to shorter durations of the design process, increased reliability, and a more economical operation of the system. In recent years, sophisticated methods and tools have been developed for all stages of the design of controlled systems, ranging from requirement analysis and simulation to automatic controller synthesis and verification of the implementation of the control software. Although many of these model-based methods and tools are already used for specific tasks in industrial design projects, several challenges have to be solved to enable *integrated model-based design* in industry. The efficiency of the design process as well as the quality of the designed system crucially depend on the consistency of the design data set throughout the design process, since errors due to inconsistent design parameters or misunderstandings are costly if they are detected late in the design process. In addition, the manual management and adaptation of the design documentation, the design parameters, and of the variety of models present in modern

industrial design projects leads to duplications of work, is error-prone, and increases the duration (and thus the cost) of the design cycle. To overcome these challenges, a *Design Framework* (DF) for consistent integrated design with model-based tools has been developed in the European research project *MULTIFORM* (MULTIFORM (2008-2012)), with the Embedded Systems Institute (ESI) in Eindhoven, the Netherlands, as the main contributor (http://df.esi.nl). This framework supports a wide range of different design flows, enables the automated exchange of models between different design and analysis tools, provides design data and model management facilities, and enables a consistent representation and propagation of design parameters, including the detection of design conflicts (see Moneva et al. (2010) for more information on the DF). In this paper, the capabilities of the *Design Framework* are presented using a challenging case study, the model-based design of a pilot-scale chemical pipeless plant.

2. The Pipeless Plant

The pipeless plant (see Fig. 1) is a pilot-scale demonstration process that provides design and control challenges on different levels of the control and design hierarchies (which are also relevant in industrial design processes). It employs filling stations that feed colored water to mobile vessels. After filling, the vessels are transported by *Automated Guided Vehicles* (AGVs) to a mixing station, where plaster is added and the compound is mixed. The vessels are then transported to a storage station, where the plaster layer hardens. Several cycles of this process can be executed to obtain individually colored pieces of "plaster art". A central computer is responsible for the overall scheduling and control of the plant, while local controllers are installed on the hardware of the AGVs and of the stations. The movement of the AGVs is tracked by a camera. This flexible and dynamic production environment demands a design approach that is different to that used for traditional chemical plants, as the throughput in a pipeless plant depends not only on the production capacities, but also on their time-optimal usage. Although the chemical processes still have to be considered, the focus lies on the scheduling of the recipe steps, the coordination of the AGVs (path planning, collision avoidance, and docking control) and on a multitude of low-level control tasks. In this work, most of the design tasks are solved using model-based techniques within the *Design Framework*.

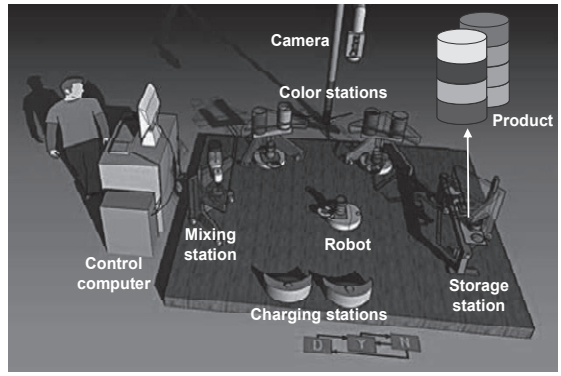

Fig. 1 Scheme of the pipeless plant.

3. The *Design Framework*

The *Design Framework* structures the overall *Design Flow* (see upper part of Fig. 2) into a number of *Design Steps* (DS), which represent the current design stage, and a number of *Design Decisions* (DD). While the *Design Flow* concept of the DF is generic and can be adapted to arbitrary design processes, the model-based design approach employed here follows the top-down approach that has been established in industrial practice. It starts with abstract models of the complete system that are used to roughly estimate the performance that can be expected from the chosen system structure, and to identify critical design problems and potential bottlenecks. In subsequent design steps,

these problems, and the system itself, are investigated and designed in more detail using refined models. To structure the plethora of design information that arises in such a design flow, each *Design Step* employs one or more *Design Views* (center part in Fig. 2), each representing a specific view on the system, e.g. structural composition or control systems hierarchy. The views are structured using *System Blocks* that may contain arbitrary design information, such as documents or models at different levels of abstraction. As different model types (possibly using different formalisms) are often employed in practical design processes, the DF provides a low-level integration and model exchange framework for the tools required in a design process. It currently supports many model-based engineering tools such as *UPPAAL* (Larsen et al (2010)), *Matlab/Simulink*, *Modelica* (MA (2011)), *gPROMS* (PSE (2011)), and *EcosimPro* (Jorrín et al. (2008)), as well as text processing tools. The exchange of models between different formalisms is achieved by automatic model transformations, enabling the designer to use the best tool for a given task. To store design information and parameters, the DF employs *System Parameters*, whose values can be propagated between the different models and design layers and whose consistency is monitored by the DF. Consistency and traceability is in addition facilitated by *Experiments* that store the parameters (i.e. the inputs, tools, tool parameters, models, and results) of any tool execution within the DF (see lower part Fig. 2). These *Experiments* can be reused, and their input parameters and results can directly be obtained from / stored in *System Parameters*.

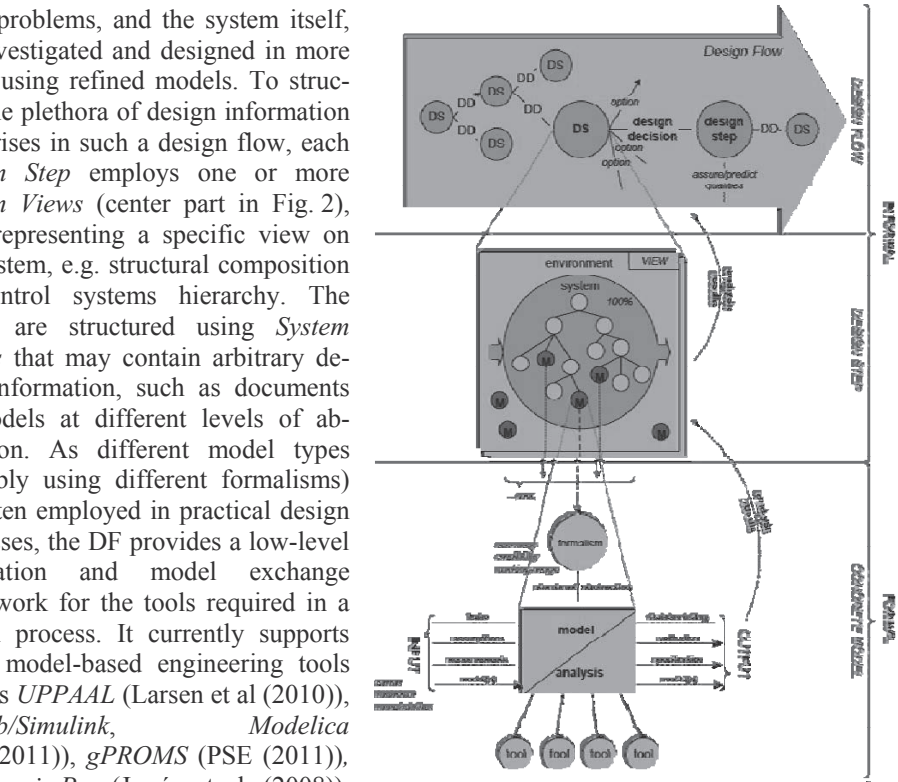

Fig. 2 Conceptual model of the *Design Framework* [2].

4. Model-based Design of the Pipeless Plant

Fig. 3 shows the design process that was developed for the pipeless plant in the *Design Framework*. The design flow starts with the ***Requirement Specification*** in which the requirements are collected and key design drivers are developed. In this step, a requirement view is created that contains a single system block that stores design parameters, such as the number of stations, the size of the plant area, the positions of the stations, and the desired throughput. In this stage, the values of these *Design Parameters* are roughly estimated since detailed information of these properties is not yet available.

In the step ***Layout Design***, rigorous model-based design based on the chosen parameters is started. A new *Design View* is created that contains a system block for the complete plant, which in turn contains sub-blocks for AGVs, the stations, and the plant area size. The design parameters from the requirement step are distributed to these new blocks, as shown in Fig. 3. In this step, the number and positions of stations and AGVs that will

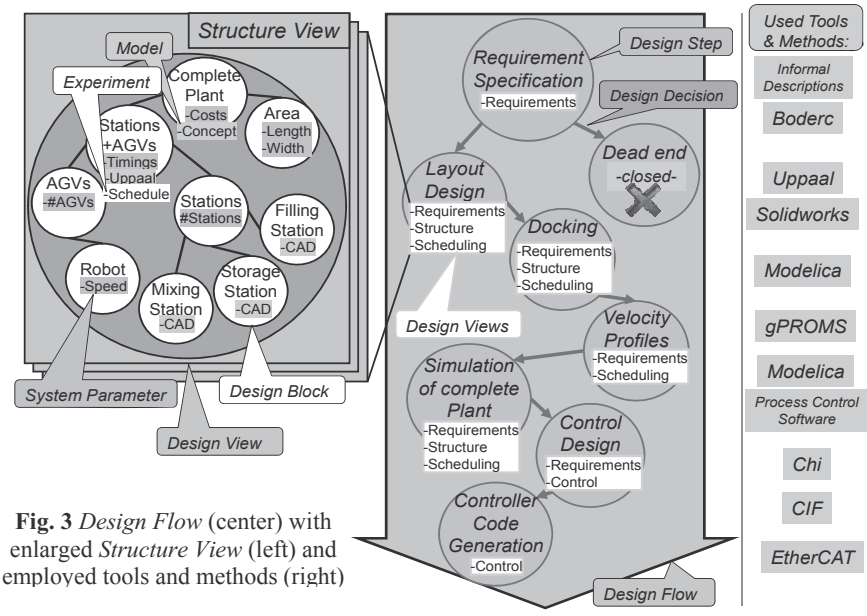

Fig. 3 *Design Flow* (center) with enlarged *Structure View* (left) and employed tools and methods (right)

provide the demanded throughput at minimal cost is determined using abstract plant models with timed dynamics, in which the durations of all plant activities are estimated based on tests at existing hardware. Then, the tool *UPPAAL* is used to derive optimal schedules for different plant configurations. All experiments are executed using parametrizable DF *Experiments*, and the results are stored in the DF database. After a suitable plant layout has been determined, its parameterization is stored in the DF parameter set (or existing parameters are updated)[1].

In the third step, the ***Docking Maneuver*** of the AGVs is explored in more detail, as it is a critical part in the operation in the plant that might have a strong impact on the throughput. To this end, a detailed spatial hybrid docking model based on differential-algebraic equation (DAE) systems is developed in *Modelica*. The results of this design step indicate that the initially assumed parameter values are valid.

To avoid the spilling of liquid during vessel transportation, in the fourth step the acceleration profiles of the AGVs are investigated. A detailed PDE *gPROMS* model of the liquid in the vessels is created, and the *gPROMS* optimization facilities are used to determine the maximally allowable acceleration of the AGVs to avoid spilling of the liquid, which also leads to the realization that the docking must be done more carefully than previously determined. Thus, the *Modelica* docking model is adapted with these results and is re-evaluated. The resulting longer docking time is propagated to the high-level *UPPAAL* model, and the scheduling *Experiment* is re-evaluated providing new values in the *Modelica* and *gPROMS* models. This circle is repeated until a fixed point of the system parameters is reached. In the fifth design step (***Simulation of Complete Plant***), a detailed plant model is created based on the design parameters determined in the previous steps, and the operation schedule determined in step 2 is validated on the detailed model, again leading to iterations through the design process in which the durations considered in the timed models used for scheduling are updated according to the

[1] Note that if any new parameter values conflict with other parts of the design, or if they invalidate previous experiment results, the consistency mechanism will notify the designer of these potential inconsistencies.

simulation results. All of the parameter propagations, experiment executions, and the design information management are handled by the *Design Framework*, ensuring a consistent design process documentation and a time-efficient design process.
After the high-level design steps, the low-level controllers are designed in the steps ***Control Design*** and ***Controller Code Generation*** using tools based on *Chi* (a process-algebraic modeling language, van Beek et al. (2008)) and *CIF* (an interchange format for hybrid systems, van Beek et al. (2009)) . The models for these steps can (partly) be transformed from the existing *UPPAAL* model via the DF, making manual model recoding mostly obsolete (Nadales et al. (2011)). The *Chi*/*CIF*-based tools employed here support the automatic generation of supervisory low-level controllers for the processing stations that can directly be connected to the pipeless plant via the *EtherCAT* protocol.

5. Conclusions and Future Work

This paper illustrates on a realistic case study that integrated software-supported model-based design can significantly speed up the design process compared to traditional design methodologies, as many of the previously manually executed tasks can be automated. In addition, it provides controlled processes of higher quality, since the integration ensures that design errors are detected very early. In future work, we will improve on the design process (e.g. by using correctness verification using tools such as *SpaceEx* (Frehse et al. (2011)) and *[mc]square* (Schlich & Kowalewski (2006)), and we are building a pipeless plant demonstrator based on the design presented in this paper.

Abstract

The oxidation of sulfur dioxide over vanadium pentoxide catalysts represents a basic step in the sulfuric acid production process. In conventional sulfuric acid plants the SO_2 oxidation represents the limiting step with respect to the SO_2 emissions. Due to the fact that the SO_2 oxidation is an equilibrium reaction, sulfuric acid plants always have SO_2 emissions. In this work, a new process concept is presented, which uses the transient behaviour of the reaction in two reactors operating under unsteady conditions (**S**aturated **M**etal **P**hase reactor). Besides several advantages, which can increase the efficiency of the whole sulfuric acid process drastically, the SMP Reactor is a key component for an efficient operation of a sulfuric acid plant which reduces the emissions down to zero while keeping the necessary conditions for the hydrogenation unit installed downstream. For this purpose, a mathematical model is used, which describes the dynamic effects of the SO_2 oxidation. The model has been experimentally verified in a Miniplant, which works with commercial catalyst pellets.

Keywords: sulfur dioxide oxidation, unsteady state, sulfuric acid production

1. Introduction

Vanadium pentoxide based catalysts for the oxidation of sulfur dioxide to sulfur trioxide are some of the best investigated catalysts in heterogeneous catalysis. Due to the fact that sulfuric acid is one of the most important chemicals and sulfur dioxide oxidation is the basic step of the production process, research on the oxidation catalyst has been conducted for almost 40 years. Because of the equilibrium limited character of the reaction ($SO_2 + ½\ O_2 <-> SO_3$), it is impossible to reduce the SO_2 emissions down to zero at standard operating temperatures.

Investigations about the dynamic behavior of the reaction by Boreskov and Matros [1] observed a change of the catalyst structure depending on the exposed gas mixture. Also, several authors observed different behavior of the reaction between dynamic and steady state operation [1-4]. In our previous experimental kinetic studies, Schöneberger [4] observed a peak of the reaction rate whenever the catalyst is first exposed to oxygen and then to the reaction mixture that contained oxygen and sulfur dioxide. A reaction network that describes the whole catalytic cycle can explain this behavior [1]. The usage of the additional dimension of time gives the possibility to achieve a super-equilibrium which is limited by the equilibrium of one specific partial reaction in the catalytic cycle, which is then positioned far at the product side.

In the context of coking plant gas treatment, a new sulfuric acid process concept without any emissions is proposed. In this process concept, the sulfur dioxide in the sulfuric acid plant rest gas is hydrogenated to hydrogen sulfide and then recycled in the coking plant gas treatment. The use of a transient working oxidation is a promising process

alternative in order to meet the restrictions of sulfur dioxide and oxygen content in the hydrogenation reactor and the recycle gas.

2. Emission free sulfuric acid process

The simplified process concept of a classical wet sulfuric acid process in the context of coking plant gas treatment contains three basic unit operations. First, the H_2S in the sour gas is oxidized in a combustion unit to SO_2. In the following process step the SO_2 is oxidized to SO_3 over a vanadium pentoxide based catalyst. In a last step, the SO_3 is absorbed with water to H_2SO_4. The offgas of the limiting process step of the SO_2 oxidation in the vanadium pentoxide catalyst filled fixed bed reactor always contains SO_2 because of an incomplete conversion of the equilibrium reaction.

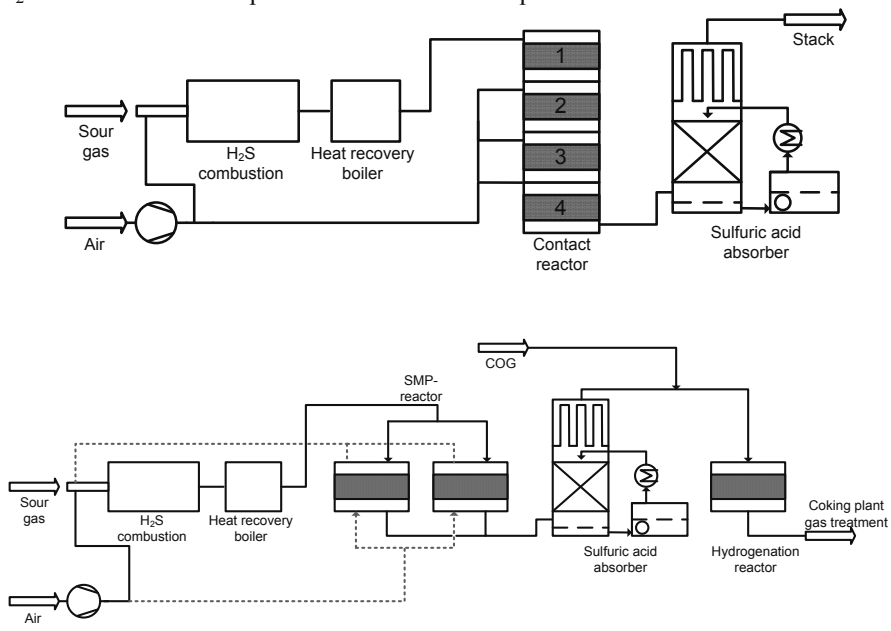

Fig. 1. Sulfuric acid plant and emission free sulfuric acid plant with SMP-reactor

In the emission free sulfuric acid plant this SO_2 will be hydrogenated completly to H_2S (SO_2+3H_2 <-> H_2S+2H_2O). Because of the intolerance of the hydrogenation reactor to high oxygen concentrations in the process gas stream, it is necessary to optimize the oxidation reactor. To achieve an oxygen free outlet stream of the oxidation reactor, the SMP reactor is implemented, which uses the transient behavior of the reaction. This effect is based on the fact that vanadium pentoxide exists as a liquid metal phase at operation temperature. In this liquid metal phase, oxygen is chemisorpt. However, in the steady state operation, this partial reaction (Eq. 3) represents the limiting step. By passing only oxygen across the catalyst, for instance in form of air, the oxygen accumulates. The oxidation is initiated by feeding the reactor with a reaction mixture (SO_2, O_2, N_2). Thereafter, the rate limiting reaction changes into another much faster reaction (Eq. 1 or Eq. 2) for the time of oxygen excess. Thus, much higher reaction rates are possible during this period. With a proposed two reactor concept, one reactor oxidizes the SO_2 in the process gas, while the other reactor is saturated with oxygen. In Fig. 1, a conventional and an emission free sulfuric acid process is shown in

comparison. In the conventional process the sour gas is oxidized hyper-stoichiometrically to set the oxygen concentration for the first bed of the oxidation reactor. In the next beds, quench air is used to set the optimal temperature and reach a higher conversion. After the sulfuric acid absorber, the rest gas is realeased into the environment via a stack. In the emission free sulfuric acid process the sour gas is oxidized nearly stoichiometrically. Behind the heat recovery boiler, the SMP reactor oxidizes the SO_2 to SO_3 with a drastically increased reaction rate compared to the steady state process. Because of the oxygen free reactor inlet stream, an oxygen free reactor outlet stream is realized, which meets the requirements of the hydrogenation unit that is installed downstream. In the oxygen saturation halfcycle, the reactor outlet stream contains decreased oxygen content because of the chemisorption of the oxygen at the catalyst. The oxygen reduced process gas stream is fed into the combustion to lower the combustion temperature and reduce NOx formation. Behind the sulfuric acid absorber coke oven gas is mixed into the gas stream so as to provide the hydrogen for the hydrogenation reaction. The process gas is fed into the hydrogenation reactor which hydrogenates the SO_2 and the remaining O_2 to H_2S and H_2O. The process concept of the emission free sulfuric acid plant can generally be applied to every sulfuric acid process. However, in the context of coking plant gas treatment it is very efficient because scrubbers for H_2S containing gas streams are already in place and the offgas stream of the emission free sulfuric acid process can easily recycled into the coking plant gas treatment.

3. Model and numerical methods

For the simulation of the SMP process, the model needs to represent the dynamic behavior of the reaction. A model based on the overall reaction of the SO_2 oxidation (SO_2 + ½ O_2 <-> SO_3) does not consider the intermediate forms of the vanadium catalyst. The SO_2 oxidation takes place in a liquid metal phase [6] with the active species. Hence, besides interphase mass transfers, the reactions inside the metal phase have to be taken into account. Balzhinimaev [6] postulates the catalytic cycle with vanadium intermediates as follows:

$$V_2^{5+}O_2^{2-} + SO_2 \leftrightarrow V_2^{5+}O^{2-} + SO_3 \qquad \Delta_R^h = 42\ kJ/mol \qquad (1)$$

$$V_2^{5+}O^{2-} + SO_2 \leftrightarrow V_2^{5+}SO_3^{2-} \qquad \Delta_R^h = 80\ kJ/mol \qquad (2)$$

$$V_2^{5+}SO_3^{2-} + O_2 \leftrightarrow V_2^{5+}O_2^{2-} + SO_3 \qquad \Delta_R^h = 63\ kJ/mol \qquad (3)$$

$$2SO_2 + O_2 \leftrightarrow 2SO_3 \qquad (4)$$

$$V_2^{5+}SO_3^{2-} \leftrightarrow V_2^{4+} + SO_3 \qquad \Delta_R^h = -42\ kJ/mol \qquad (5)$$

The capacity for the absorption of SO_2, O_2, and SO_3 in the melt is described by Henry's law because of the high adsorption velocity. The reaction rates are described by the law of mass action proposed by Bunimovich [5].

The reactor model has been implemented as a heterogeneous and transient process model of a fixed bed reactor, which considers the gas phase and the catalyst phase separately. This modeling approach is necessary to display the components of the mobile phase (SO_2, O_2, SO_3) and of the immobile phase (SO_2, O_2, SO_3, $V_2^{5+}SO_3^{2-}$, $V_2^{5+}O_2^{2-}$, V_2^{4+}, $V_2^{5+}O^{2-}$). Furthermore, it makes sense for dynamic simulations to consider the delaying effects of the interphase mass and energy transfer. According to changes in the steady state solution, they have great impact on the dynamic solution [4].

The parameters assumed by Balzhinimaev et al. [6] could not be used because of working with real catalyst and not powdered catalyst like in common kinetic investigations. The deviation is assumed to be due to transport limitations, modified catalyst compositions, and different experimental conditions. The kinetic parameters are estimated with the measurement data from the miniplant as per description in [4]. The effort has to be made for each catalyst, which is used for dynamic processes, provided that reliable predictions shall be achieved.
For the numerical calculation, the model is discretised with finite differences along the spatial coordinate. The temporal coordinate is solved by a multistep solver using Backward Differential Formulas (BDF). Because of the finite differences discretisation in space, the jacobian matrix is very sparse and has a bandstructur. Therefore, the ODE solver works with a sparse jacobian matrix, which makes it much more efficient.

4. Experimental set up and process synthesis

To reduce development time for the new process, a methodology [4] is used which skips the estimation of kinetics in a lab, which is carried out in conventional approaches. The experimental data was obtained by a miniplant which works with commercial catalyst pellets directly. Hence, the generated data could be used for industrial reactor design. After the model validation in the pilot plant at the TU Berlin under ideal conditions, the involved reactions are to be investigated with real process streams parallel to the real process. Fig. 2 shows the experimental set up and the mobile miniplant for investigation of heterogeneous catalysts under industrial conditions.

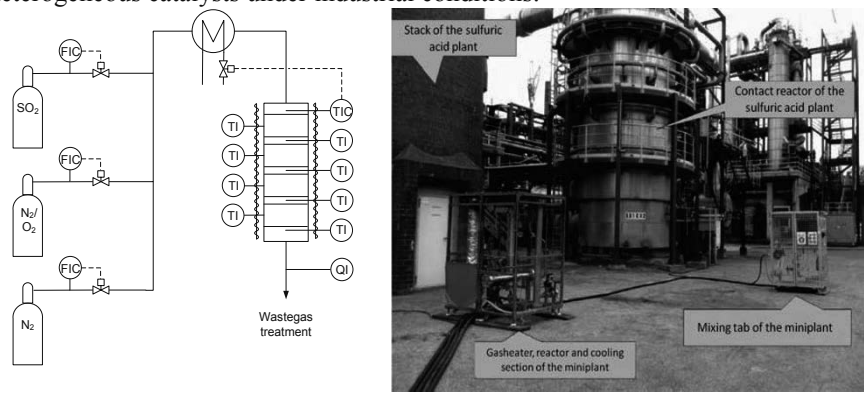

Fig. 2. Experimental set up for kinetic investigations of the sulfur dioxide oxidation and the mobile miniplant for reaserch under real plant conditions

5. Results and discussion

The obtained data is used for model validation and estimation of the kinetik parameters. Fig. 3 (left) shows the comparison between the temperature measurement behind each reactor bed and the corresponding simulation results. Each reactor bed has the same height such that measurement points are equidistantly distributed along the reactor. The reactor inlet stream contains SO_2, O_2, and N_2. Before the reaction starts, the reactor is heated up with air, which saturates the catalyst with oxygen. From t=0s to t=1500s, an increased reaction rate can be observed. During this periode a nearly sulfur dioxide and oxygen free reactor outlet stream is present. At t=3000s the steady state operation has been established.

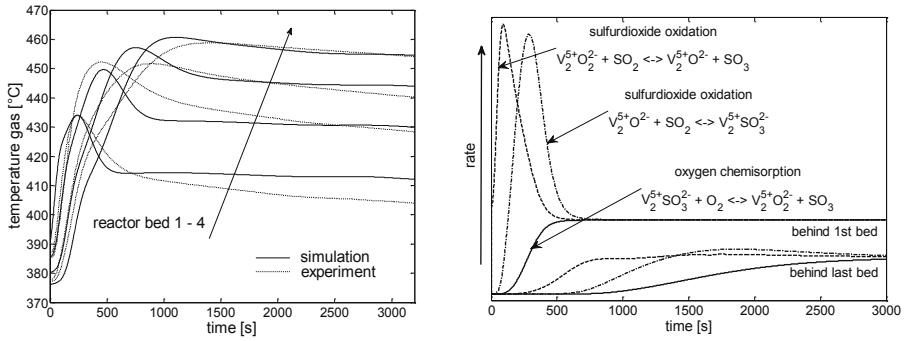

Fig. 3. Temperatures at four equidistant points in the reactor with the corresponding simulation results of the model and rates of the reactions Eq.1-3

Fig. 3 (right) gives a more detailed insight into the reaction. It displays the simulation associated reaction rates. For the sake of clarity, only the rates behind the first and the last reactor bed are shown. A large increase of the rates of reaction Eq.1 and Eq.2 can be observed during the time of $V_2^{5+}O_2^{2-}$ excess, before the rates converge to the limiting reaction of the O_2 chemisorption (Eq.3). In order to decrease the amount of kinetic parameters of the four reactions, the problem was divided into the oxygen enrichment and the oxidation of SO_2. While the model for the steady state operation could be fitted with temperature measurement data and the complimentary heat of reaction, a model considering the catalytic cycle with the elementary reactions has to be identified with concentration measurements. In both cases, a dynamically optimal experimental design has to be used so as to carry out the different phenomena of kinetics and absorption. After a fully identified model, plantwide optimization studies have to be carried out and the reaction has to be analyzed in terms of adaptability with real process gas streams at a last step in process synthesis.

Thinking Ontologies

Heinz A Preisig *
Department of Chemical Engineering; NTNU; Trondheim, Norway

Abstract

Ontologies are a means of abstraction and concentrating information. Whilst it has mostly found acceptance in the computer and information technology domain, it is an excellent thinking pattern promoting a more structural approach to chemical engineering problems on all levels, starting with the representation of functionalities, their combination to form processing units and combined again as whole plants. The concepts helps in constructing models that adhere to basic concepts as they are the foundation for physical processes: the conservation principles and the description of transport phenomena. The material models, the interaction between different chemical species or biological species form a knowledge framework suitable in in case of biological processes also intensively mapped into ontologies. When properly used, The high density of information, makes it easy to check consistency and the consistent use in all applications yields a framework that produces reliable, checkable results quickly and efficiently and consistency across applications that in the past have been without any information link.

Keywords: computer-aided modelling, software tools, process engineering

1. Structure is the Key

Ontologies have entered the chemical engineering community a couple of years ago stimulating their use as a thinking model. To the Chem Eng the concept of an ontology is almost provoking as its meaning implies foundation, in terms of knowledge and pure existence. Why provoking? Well because we all believe that we know our profession and we are using, and realising tools and solutions on the background of basic knowledge. So what about these ontologies? They do indeed provide base knowledge. They do though also offer a thinking pattern that first provides a motivation to put structure over our knowledge and secondly an abstraction lifting things up a level. Being harvested are the benefits of abstraction, namely a widening of the horizon, and a reduction of faults. Latter is mainly due to the direct use of theory in software for basic correctness checks, which also leads to the design of simpler underlying building blocks. Ontologies are not a source of new chemical engineering related information, but ontologies do add structure, which opens doors to do things differently and to do more of different things. In other words we really do not want to argue with our old fierce lady chemical engineering, but to give her a new nice chair to relax.

2. Ontologies are models

Ontologies are structures capturing the essential of a knowledge domain. The definition of a ontology is thus context dependent. Wikipedia defines ontologies in the context of computer science as: *...and information science, an ontology is a formal representation of knowledge as a set of concepts within a domain, and the relationships between those*

*Heinz.Preisig@chemeng.ntnu.no

concepts. It is used to reason about the entities within that domain, and may be used to describe the domain. In theory, an ontology is a "formal, explicit specification of a shared conceptualisation". An ontology provides a shared vocabulary, which can be used to model a domain – that is, the type of objects and/or concepts that exist, and their properties and relations. The concept of ontologies has been readily adapted by the system's biology community Courtot et al. (2011) and also chemical engineering has been working on conceptualising its knowledge Morbach et al. (2009); Yang and Marquardt (2009); Preisig (2011). These efforts focus on the representation associated with the core model, the model describing the process behaviour and its structure.

The ontology idea can though be carried further in the process involved in modelling and utilisation of models in computational engineering and it can also be expanded into the other direction, namely more towards capturing the nature of the process in terms of its basic functionalities. The ontology concept is applicable to any activity that involves abstract structures. The innovation, modelling, realisation and operation process all build on concepts, which can be thought of ontologies.

2.1. Process functionality dimension

Being confronted with a suggested process, a chemical engineer will use his experience to design a process Charpentier (2003), which involves understanding the chemistry and material properties of all chemical species involved. He will then suggest what network of unit operations will in his view produce the desired product.

But what unit operations to use? and in what network? The "basket" of operations can be seen as an ontology in which the functionality is primarily mapped into basic operations and secondarily into unit operations. For example functionality can be separation, which can be further detailed into for example co- and counter-current staged process, which in turn may be further detailed into liquid/liquid or gas/liquid separation systems leading to alternative realisations in the form of filter-like operations (membranes), crystallisation, extraction, distillation and the like. It can readily been seen that this structure is largely hierarchical where some of the layers may be interchanged but where the leave nodes are basic operations realisable as unit operations or combinations there off.

This dimension sets the industrial process in the centre, reflecting the paradigm-shift taking place in industry in which the intensified processing unit is set in the centre and all developments focus on this unit until production level is reached. The core is based on an ontology, representing the physical phenomena and process operations. Integration of these phenomena and operations results in process intensification; for example the concept of maximising surface/volume ratio, or the combination of different mechanism: e.g. diffusion and phase change. It is these set of rules and concepts, which form a type of "ontology".

Having derived an intensified unit from this core ontology, all activities focus on the development of this unit, i.e. the simultaneous development of all design and control aspects. Once developed and validated, the unit is multiplexed and embedded in the auxiliary parts of the plant providing feed preparation and product handling / separation units. In some cases the approach is different: devices are constructed such that the scale-up is solved a priori, when a series of equipment pieces exists for which the main characteristic design variable remains essentially constant. A very common one is a constant surface/volume ratio. Others multiplex in a different way, in that for example the mixing dynamics is being multiplexed, whilst dimension-related insensitive characteristics are scaled.

2.2. Modelling dimension

The units of the functionality ontology are to be modelled in order to enable studying the potential use of the unit in a network of units. The elements of the functional units are thus to be represented as mathematical objects describing their behaviour in the form of (partial) differential-algebraic equation systems. The mechanistic models are constructed on hard first principles such as the conservation principles of physics, fundamental energy functions and geometry (Preisig (2010)). The physical principles are augmented with structural principles, associated with constructing a network of systems that appropriately represents the plant. The latter is on the basis a spatial composition of the physical system augmented with the information processing system providing control. The first we term the physical topology, whilst the second is the information processing topology. The link between the physical topology and the conservation principles is formed by "what" is being "put" into the physical topology, in terms of mass and energy Preisig (2011).

For the formulation of the conservation principles one requires the information on how material, energy and momentum is crossing the surface of systems, how these quantities progress inside the system and how they are being modified. These descriptions involve material properties defining the need for material models, which, besides the exceptional ideal cases, are empirical models. These model components can also be represented as ontologies, which not only can be utilised in high-level modelling tools, but also in expert systems aiding the user to make an optimal model selection for their application.

The process-physics ontology, the material model ontology and the kinetics ontology are all having a structure that can be described as a multi-graph, which is a superstructure that combines several graphs thereby accommodating alternatives. For example for a type of transfer one may have more than one possible description, but only one can be used in an instantiated model. Thus a choice must be made. This can be done with an expert system or the user is given the opportunity to choose.

The view is that the ontologies are used in a modelling tool to assemble the plant model. They are also used to construct the modelling tool itself, so that the tool is context sensitive with the context being defined by the ontologies. The latter utilises the "rules" defined in the ontologies and implements them in the model editor.

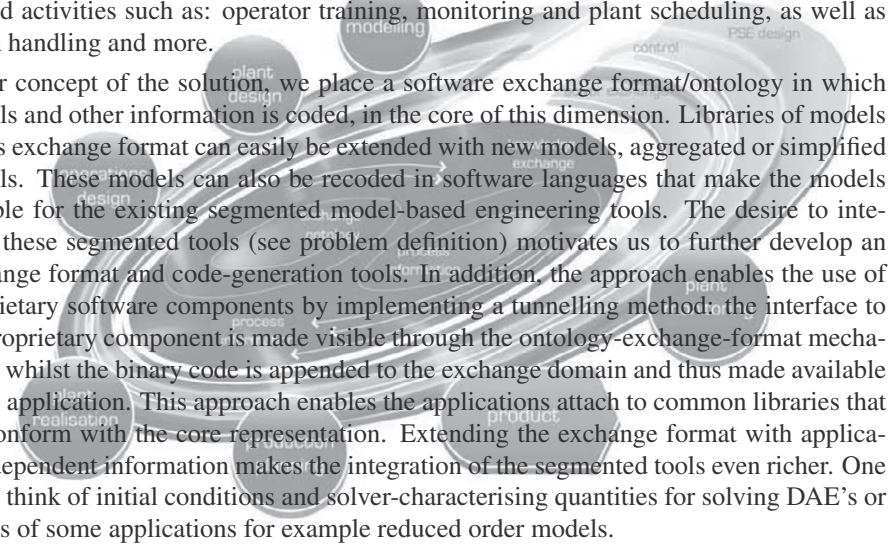
The model then becomes an extract and a combination of elements of the involved ontologies, which is to be compiled into a target language and instantiated to form a mathematical problem. This in turn enables the use of tools for solving the problems associated with the plant: such as product design, process design all the way down to the detailed engineering design and operations design: control structure design, controller design, operator simulator, operator interface and process monitoring as well as planning and scheduling. This can also be extended to logistics. The here-defined ontology contains the structures to building models as dynamic systems represented as (partial) differential - algebraic equation systems together with structural elements such as hierarchical structure of the control volumes and control blocks, the species being involved, reactions and the like. The ontology may be hierarchical consisting of a root ontology which inherits structural information from subsidiary ontologies, examples being thermodynamic material models and kinetic models (Preisig (2010)).

The core modelling dimension must have the ability to generate, aggregate, decompose and link multi-scale application-tailored models efficiently and robustly. These models must then be made to match the applications requirements, which adds the next dimension.

2.3. Information technology dimension

The main issue in the information technology dimension is to enable a flexible exchange of information whilst avoiding duplication of information. Thus the idea comes about that there should be a centralised administration of information from which the software components required by the application can be produced through a factory.

So process information is put into the centre and parts of this information can be exchanged to various computational engineering applications. This approach builds a gear-network that links a large number of process systems and computational engineering applications together, stretching over: modelling, model simplification, approximations, different levels of design (screening, plant, engineering); but also control and operation-related activities such as: operator training, monitoring and plant scheduling, as well as alarm handling and more.



In our concept of the solution, we place a software exchange format/ontology in which models and other information is coded, in the core of this dimension. Libraries of models in this exchange format can easily be extended with new models, aggregated or simplified models. These models can also be recoded in software languages that make the models suitable for the existing segmented model-based engineering tools. The desire to integrate these segmented tools (see problem definition) motivates us to further develop an exchange format and code-generation tools. In addition, the approach enables the use of proprietary software components by implementing a tunnelling method: the interface to the proprietary component is made visible through the ontology-exchange-format mechanism, whilst the binary code is appended to the exchange domain and thus made available to the application. This approach enables the applications attach to common libraries that are conform with the core representation. Extending the exchange format with application dependent information makes the integration of the segmented tools even richer. One could think of initial conditions and solver-characterising quantities for solving DAE's or results of some applications for example reduced order models.

The top-level ontology is the one for the representation of the exchange format. It will typically use a template for the representation of all knowledge associated with the various computational engineering tasks. An ontology interfacing the exchange format with the centralised knowledge base enables the construction of a model warehouse. One such effort is reported on MODELISAR webpage (Modelisar (2012)), an effort of the Modelica Modelica (2009) community to define a simpler interface and presentation of process models and associated data. The extensions are mainly in the direction of optimisation. Whilst this effort is mainly used in the domain of megatronics applications, the idea is absolutely transferable to chemical engineering models. It is no parts specific to the application domain. The approach promises to be easier and more broadly applicable than the CAPE-OPEN approach (CoLan (2012)), which though has similar objectives.

3. Discussion

The concept of ontology can be directly projected into chemical engineering. For example we can define basic operations as elements of a plant ontology and construct new plants by generating different combinations of them. This would be a substitute of our old "bag of tricks", enabling a logical formal handling of the information and for example generate combinations automatically or in an optimal way, given a measure for quality of the design, a process which is likely to enable us to generate a very wide range of

combinations that we today term as ”intensified processes”. So this ontology would serve in the first place as our design ontology.

Collecting the theoretical pieces of chemical engineering into an ontology, capturing the basics of physical behaviour, adding the chemistry and the biology, yields a formal body of information to be used for constructing models for the processes. Obviously there is a close relation between the design ontology mentioned above and the modelling ontology, though in a quite different form, with the modelling ontology providing detailed process information.

The ontology concept applies equally well to the information processing and handling framework. Here we have a model for the plant design, plant control, operations design, plant realisation, product planning and product information as well as knowledge exchange. This ontology captures the different processes associated with design and operations on the different levels.

By clearly separating process ontology, from math model ontology and information handling ontology, we enable an integrated model-based computational engineering approach covering the range from process design to process realisation and process operations. The interlinking reduces the time from idea to realisation in all aspects whilst reducing the costs and increasing the efficiency. This in turn enables also the testing of many more alternatives in the same time, increasing the chance for finding a better solution, in terms of any objectives one may have in mind: profit, inter-operability, embedding in the environment, ecology and the like.

Abstract

The Computational Fluid Dynamics (CFD) has been used recently to develop comprehensive models to study and represent the largest possible number of physical and chemical process inside the equipment. The objective of present work is to evaluate two different numerical radiation method to simulate a Kraft recovery boiler by a comprehensive model on the commercial CFD code for the homogeneous combustion of the volatiles released from black liquor pyrolysis. The model considered the turbulent flow represented by the SST, and the gaseous homogeneous combustion of the volatiles CH_4 and CO by the EDM. The radiation was evaluated discussing no radiation, P1 Model and Discrete Transfer Model. As an additional result, the black liquor drops trajectories were calculated for a representative number of particles by one way coupling using the Ishii-Zuber drag particle model without any influence on the continuous phase. A detailed discussion about the radiation numerical methods is presented to pave the preliminary work aiming to reach the complete black liquor combustion with drying, devolatilization, pyrolysis and char combustion. The full discussion of the temperature and chemical composition profiles indicates several insights for better operational conditions.

Keywords: Combustion modeling, CFD, Radiation, Recovery boiler,

1. Introduction

According to the Brazilian Association of Pulp and Paper Inds, almost 91% of Brazilian pulp production are Kraft process whose chemical recovery boiler recycles reactants generating power and live steam (Vakkilainen et al., 2000). As any boiler, after bullnose there are convective heat transfer zones as economizers, pre-heaters and super-heaters. Bellow the bullnose, the in-flight black liquor drops are releasing volatiles and producing char in furnace. At the bottom of the boiler there is a porous structure called char bed where occurs the heterogeneous char combustion and reduction reactions of sodium and sulfur compounds. The control of the boiler temperature relies, basically, on the air supply strategy composed by three or four air. The specific function and impacts of each air level and *velocity profiles are detailed* in Ferreira *et al.*(2010). Under high temperatures (>1000°C) the radiation is a very significant heat transfer mechanism in the furnace (Siegel & Howell, 1992). The rates of the drying and pyrolysis of the black liquor combustion are strongly influenced by temperature, so the accurate prediction of the heat transferred by radiation is a very important task in the design and operation of combustion chambers (Carvalho & Farias, 1998). The objective of the present work is to analyze two different radiation models in the homogeneous gaseous combustion of the volatiles inside the recovery boiler furnace by CFD, aiming to obtain a comprehensive model.

2. Methods

What happens inside a boiler can be evaluated by numerical simulations for flow involving heat transfer, mixing of gaseous components, chemical reactions and particulate material drag into a computational domain representing its geometry, and it is possible to analyze a large amount of physical and chemical processes connected to the flow of combustion. Here the comprehensive modeling is adopted as the strategy to incorporate the turbulent flue gas flow, homogeneous combustion of volatiles and particulate drag. The turbulence is represented by the SST (Shear Stress Transport) model RANS because it is adequate to flow near domain walls (Versteeg & Malalasekera, 2007) and to the heat transfer between flue gases and surfaces (boiler walls and super-heaters) with heat conduction on the boundary layer. Even in regions with the lack of oxygen, the homogenous combustion of fuel gases from pyrolysis is highly dominated by gas mixing rate, with high Damköhler number, very suited for Eddy Dissipation Model (EDM), which one is simpler than Flamelet, without the needs for defining specific inputs for fuel and oxidant inlets to obtain values to mixture fraction on the β-PDF (Turns, 1996). EDM is controlled by turbulent time scales, able to represent the combustion of volatiles released by black liquor. The liquor spray is represented by the one way coupling model because the particles are very small and are diluted in the field. The flashing phenomena produces small regions of dense spray and another regions of transient diluted dispersed spray (Mikkulainen et al., 2007), promoting the insert of liquor in the boiler preferably into small droplets enough to make negligible influence on the continuous phase flow. The drag force of the flow in the droplets is represented by Ishii-Zuber model, that consider the drag on particles that could strain the shape of the droplets, it is a robust disperse phase drag model (Ishii & Zuber, 1979). The droplet size distribution for the insertion liquor chosen was the Rosin-Rammler distribution, widely adopted for liquor spary in Kraft recovery boilers (Englblom *et al.*, 2010, Bergroth *et al.*, 2010). The radiative heat transfer is described by:

$$\rho c_P \frac{DT}{Dt} = \beta T \frac{DP}{Dt} + \nabla.\left(k\nabla T - \vec{q}_r\right) + q''' + \Phi_d \qquad (1)$$

where the radioactive heat fluxes is $\vec{q}_r$. The last two terms means the heat generation per unit volume and time and the viscous dissipation function, respectively. The spectral radiation heat transfer equation (RTE) can be found in Versteeg & Malalasekera, (2007):

$$\frac{dI\left(\vec{r},\vec{s}\right)}{ds} = \kappa I_b\left(\vec{r}\right) - \kappa I\left(\vec{r},\vec{s}\right) - \sigma_s I\left(\vec{r},\vec{s}\right) + \frac{\sigma_s}{4\pi}\int_{4\pi} I_{-}\left(\vec{s}_i\right)\Phi\left(\vec{s}_i.\vec{s}'\right)d\Omega_i \qquad (2)$$

The left hand term represents the rate of variation of radiation intensity per path length. The first right hand term is the emitted radiant intensity, the second the absorbed radiant intensity, the third is the out-scattering radiant intensity and the last represents the in-scattering radiant intensity. Combining the absorbed and out scattering terms as a sum and manipulating them to define the single scattering albedo (Versteeg & Malalasekera, 2007),

$$\varpi = \frac{\sigma_s}{\kappa + \sigma_s}, \quad \text{and} \quad \tau = \int_0^s \left(\kappa + \sigma_s\right) ds' \qquad (3), (4)$$

So rewriting the eq. (2) with this variables and defining the source function as

$$S\left(\tau,\vec{s}\right) = \left(1-\varpi\right) I_b\left(\tau\right) + \frac{\varpi}{4\pi}\int_{4\pi} I_{-}\left(\vec{s}_i\right)\Phi\left(\vec{s}_i,\vec{s}\right)d\Omega_i \qquad (5)$$

the variation of radiation intensity now is :

$$\frac{dI(\tau,\vec{s})}{d\tau}+I(\tau,\vec{s})=S(\tau,\vec{s}) \tag{6}$$

Due to the complexity of the RTE integral-differential nature, analytical solutions aren't current available and the numerical models consider approximate equations for the source function. Both P_1 approximation and Discrete Transfer Method (DTM) are adequate for the radiation inside the boiler, the computational domain doesn't show high aspect ratio regions and its continuous participant medium is semi-transparent. The P_1 method provides an expression for the local divergence of the radiative flux in differential form Siegel & Howell (1992) expressing the radiative intensity field $I(\vec{r},\vec{s})=\sum_{l=0}^{\infty}\sum_{m=-l}^{l} I_l^m(\vec{r})Y_l^m(\vec{s})$ as 2-D generalized Fourier series. The radiative heat flux as function of incident radiative intensity, accordind to P_1 approximation has is:

$$\vec{q}_r=-\frac{1}{3(\kappa-\sigma_s)-A\sigma_s}\nabla I_- \tag{7}$$

Despite of the method doesn't present any restriction about isotropic emission, scattering or reflection, it presents significant errors to thin media with strongly anisotropic intensity distributions in 2D or 3D geometries (Lockwood & Shah, 1981). Higher order approximations (like P_3) can minimize, but not vanish, this problem but needs higher computation effort and implies in few increase in accuracy. The DTM uses the consideration of isotropy radiation directions and wavelengths. It was built on the concept of solving determinate rays inside the domain with specified directions solved only for paths between the determinate pairs of boundary walls (Marklund & Gebart, 2007). DTM establishes an equal division of hemispheres in N parts with azimuthal $\delta\theta=(\pi/2N_\theta)$ and polar $\delta\phi=(2\pi/N_\phi)$ angles. Each hemisphere has vectors tracing the emitted, absorbed, scattered and reflected radiation intensity distributions. The source function $(\varpi/4\pi)\int_{4\pi} I_-(\vec{s}_i)\Phi(\vec{s}_i,\vec{s})d\Omega_i$ from (5) is expressed in function of a sum of averaged intensity $I_{-,ave}(\vec{s}_i)$, so one has

$$S(\tau,\vec{s})=(1-\varpi)I_b(\tau)+\frac{\varpi}{4\pi}\sum_{i=1}^{N} I_{-,ave}(\vec{s}_i)\Phi(\vec{s}_i,\vec{s})d\Omega \tag{8}$$

The initial intensity of each ray at its originating surface element is given by:

$$I_0=\frac{q_+}{\pi} \quad \text{where } q_+=\varepsilon_s E_s+(1-\varepsilon_s)q_- \text{ and } q_-=\sum_N I_-(\vec{s})\vec{s}.\vec{n}d\Omega \tag{9}$$

The $\nabla\vec{q}_r=\frac{1}{\Delta V}\sum_{k=1}^{N}\delta Q_{gk}$ can be calculated by the net radiative heat flow with

$$Q_{si}=A_i(q_+-q_-) \quad \text{and} \quad \delta Q_{gk}=\int_{\delta\Omega}(I_{n+1}-I_n)A_i(-\vec{s}_k.\vec{n})d\Omega_k \tag{10), (11}$$

3. Simulation

The considered domain doesn't contain the superheaters ducts. The geometry and computational mesh is composed by 1,427,799 cells, refined in several regions, as shown in Figures 1 and 2. There are 5 inlet boundary conditions: air1, air2 and air3 air supplies, 12 liquor feeding ports and the char bed at bottom. The char bed where the residual char/ashes are leaving the system, is also considered as an open boundary which one allows the entrance of CO and CO_2 to the furnace as conversion of 70% this

char bed. The wall temperature was estimated on the coal boiler simulated in Butler & Webb (1991) and the Kraft recovery boiler wall ducts temperature. The volatiles are inserted directly in the liquor guns ports between the secondary and tertiary air. The surface coefficient tension comes from Adams *et al.* (1997) and the Rosin-Rammler distribution were obtained from Bergroth *et al.* (2010). As scattering effects should be considered in further particle heat transfer simulations using two-way, it was tested 8, 16, 24 and 32 ray tracing directions for DTM. One simulation considers homogeneous volatiles combustion without radiation, two simulations uses P_1 method and more 8 simulations use DTM.

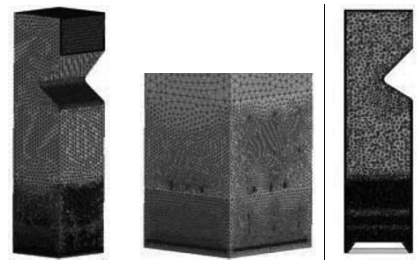

Figure 1: Cell distribution in computational mesh

4. Results

The results to the simulation without radiation show high temperatures above tertiary air level. When radiation is considered, the results showed profiles more coherent with expected behaviour presenting higher temperatures between the first tertiary air level and the bullnose in the Figure 2.

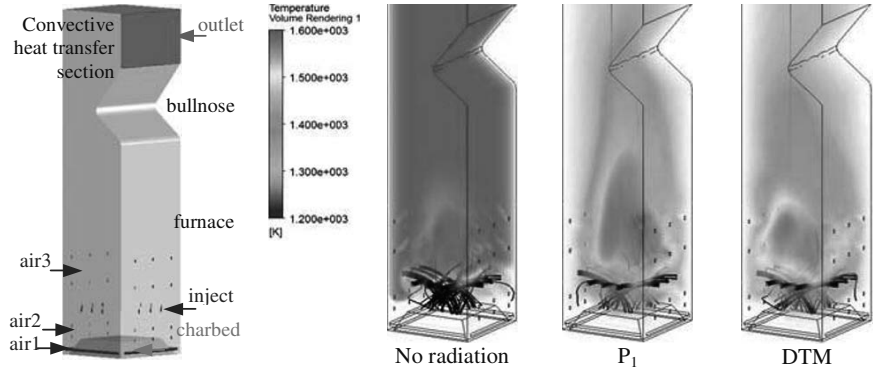

Figure 2: Geometry details and comparison of particle tracking trajectories and volume renderings to simulations a) without radiation; b) P_1 approximation; and c) DTM using 16 directions.

The P1 results showed a vertical larger region with higher temperatures than DTM results. Them temperature profiles follow the flow channeling shape observed in the velocity profiles as described in Ferreira *et al.* (2010). The obtained results to CH_4, O_2, CO, CO_2 and H_2O composition are coherent with the Eddy Dissipation Model proposal which reaction rate is strongly affected by turbulent eddies: CH_4 and CO react practically as soon as them enter the furnace. All profiles for the chemical compounds didn't present differences in all simulated cases, its consumption appears to be independent of radiation. The 90,000 liquor drop particles are represented by 70

trajectories chosen randomly. It was observed that the velocity and temperature profiles weren't affected by the number of directions, so it was chosen 16 directions to run the post processing to obtain the particle tracking trajectories. The comparison of particle trajectories and temperature volume rendering for the simulations without radiation, for P_1 approximation and DTM using 16 directions results is showed in Figure 2. The significant high value from simulation without radiation suggests that radiation works as way to distribute energy inside boiler and allows the heat loses through walls.

5. Conclusions

The presence of radiation showed influence on the velocity profile. Both velocities profiles from P_1 and DTM are similar presenting flow channeling as expected but the results without radiation showed ascendant flow near the walls. Anyway, radiation should be considered, even if there isn't disperse phase on simulations of combustion under high temperatures. According to the temperature profiles obtained, the most appropriate method among the tested to represent radiation for the comprehensive CFD model to a Kraft recovery boiler is the DTM due to its better similarity with expected and theoretical behavior. As all profiles obtained to DTM cases are equal, the choice of the amount of ray directions should be based on minimizing computational effort and to be accurate enough to represent radiation disperse particles in a further two-way coupling. A more accurate thermal profile, considering an adequate radiation heat transfer to represent the operation, can provide valuable information about a new air supply arrangement or better positions to insert the combustible or combustion air.

Process development in a miniplant scale – A multilevel - multiscale PSE approach for developing an improved Oxidative Coupling of Methane process

Steffen Stünkel, Konstantin Bittig, Hamid-Reza Godini, Stanislav Jašo, Walter Martini, Harvey Arellano-Garcia, Günter Wozny

Technische Universität Berlin, Department of Process Engineering, Chair of Process Operation and Dynamics,Straße des 17. Juni 135, 10623 Berlin, Germany

Abstract

The oxidative coupling of methane (OCM) is a promising alternative route to olefins that converts methane to higher hydrocarbons and open up a new feedstock for the oil based industry. However, due to yield limitations of available catalysts and high separation costs for conventional gas processing, the OCM process has not been applied yet in the industry. Starting with process simulation and sensitivity studies a flexible mini-plant was built in this research so as to demonstrate technical feasibility of an efficient OCM process, model validity and to study long term effects. By this means a concurrent engineering approach was applied for the whole process while investigating each unit parallel. Moreover, catalyst with several reactor concepts like the fluidized bed and membrane reactor were investigated by CFD simulation, process simulation and experiments, in order to study catalyst life time, operation conditions and technical feasibility. Thus, the reaction section was improved from 16% yield to 18%. Furthermore, the separation part of the OCM process was energetically improved by an integrated down streaming unit for the CO_2. Thus, an energetic improvement of more than 40% in comparison to a benchmark absorption - desorption based CO_2 separation process was achieved. In addition to this, novel absorbents were studied starting with molecular simulation up to process simulation and experimental validation for the CO_2 separation. The results of the integrated process development and optimization process for the OCM will be presented and an overview of the multi scale and multilevel Process System Engineering (PSE) approach will be given for the case study.

Keywords: Oxidative Coupling of Methane, concurrent PSE approach, miniplant

1. Introduction

Oxidative coupling of methane to ethylene provides with natural- or biogas a new feedstock for the chemical industry and represents in combination with other alternative processes a promising alternative for the petro chemistry. However, although several process alternatives have been proposed in the literature (Lunsford, 1988), the industrial application of the stand-alone OCM process suffers in yield limitation and high separation costs for by-products, (Salerno, 2011). In a novel approach of concurrent engineering, the whole OCM process is investigated in miniplant scale, in order to study novel reactor concepts, as well as alternative separation processes and thus following new process concepts of Salerno (2011). Beside engineering aspects, the research cluster focus is also put on catalyst design. Therefore, the most promising catalysts that

tested in milligram scale under laboratory conditions by the cluster chemists (Simon et. al., 2011; Zavyalova et. al., 2011), was tested in gram scale in the miniplant under industrial close operation conditions (Jašo et. al., 2011). By this means that macro- and micro-kinetics of the catalyst are then studied.

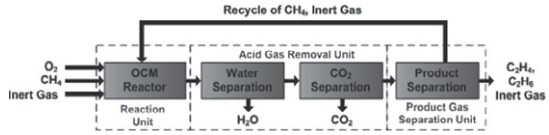

Figure 1: OCM Process flow sheet

To focus on the reaction part, fixed bed reactor (FBR), a fluidized bed reactor and a membrane reactor were investigated since they are the most common reactor types for OCM. Besides, in order to achieve high product quality, the reaction product gas has to be treated and the undesired side products have to be removed. Therefore, CO_2 has to be separated early in the process so as prevent condensation or freezing in the further product separation unit. The purpose of separation process synthesis for this design task was primarily the development of an integrated energy efficient gas treatment for 90% CO_2 removal under the particular OCM conditions of up to 25 mol% CO_2 in the raw gas with a feed pressure of 32 bar. The general flow sheet of the installed OCM process is presented in Fig. 1 and its implementation in a mini-plant scale can be seen in Fig. 5.

2. Catalyst selection – laboratory scale

In the novel multi-level PSE approach is a big emphasis of the research cluster put on catalyst design, concurrently to the process development. Thus studied Zavyalova et. al. (2011) more than 1000 full text references from about the last three decades of OCM's catalyst composition concerning their performance. Their statistical analysis of binary and ternary interactions between the elements showed, that Mg and La oxide based catalyst provides the highest performance concerning C_2 yield and selectivity.

However, the studies of Simon et. al. (2011) show, that the preparation route has a strong effect on the catalyst performance in OCM, especially for large scale heterogeneous catalyst preparation, like miniplant scale. Simon et. al. (2011) developed a homogeneous coating procedure of amorphous silica with dispersed Mn_2O_3 and Na_2WO_4 crystal layer in a fluidized bed technique. A Na–W–Mn/SiO_2 catalyst was prepared in a fluidized bed technique through which the core amorphous SiO_2 granules are homogenously coated by an injected solution containing Mn_2O_3 and Na_2WO_4 and results in a catalyst with 2wt% Mn(II) ions and 5wt% Na_2WO_4. Their catalyst remained constant performance over 24 h stability test in a packed-bed tubular reactor in laboratory scale with acceptable methane conversion and high C_2 selectivity. However, to approve the catalytic performance and to adjust the operation condition for the catalyst, it was tested in a miniplant scale fluidized bed reactor by Jašo et. al. (2011) and is discussed in detail.

3. Reactor concepts – mini-plant scale

In our miniplant scale research activity on the OCM process, the different reactor concepts were investigated from fixed bed reactor up to membrane and fluidized bed reactor. They are investigated concerning their performance in case of efficiency of selective-conversion and operability for the most promising catalyst. These reactor concepts include different feeding policies as well as safety and operating issues (Jašo et. al., 2011; Godini et.al., 2009). In this context, effect of operating parameters such as

temperature, pressure and inert gas along with the catalyst and reactor types, reactor dimension and combination of reactors not only on the performance of the reactor section, but also in the content of the downstreaming process, for the whole OCM process performance are analyzed.

3.1. Fluidized bed reactor

Fluidized bed reactors have been studied in several reactor engineering researches for OCM, also quite stable and efficient performance was reported especially in case of reactor operability and safety concerns. Due to the large exothermic of the OCM reaction, a fluidized bed reactor enables an almost isothermal reactor performance in OCM and was therefore the first investigated reactor type.

The activity and characteristics of the catalyst as well as the reactor operating conditions and taking some measures such as using inert gas diluents, affect the observed hot spot formation and therefore the reactor performance. However, the observed methane conversion was up to 45% with a C_2 selectivity of up to 84 % for a methane to oxygen ration of 10:1 and the particular ethylene yield results to 19.6 %.

Figure 2: CFD-Simulation, investigation of 4 different reactor geometries

3.2. Membrane reactor

Membrane reactors using porous inert membrane or catalytic dense membrane are among the most promising reactor concepts utilized for OCM (Godini et.al., 2009). Usually, a high selectivity toward C_2 production is achievable in a membrane reactor because of the fine dosing policy of oxygen. In the porous packed bed membrane reactor of Fig. 3, simultaneous high amount of methane conversion and C_2 yield was achieved by the fine oxygen dosing policy.

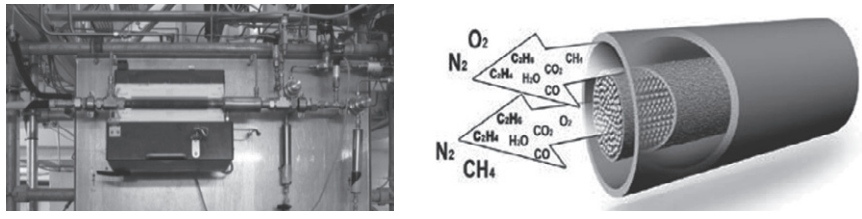

Figure 3: Experimental packed bed membrane reactor facility and principle

Moreover, the hot-spot formation is reduced by using porous membrane compared to a fixed bed reactor due to the feeding policy and its consequent low value of local methane to oxygen ratio. Although the observed nearly isothermal fluidized bed reactor performance was not reached in porous membrane reactor, the observed C_2 selectivity and yield was higher than in the fluidized bed. According to our experimental observations, porous packed bed membrane reactor shows 4-6 percent higher C_2 yield than the fixed bed reactor for the comparable set of operating conditions.

4. Downstream concept – miniplant scale

The gas purification of the reaction product gases as a major energy sink effects the overall process performance. Thus, it was improved particularly and is described in detail for the CO_2 removal. In the benchmark process for CO_2 removal was the developed rigorous process model for 30 wt% Monoethanolamine validated and a parity plot is presented in Fig. 4 for the experiments in miniplant scale. Furthermore, processes options using alternative absorbent and novel process concepts was studied concerning their energetic improvement for the OCM process and described below.

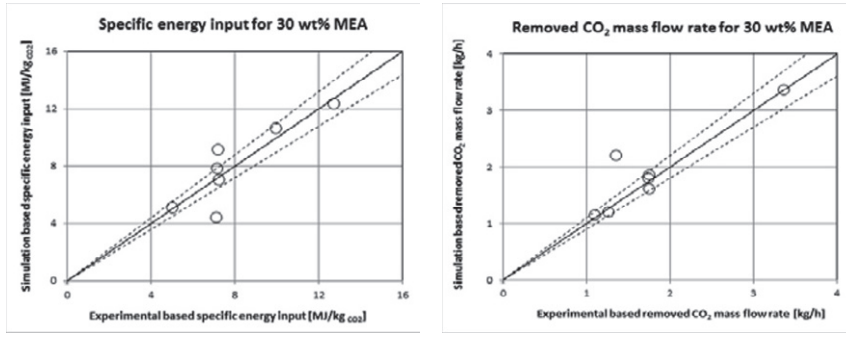

Figure 4: Parity plot of simulation results compared with the experiments for the specific energy input and CO_2 removed mass flow rate with +/- 10% relative deviation

4.1. State of the art CO_2 removal

The benchmark CO_2 gas purification unit for high purity and high selectivity consists of a chemical absorption process using an amine based absorbent. An energetic optimum for 30 wt% Monoethanolamine to achiev 90% CO_2 removal of the OCM product gas stream was found with 5 MJ/kg_{CO2}. Moreover, 37wt% N-Methyldiethanolamine (MDEA) as a ternary amine was investigated concerning the energetic advantage in the regeneration step. Due to the low reaction kinetics of the MDEA it was increased by using 3wt% of Piperazine as an activator. More than 30 % energy saving was achieved using the alternative absorbent in comparison to the benchmark absorbent.

4.2. Alternative process – membrane process

In previous studies membrane separation showed a high potential as an alternative for the OCM downstream (Stünkel et.al. 2011). The applicability and first evaluation of the separation efficiency in a OCM process was investigated using process simulation in Aspen Custom Modeler® (ACM). Therefore, a rigorous simulation model was implemented (Stünkel et. al. 2011) and several membrane materials were studied. Based on the simulation results, a matrimid based flat sheet membrane module from the HZG* with 0.5 m² membrane material was installed in the miniplant and the ACM model was validated.

4.3. Improved CO_2 removal

In order to reduce the energy demand a membrane was implemented prior to the absorption process so as to achieve a CO_2 stage cut of 0.5 with each separation principle. The CO_2 concentration was reduced from 25 vol% down to 17 vol% by the membrane. However, for further energy reduction regarding the benchmark process was Piperazine activated MDEA used in the hybrid process mode. Hence, the overall

* Helmholtz Zentrum Geestacht, Max-Planck-Straße 1, 21502 Geesthacht, Germany

specific energy demand per captured kilogram CO_2 was reduced to 2.74 MJ/kg_{CO2} with the hybrid membrane-absorption process configuration. Furthermore, the CO_2 removal rate for the hybrid process is much higher than the one of the benchmark process and a saving in column height results for the hybrid process to reach the 90% CO_2 removal. Moreover, in the hybrid process 20% of solvent flow rate was reduced in comparison to the benchmark.

5. Conclusion

An efficient state of the art OCM process was designed and improved using a multilevel, multiscale approach in a miniplant (Fig. 5). Several reactor concepts and catalysts studied in different scale, accompanied by fundamental catalyst research while using the most promising catalyst in the miniplant. Furthermore, an energy efficient CO_2 capture process for the oxidative coupling of methane was developed and compared with a benchmark process. Thereby, more than 40% energy reduction, more than 30% reduced column height and more than 20% solvent flow rate reduction was achieved experimentally with the membrane-absorption hybrid process in miniplant scale. More approach details as well as further results will be discussed in the presentation.

Phenomena-based Process Synthesis and Design to achieve Process Intensification

Philip Lutze, Deenesh K. Babi, John Woodley, Rafiqul Gani

Department of Chemical and Biochemical Engineering, Technical University of Denmark (DTU), DK-2800 Kgs. Lyngby, Denmark; rag@kt.dtu.dk

Abstract

Process intensification (PI) has the potential to improve existing processes, necessary to achieve a more sustainable production. PI can be achieved at different levels. That is, the unit operations, functional and/or phenomena level. The highest impact is expected by looking at processes at the lowest level of aggregation: phenomena. Therefore, in this paper, a phenomena-based synthesis/design methodology is presented. Using this methodology, a systematic identification of necessary and desirable (integrated) phenomena as well as generation and screening of phenomena-based flowsheet options are made using a decomposition based solution approach. The developed methodology is highlighted through a case study involving the production of isopropyl-acetate.

Keywords: Methodology, Phenomena, Process Synthesis, Process Intensification

1. Introduction

In recent years, PI has attracted much interest as a potential means of process improvement and to meet the increasing demands for sustainable production. A variety of intensified equipment have been developed, which potentially creates a large number of options to improve a process by PI. However, to date, only a limited number have achieved implementation in industry such as reactive distillation, dividing wall columns and reverse flow reactors [1]. One reason for this is that the screening of options and the identification of the best PI option is neither simple nor systematic.

In previous works [2, 3] we reported the development of a general systematic PI synthesis/design methodology in which the initial search space is defined by PI unit operations stored in a knowledge base. Even though process improvements have been achieved in several case studies, the methodology is limited to PI unit operations available in our knowledge base. In order to go beyond those and achieve even greater benefits by PI, process synthesis/design needs to be investigated at a lower level of aggregation, namely the phenomena level. The phenomena level has been considered before [4] with respect to synthesis and design of reactive distillation, but solution strategies for phenomena based design of whole processes not fixing the phenomena a priori, have not been developed, which is the objective of this paper.

In principle, synthesizing processes from phenomena may lead to a large number of process options. Thus, an efficient solution procedure for the mathematical synthesis problem is needed. The decomposition based solution approach has been selected to break down the complex mathematical synthesis problem into manageable sub-problems (steps) that allows the stepwise reduction of the search space. This approach has been used successfully in the area of computer-aided molecular design (CAMD) [5] and for synthesis of process flowsheets based on different building blocks [3, 6].

In this paper, the needed workflow to apply this methodology is presented together with illustration of its application through a new case study.

2. Methodology

In this section, the concept as well as the workflow of the phenomena-based synthesis/design methodology based on the decomposition approach is explained.

2.1. Phenomena building blocks and their interconnection/connection

Phenomena building blocks are based on mass, energy and momentum balances. They can be classified in terms of: mixing, stream dividing, phase contact, phase transition, phase change, phase separation, reaction and energy transfer phenomena [7]. The combination of phenomena to form simultaneous phenomena building blocks (SPB's in Fig.1) is governed by a set of interconnection rules. For example, a necessary interconnection of phenomena is phase transition phenomena needing a phase contact phenomenon. Integrating phase transition phenomena may be desirable for a reaction phenomenon limited to an unfavorable equilibrium. A dividing phenomenon cannot be connected to any other phenomena. SPB's may be connected in co-, cross- and counter-current forms by placing them into one or a number of stages of an operation to achieve a process task. This connection is following another set of rules based on the connectivity of inlet/outlet streams of SPB's that depend on their operating window. As shown in Fig.1, one or more phenomena form a SPB; each SPB may represent a stage; one or more stages form a unit operation; and one or more unit operations form a process flowsheet.

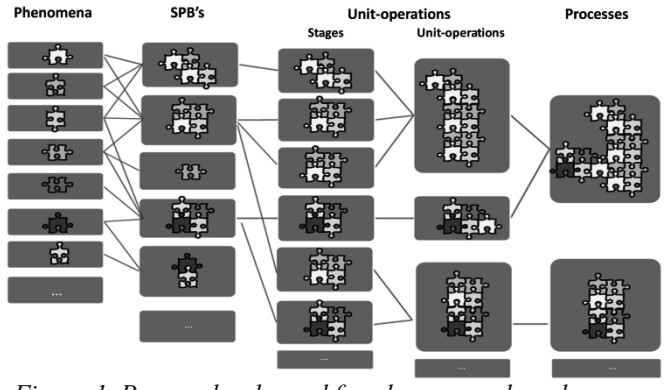

Figure 1. Process levels used for phenomena-based process synthesis/design.

2.2. Workflow of the phenomena-based synthesis/design methodology

The workflow of the methodology is given in Figure 2. The starting point of the methodology is either a base case design of an existing process or a new process.

In step-1, the synthesis/design problem with respect to PI is defined, including: the definition of the objective function; the process/operation scenario; and the constraints that the options need to match. Also, the performance metrics for evaluation of generated options are selected. In step-2, all process data, necessary to gain full understanding of the process is collected, and, based on this, limitations and their corresponding phenomena are identified. In step-3, the information from above is used for identification of suitable or desirable tasks that must be integrated to overcome the limitations. Output of this step is the search space of necessary and desirable phenomena within the process. In step-4, all phenomena are interconnected to form SPB's. Subsequently, the number of stages as well as their connections (co-, counter-, cross-current) to fulfil the necessary tasks is determined using an extended Kremser method [8]. This allows the identification of generic superstructures retrieved from a model library. SPB's can be inserted into stages of generic superstructures to form processes which are subsequently screened by logical and structural constraints (Eqs.2-3). In step-5, all PI options are screened for matching operation constraints (Eq.4-5). The remaining process options are screened for additional process constraints based on performance criteria (Eq.6).

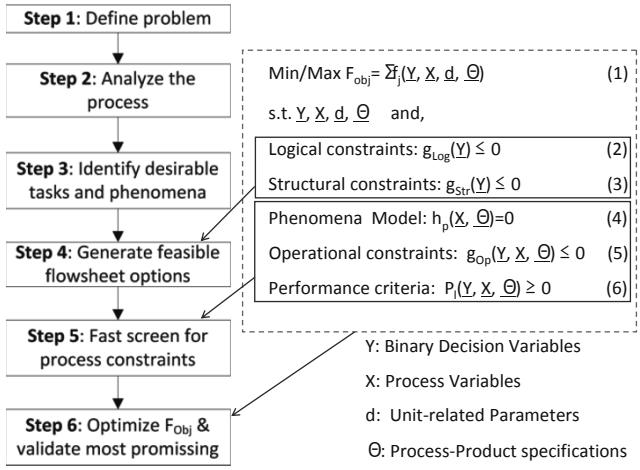

Figure 2. Workflow based on the decomposition approach.

Remaining options are transformed to unit operations using a set of integration rules. Subsequently, they are screened by operational constraints as well as performance criteria at the unit operational level. In step-6, in case after step-5 process variables are still not fixed, the remaining options are optimized (Eqs.1-6). If all variables have been already fixed in steps 1-5, the objective function (Eq.1) is calculated and all alternatives are ranked.

3. Case study

The methodology is applied to the production of isopropyl acetate (IPAc) which is an important bulk chemical product used widely as organic solvent [9].

IPAc is produced from isopropanol (IPOH) and acetic-acid (HOAc) heterogeneously catalyzed by Amberlyst 15 (Eq.7). The reaction takes place in the liquid phase.

$$CH_3COOH + C_3H_7OH \leftrightarrow C_5H_{10}O_2 + H_2O\,. \quad (7)$$

The base case design is a simple CSTR for a production of 50000 t/y of IPAc. The CSTR is assumed to run isothermal by T=330K and P=1bar. The feed is an equimolar mixture of the reactants. The reaction is not complete. In step-1, the scenario is restricted to design of a reactor with or without built-in separation for the continuous production of IPAc. The objective is to identify one apparatus with the lowest operational costs at lowest capital costs that achieves a conversion of 0.99. From the PI performance metric [2], options for energy, simplification, volume and waste are selected. Based on these, logical and structural constraints are retrieved from a knowledge base and operational constraints are set. In step-2, using a set of rules, the unit-operation based flowsheet is transformed to a task based flowsheet (necessary to identify the necessary phenomena for the process) and a phenomena-based flowsheet. The task is the conversion of IPOH and HOAc to produce IPAc. Hence, the reaction phenomenon is necessary. The involved phenomena to start with are liquid phase mixing, reaction and convective cooling for isothermal operation. Pure component, mixture and reaction analyses [2, 3] are performed to identify the limitations of the involved phenomena. The reaction analysis based on kinetics given by Lai et al. [9] confirmed the exothermic irreversibility and the equilibrium limitation of the reaction (K>1). In step-3, the knowledge base is contacted to identify possibilities for PI to overcome the identified limitations in order to achieve a conversion of 0.99. Since this case has an unfavorable equilibrium, the integration of the reaction task with a second reaction (of IPAc and/or H_2O) or a separation task (to remove IPAc and/or H_2O) using suitable phenomena are options obtained from the database. The latter is selected here because reactions converting water into a valuable product or reactions converting the target product are not recommended. The following phenomena were identified as suitable: phase transition by relative volatility

(identified by differences in boiling points) to remove H_2O and IPAc; phase transition by pervaporation (identified by differences in radius of gyration) to remove H_2O. Additional necessary phenomena are: mixing (Liquid (L): ideal, tubular flow, rectangular flow; Vapor (V): ideal; 2-phase V-L: ideal); stream dividing; convective heating and cooling; heterogeneous reaction; phase contact (ideal V-L); phase separation (ideal V-L). In total, $n_{P,tot}$=13 phenomena are in the search space. In step-4, SPB's are generated through combination of the selected phenomena. Based on $n_{P,tot}$ and the maximum number of phenomena allowed within an SPB $n_{P,max}$ (see Eq.8), a total number of 4019 SPB's ($NSPB_{max}$, see Eq.9) are generated. First, the number of competing phenomena (see Eq.8) which cannot be present within one SPB because they cannot occur at the same time and space is $n_{P,compete}$=4. Competing phenomena are heating vs. cooling; the different liquid flow mixing phenomena; and, dividing vs. all other phenomena because dividing is by definition a single phenomenon SPB.

$$n_{P,\max} = n_{P,tot} - n_{P,compete} = 13 - 4 = 9 \tag{8}$$

$$NSPB_{\max} = \sum_{k=1}^{n_{P,\max}} \left(n_{P,tot,w/oD}\,!/\left(\left(n_{P,tot,w/oD} - k\right)!k!\right)\right) + 1 = 4019 \tag{9}$$

Screening of all SPB's for feasibility: Using connectivity rules and the information of the operating window of each phenomenon, a total number of 58 SPB's are found to be feasible in terms of conditions of the operating windows of the integrated phenomena (not shown here). The potential outlets of the 58 SPB's are checked by using an extension of the Kremser method [7]. When the reaction phenomenon is coupled with phase transition by pervaporation a conversion of 0.99 may be achieved within one stage. This performance criterion together with the needed volume for the task and the simplification of the superstructure leads to the selection of the usage of up to three cross-current stages. The simplified superstructure for this form is retrieved from the model library. The insertion of a dividing phenomenon into one stage of the 3-stage superstructure points to 6 recycles of the liquid while for configurations with 2 stages, in total 3 recycles are possible. Hence, in total 218892 different process options are generated (Eq.10) based on the 58 feasible SPB's in the search space (Fig.3).

$$NOO_{\max} = 58^3 + 58^2 + 58^1 + 6 \cdot 58^2 + 3 \cdot 58^1 = 218892 \tag{10}$$

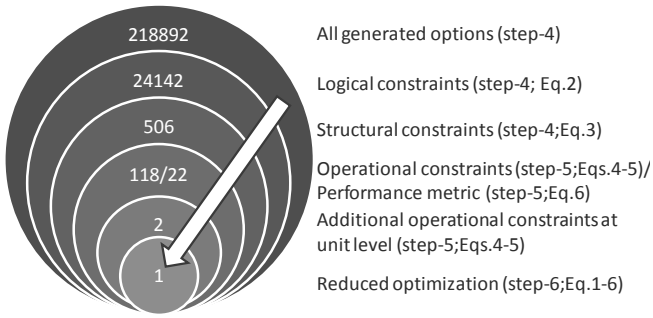

Figure 3. Search space reduction.

In step 4, all options are screened by logical constraints (Eq.2) fixing the binary variables $\underline{Y}$ for feasible processes by ensuring matching operating window of inlet/outlet streams of the SPB's and by ensuring the formation of the product. That gives 24142 remaining options. By subsequent structural screening (Eq.3), e.g. by removing energy redundant options, 506 structural promising processes are identified. In step-4 and step-5, the remaining options are screened by operational constraints (Eqs.4-5) to identify all options having a feasible set of process variables $\underline{X}$ and, subsequently, by identifying the most promising options based on a ranking by the defined performance metric (Eq.6). In total, 2 options remain in the search space which have been identified achieving the lowest operational costs (represented by raw material and

energy consumption). These two are: a tubular (#1) or a rectangular (#2) flow reactor-pervaporator with integrated heating in parallel (see Fig.4). The pervaporation has been modeled using correlations for selectivity and flux of a membrane based on experimental data from Van Hoof *et al.* [10].

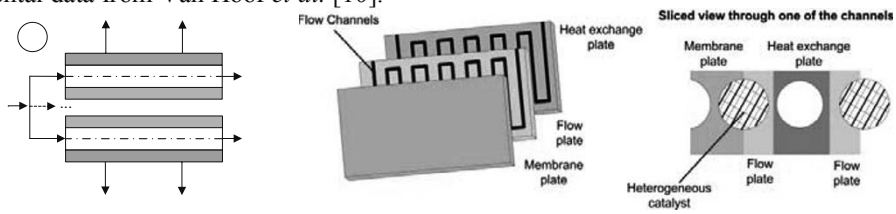

Figure 4. Tubular flow reactor-pervaporator with integrated heating (Option #1).

In step-6, a reduced NLP optimization problem involving the remaining two options is solved in which the diameter (and/or volume) of the tube/channel is optimized to achieve a conversion of 0.99 and a pressure drop $\Delta p<1$bar. The results are given in table 1. The best option is option #1 (see Fig. 4). The achieved concentration of the product in the outlet stream is 98 mol.% IPAc.

Table 1. Simulation results for both remaining process option #1 and #2 for a number of 100 reactors in parallel (W: width; H: height).

Option	T	Rectangular channel			$A_{membrane}/V$	V_{single}	r or r_h	Δp
	[K]	W/H	H [m]	W [m]	[m^{-1}]	[m^3]	[m]	[bar]
#1	373				100	1.46	0.01	1.0
#2	373	4	0.01	0.04	100	1.51	0.008	1.0

Conclusions

A phenomena-based methodology for synthesis/design to achieve PI has been developed and tested through a case study. With this approach it is possible to generate potentially novel process options. That is truly predictive models lead to reliable predictive solutions as well as the simultaneous development of the necessary process models. Current and future work is the development of necessary tools to support the workflow and the implementation of this approach into a software tool.

Three-layer solution strategy for multi-objective process synthesis

Jincai Yue,* Shiqing Zheng, Xia Yang

Research Center for Computer and Chemical Engineering, Qingdao University of Science and Technology, Qingdao266042, China

Abstract

Multi-objective process synthesis can be described as a multi-objective mixed-integer nonlinear programming (MOMINLP) problem. To solve such problem, the main goal of this work is to develop a three-layer solution strategy, which includes simulation layer, synthesis layer and decision-making layer. Simulation layer is used to simulate and analyze the process system. In synthesis layer, NSGA-Ⅱ is used to deal with the process data and generate an optimized population that transfers to simulation layer. In decision-making layer, the compromise solution is generated. The computer user interface is developed to support the data transmission. As a case study, MDA brine treatment process is used to illustrate the proposed strategy. The rigid process model and the optimization model are presented. The non-inferior solution curve is obtained and the final results are used to design industrial process.

Keywords: Process synthesis; MOMINLP; MOGA; NSGA-Ⅱ

1. Introduction

Multi-objective process synthesis is a key step during designing a sustainable process and needs to solve a multi-objective mixed-integer nonlinear programming (MOMINLP). The MOMINLP model is given by

$$\begin{aligned} \min \quad & F = \left[f_1(x,y), f_2(x,y), ..., f_p(x,y) \right]^{\mathrm{T}} \\ \text{s.t.} \quad & h(x,y) = 0 \\ & g(x,y) \le 0 \\ & x \in X \subseteq R^n \\ & y \in Y \subseteq Z^q \end{aligned} \tag{1}$$

Here, x is a n dimension vector of continuous variables, y is a q dimension vector of integer variables, R and Z are decision spaces, F is a p dimension vector of objectives, and $h(x, y)$, $g(x, y)$ are the equality and inequality constrains, respectively.

Multi-objective mathematical programming and multi-objective optimization algorithm based on evolutionary strategy are two main research methods often used. It's difficult especially for complex processes to solve MOMINLP using mathematical programming, so the process model has to be simplified and the results cannot be used to design industrial process. Schaffer (1985) proposed using genetic algorithm (GA) to solve multi-objective optimization problem firstly. Up to now, many MOGA algorithms, such as NSGA-Ⅱ, are developed. Some scholars (Bhaskar et al., 2000; Ravi et al., 2000; Kasat et al., 2003; Amy et al., 2003) have done some research on process synthesis using MOGA, but the process model, based on equations, are still very simple.

Integrating with module simulator such as Aspen Plus, MOMINLP will be simplified and easy to solve. Furthermore, the results can be use to design industrial process because of using rigid process model. Leboreiro & Acevedo (2004) presented GA and modular simulator to optimize sequences of distillation which has one objective. Zheng (2006) proposed mathematical programming and modular simulator to solve waste minimization problems.

A new three-layer solution strategy for MOMINLP based on NSGA-Ⅱ in modular simulator is proposed in this work.

2. Three-layer Solution Strategy

The framework of three-layer solution strategy is given in Fig.1. Three layers are simulation layer, synthesis layer and decision-making layer. Data and information are transferred by the interface program.

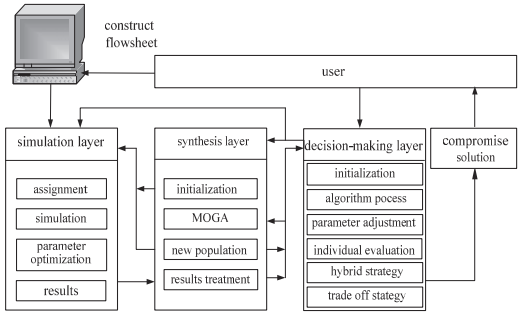

Fig.1 Framework of three-layer solution strategy

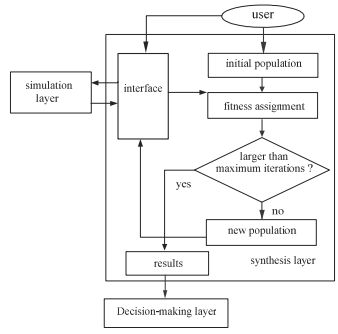

Fig. 2 Flowchart of synthesis layer

2.1. Simulation Layer

Simulation layer is the basic layer. The user constructs flowsheet on Aspen Plus according to the superstructure of the problem, and then assigns initial value data of operating parameters. Finally, the flowsheet is simulated and optimized. As long as a set of decision variables (an individual of the population) is given to Aspen Plus by synthesis layer, all the process variables can be obtained after simulation. The interested variables and simulation information are transferred to the synthesis layer and decision-making layer.

2.2. Synthesis Layer

Synthesis layer's main functions are to deal with the interested variables and simulation information returned from simulation layer. NSGA-Ⅱ is used to generate new population that is transferred to simulation layer. Fig. 2 is the flowchart of synthesis layer.

The interface(Yue et al., 2009a)is programmed using Visual Basic. The interface enables Aspen Plus to open simulation file, simulate the process, and change flowsheet structure and operating parameters. If process simulation fails to converge, the information is transferred to synthesis layer and each objective function is assigned an inferior value directly to avoid interfering with the optimization of NSGA-Ⅱ.

2.3. Decision-making Layer

The functions of decision-making layer are to (1) construct superstructure of process and MOMINLP model, (2) improve the non-inferior solutions by using local search algorithm, and (3) determine the compromise solution by using coordination strategy.

3. Case Study

3.1. Process Description and Extracting Model

Methylenedianiline(MDA) is a kind of chemical intermediate and a large amount of alkaline brine containing aniline, MDA and methanol is produced during the MDA production(Yue et al., 2009b). The brine treatment process flowsheet is given in Fig. 3. Total flow rate of brine is 20092 kg/h which contains 14.5kg/h MDA and 148.3kg/h aniline. Firstly, MDA in brine is extracted by using aniline as extractant, then the brine enters into the stripping tower, and direct steam is added into the bottom to drive off aniline and ethanol. Brine discharged from the bottom still contains a minute quantity of amines. The goal is to reduce the amines content in brine with minimum cost.

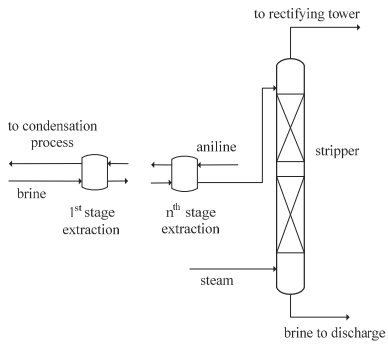

Fig. 3 Flowsheet of brine treatment process

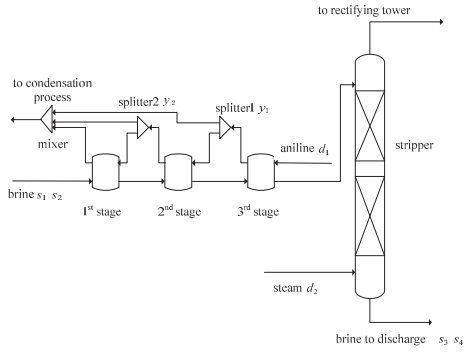

Fig. 4 Superstructure of brine treatment process

Zhang et al. (2008) studied the extraction process of MDA in brine by using aniline. The extraction distribution coefficient K is regressed. Its expression is shown as:

$$\ln K = -4.403 + 2086/T + 0.06833 \ln T + 0.01268T \tag{2}$$

Here, K is distribution coefficient, T is extracting temperature.

Equation (2) can be introduced into Aspen Plus and used to simulate the extraction process.

3.2. Process Superstructure and MOMINLP Model

For a process having maximum number of three extracting stages, the superstructure is given in Fig. 4. The split ratio of logical splitters is 0 or 1. When split ratio of splitter 1 is 0, it means one-stage extraction; when split ratio of splitter 1 and 2 are 1 and 0, respectively, it means two-stage extraction; when split ratio of splitter 1 and 2 are all 1, it means three-stage extraction. Waste w is the total flow rate of MDA and aniline in brine discharged from the stripping tower bottom. Profit p is the cost of recovered MDA and aniline minus the cost of extracting equipment and operating cost which is the sum of direct steam cost and equipment running cost. The cost of tower is fixed and not calculated in profit p. The waste minimization model is shown as:

$$\begin{aligned}
&\max \quad p = 17.5(s_1 - s_3) + 7.7(s_2 - s_4) - 0.08d_2 - 5.63(1 + y_1 + y_1 y_2) \\
&\min \quad w = s_3 + s_4 \\
&\text{s. t.} \quad 300 \le d_1 \le 2000 \\
&\qquad 3000 \le d_2 \le 6000 \\
&\qquad y_1 = [0,1] \\
&\qquad y_2 = [0,1]
\end{aligned} \tag{3}$$

Here, p is process profit (¥/h), w is waste (kg/h), $d_1$is extracting aniline flow rate (kg/h), d_2 is steam flow rate of stripping tower (kg/h), y_1 and y_2 are split ratio, s_1 and s_2 are MDA flow rate and aniline flow rate (kg/h) in feeding brine, s_3 and s_4 are MDA and aniline flow rate (kg/h) in discharged brine, respectively.

3.3. Solving Process

The first thing to do is to build the process simulation file in Aspen Plus as shown in Fig. 4 and ensure the process simulation runs normally, then to design the interface for data and information transferring between Aspen Plus and NSGA-Ⅱ. For NSGA-Ⅱ, extracting aniline flow rate and stripping steam flow rate use real type coding, and split ratio of two splitters use binary coding. The number of population scale and generations are 40 and 60 respectively. The value of mutation rate and crossover rate are 0.8 and 0.01. Finally, the non-inferior solutions obtained by NSGA-Ⅱ are weighted and coordination solution is chosen to design process.

3.4. Results and Discussion

3.4.1. Initial Population of NSGA-Ⅱ

The distribution of initial population of NSGA-Ⅱ is shown in Fig. 5. It shows that :(1) the value of profit p and waste w varies quite largely within the given range of decision variables; (2) the changing tendency for most of the points in solution set is that the profit p decreases with the increase of waste w, these points are inferior solution points; (3) the top left-hand area of Fig. 5 is enlarged which is shown in Fig. 6, the results shows that non-inferior solutions appears in this area, in which the profit p increases with the increase of waste w.

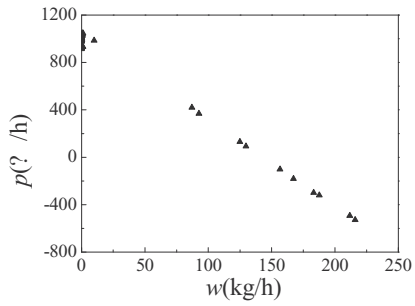

Fig.5 Initial population distribution of NSGA-Ⅱ

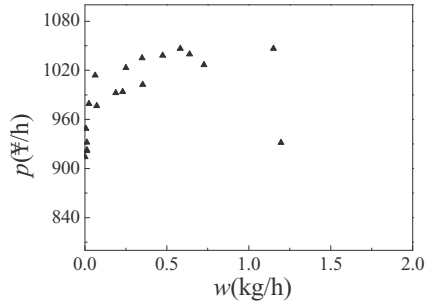

Fig. 6 Part of initial population distribution

3.4.2. Non-inferior Solutions

Fig. 7 shows the distribution of non-inferior solutions at 60th generation. The curve consists of three sections which identify three extraction structures respectively. The curve of the one-stage extraction is comparatively level, the waste w is larger and varies in a wide range, and the corresponding profit is also larger but varies in a very narrow range. The waste w and profit p both vary in a wide range for the two-stage extraction. The curve of the three-stage extraction is quite steep, the waste w is less and varies in a narrow range, and the corresponding profit p varies in a very large range.

If the amine contenting in brine is less than 0.02kg/h, it could be used to electrolyze directly. One-stage extraction process cannot meet the specification. By choosing right extracting aniline flow rate and steam flow rate, two-stage extraction process can meet the specification, but disturbance in operation may lead to fail easily. Three-stage extraction process can meet the specification in the most part of the operating range and

the operation is characteristic of robustness. To ensure the profit at a reasonable level, the choice of operating parameters is important for three-stage extraction in industrial process design. Considering the waste and profit, the operating parameters decided are as follow: the extraction aniline flow is 1875.6kg/h and stripping steam flow is 5039.6kg/h. The corresponding waste flow is 0.012kg/h and the profit is 977.8¥ /h.

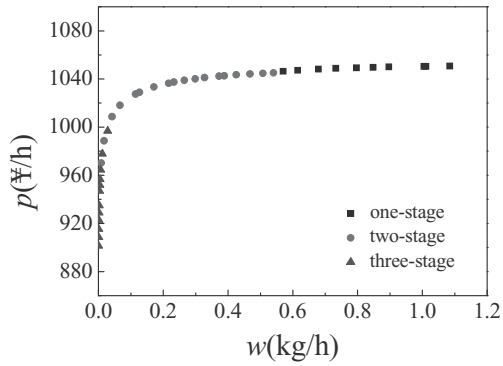

Fig. 7 Distribution of solutions at 60th generation

4. Conclusions

Three-layer solution strategy for multi-objective process synthesis based on module simulator Aspen Plus is proposed. The data and information is transferred by interface among simulation layer, synthesis layer and decision-making layer. MOGA has its advantages on solving MOMINLP which is simplified by using rigid process model in Aspen Plus. The results can be used to guide process design. The strategy was applied to a case study of the design of waste brine treatment process.

Institute of Chemical Engineering, Biotechnology and Environmental Technology, University of Southern Denmark, Niels Bohrs Allé 1, DK-5230, Odense M, Denmark; Tel. +45 6550 7481, email: bgr@kbm.sdu.dk

Abstract

A systematic method based on conceptual process synthesis for recovery of natural products from their biological sources is presented. The proposed methodology divides the task into two major subtasks namely, isolation of target compound from a chemically complex solid matrix of biological source and purification of the target compound from the crude extract. This methodology consists of three major separation techniques to achieve the task and provides a platform to generate different process alternatives by employing different combinations of separation units and with different set of key process variables. Decision making about the different combinations of separation units as well as key process variables is based upon the process information collected at every step with the help of process analytical techniques (PAT) and heuristics. The optimal combination of different separation units and set of key process variables is determined in an iterative approach. In the present work, this methodology is applied to isolate and purify artemisinin, an anti-malarial drug from the plant *Artemisia annua*.

Keywords: conceptual process synthesis, natural products, separation and purification, process flow sheet

1. Introduction

Natural products form a vast resource of compounds with unlimited chemical and functional diversity and also serve as a major resource for drug discovery. However, the isolation and purification of target compounds from their biological sources represents one of the most challenging tasks due to the presence of many other compounds in the biomass and also due to lack of basic process information. Associating compounds having similar chemical and physical properties to that of the target compound significantly influence the performance of a stand alone separation technique. In addition, the current chemical process industries face challenges like quicker development of new products and processes, making existing processes more efficient by reducing capital and operating costs, and improving the safety and environmental performance. To cater to these demands, a systematic approach in designing a commercial separation process consisting of multiple separation techniques for isolation and purification of natural products, which can evaluate different possible process alternatives within short span of time, is necessary.

The approach of conceptual process design provides such a systematic framework to rapidly evaluate different process alternatives and thus enable major decisions making at very low cost in a speedup way. It identifies the steps within a process that are the

most critical operations to determine the process economy and product quality. That will also provide insights into how costs can be reduced and what affects final product quality and thus guiding future research and development efforts. A detailed separation process design for recovery of natural products can be very time consuming and laborious, while a rapid conceptual process design can screen different process alternatives within short period of time with less resources used (Douglas J. M, 1988). A detailed description of manufacturing process design for phytochemicals along with heuristics is given by Harjo et al., while the effect of different process variables on the efficiency of different stand alone separation processes is described by Ndocko et al. However, there is scarcity of information on determination of synergistic effects between various separation processes used in combination for recovery of natural products.

The objective of this work is to perform a real case study to recover the target compound artemisinin from *A. annua*, which aims at providing a generalized model to evaluate different separation process alternatives for recovery of natural products. The methodology is expected to fit in the majority of natural product recovery problems. In the present work, the methodology is developed and formulated through evaluating different process alternatives for recovery of artemisinin from dried leaves of *A. annua*. The focus is on the interaction and synergistic effect between the chromatography and crystallization separation operations.

2. The methodology

The basic structure of the process model for isolation and purification of natural products is shown in Fig. 1. The task is divided into two subtasks of isolating the target compound from its source and then purification of the target compound from complex

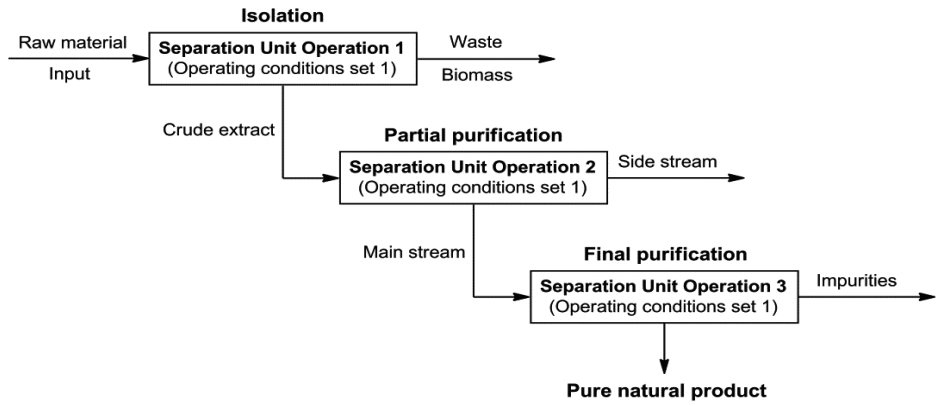

Figure 1. Basic process structure for isolation and purification of natural products.

crude extract. This methodology also emphasizes the use of process analytical technology (PAT) to analyze the process streams at various stages of the process in order to collect information about critical process parameters, which affects critical quality attributes as well as the overall design of the process.

2.1. Isolation

The process begins with the task of isolating target compound from the biomass designated by separation unit operation 1 (Fig. 1). Separation unit operation 1 can be represented by one of the numerous industrial applied separation techniques. A

comprehensive review of the separation techniques used to isolate natural products is given by Sarkar et al. The decision to pick up the best suitable one and selection of optimal operating conditions is product specific and depends upon many factors like amount of target compound present in the biomass, distribution of target compound in the source, final product specifications and also the physico-chemical properties of the target compound.

2.2. Purification

Taking into consideration the complex nature of the crude extract obtained from the previous step, the use of combined separation techniques is suggested for the purification of the target compound. In practice, high purity natural products can be obtained by highly efficient stand alone separation techniques like preparative high performance liquid chromatography (HPLC), but the cost of such process is always high. The present methodology suggests the use of preparative separation methods with less operating cost compared to, e.g. HPLC, to only partial purification of target compound combined with final purification by using cost effective techniques like crystallization. In this way, feasible process alternatives can be generated by employing different separation techniques with different arrangements in a sequence to achieve the tasks of isolation and purification of the target compound.

3. Case study of artemisinin from *Artemisia annua*

The proposed methodology is applied to generate process flow sheet alternatives to isolate and purify an anti-malarial drug, artemisinin from dried leaves of *A. annua*. In the present work, one such process flow sheet is evaluated in regard to the synergistic effect between chromatography and crystallization separation techniques. The basic process flow structure is shown in Fig. 2. Three major separation unit operations are used: solid-liquid extraction to isolate artemisinin into the crude extract, flash column chromatography (CC) to fractionate the crude extract, and crystallization to recover and purify artemisinin from the fractions of the crude extract.

3.1. Solid-Liquid Extraction

Artemisinin is extracted from the dried leaves of *A. annua* with dichloromethane (DCM) using maceration technique. DCM is chosen as the extraction solvent mainly due to the high solubility of artemisinin in DCM combined with its low boiling point that facilitates easy recovery of the solvent. The extraction procedure included immersion of 150 g of dried leaves containing 2.08% w/w artemisinin into 1 L of DCM followed by filtration after 5 hrs. The procedure is repeated one more time with 1 L of DCM. The combined DCM extract (2 L) is evaporated to obtain 12.5 g of crude extract. The concentration of artemisinin in the crude extract is determined by analytical HPLC–Charged Aerosol Detection (CAD). The yield of the extraction process in terms of artemisinin recovery using this extraction method is 90%.

3.2. Flash Column Chromatography

The crude extract obtained in the previous step is partially purified using flash CC to obtain artemisinin rich fractions with less number of other components. 15 g of crude extract is separated on a 7 cm diameter column filled with normal phase silica. Adsorbent (silica gel) to solute (crude extract) ratio of 20:1 is used. Gradient type of elution is used to run the column under the applied pressure. The eluent was selected based on the results of solvent screening by thin-layer chromatography (TLC). Column conditioned with 100% *n*-hexane and the gradient starts with 100% *n*-hexane followed by 10% stepwise gradient from 100 % *n*-hexane to 100% ethyl acetate.

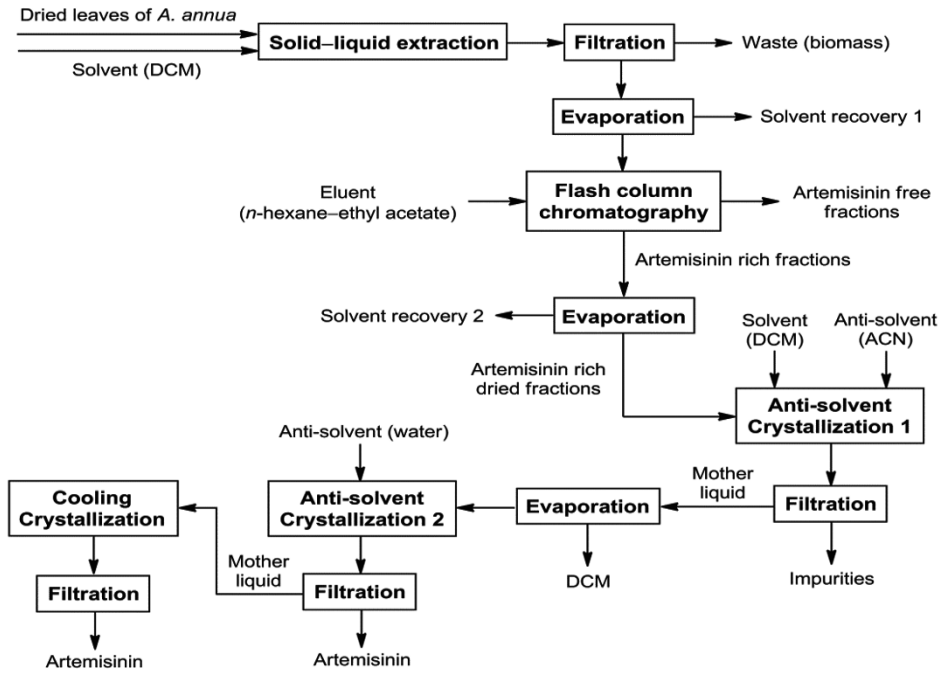

Figure 2. Process flow sheet for isolation and purification of artemisinin from dried leaves of *A. annua.* (DCM: dichloromethane, ACN: acetonitrile)

Each gradient of 900 mL is used and the size of fractions collected is 100 mL. Collected fractions were analyzed by TLC to identify the artemisinin rich fractions and these were then analyzed by HPLC–CAD for quantification of artemisinin. The results of this analysis are shown in Fig. 3.

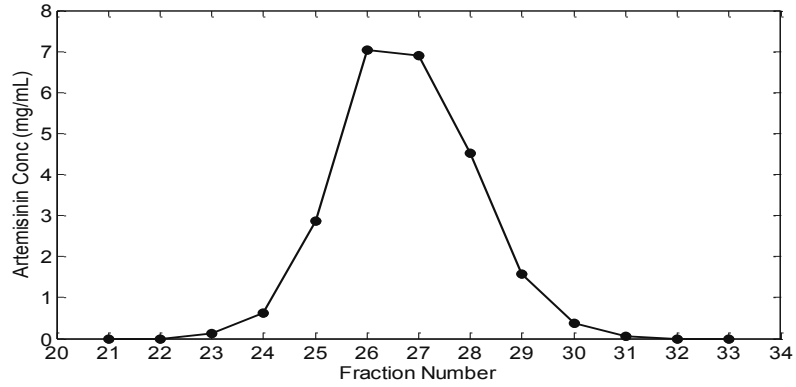

Figure 3. Concentration profile of artemisinin in fractions obtained by flash CC.

3.3. Crystallization

The artemisinin containing fractions obtained in the previous step are purified further by using a three-step crystallization process as shown in Fig. 2. The two-step anti-solvent crystallization process has been reported in our previous work by Qu et al. The artemisinin rich fractions 25-28 are processed individually, whereas fractions 23-24 and

29-31 are combined together to form two fractions. However, no artemisinin is crystallized out from these combined fractions because of the low concentration of artemisinin. Yield and purity of artemisinin crystals obtained from each fraction are shown in Table 1. Artemisinin is crystallized from fractions 25-28 with varying purity and yield. One remarkable observation from Table 1 is that the yield of artemisinin from fraction 25 is much higher than that from fractions 26, 27, and 28; regardless of the higher artemisinin concentration in the fractions 26-28. This fraction wise variation in purity and yield of artemisinin may be attributed to the associating compounds present in the fractions, which might be affecting the solubility of artemisinin and furthermore some of which may have crystallization behavior similar to artemisinin during the anti-solvent crystallization. FT-Raman spectroscopy measurement confirmed that thermodynamically stable orthorhombic polymorph of artemisinin has been obtained from all fractions.

Table 1: Purity and yield of artemisinin obtained from fractions during crystallization process.

Fraction No.	Artemisinin purity		Yield (%)
	Anti-solvent Crystallization2 (%)	Cooling Crystallization (%)	
25	91.37	100	87.4
26	84.85	92.35	45.8
27	100	100	64.0
28	66	100	28.8

4. Conclusion

The systematic method for synthesis of conceptual processes for isolation and purification of natural products from plants is investigated. A case study for recovery of artemisinin from dried leaves of *A. annua* is performed. Three major separation techniques of maceration extraction, flash CC and crystallization are selected to formulate the process flow sheet. Lab scale experiments are studied to confirm and understand the effectiveness of the separation methods. To do so, PAT is used in each step to get the necessary information and data of the process. The results showed that the formulated process flow sheet is feasible to isolate and purify the target compound artemisinin from *A. annua*. One outstanding observation is that the associating compounds in the fractions have significant effects to the purity and yield of the target compound artemisinin during crystallization steps. This indicated that seeking synergy between chromatography and crystallization to obtain optimal hybrid separation process is the key direction for commercial manufacturing process of artemisinin from *A. annua*. Effort in this direction is underway.

Abstract

A novel approach is presented for the automated generation of models representing superstructures for the synthesis and optimization of distributed energy supply systems (DESS). Based on a basic problem description (load cases, available technologies, and topographical constraints), the proposed algorithm automatically generates a model accounting for time-varying load profiles and part-load dependent operating efficiencies. Building upon the P-graph approach, the derived superstructure is extended to include multiple redundant conversion units as required for DESS optimization. In the present implementation, a GAMS model is generated that can be readily optimized. The approach is applied to the retrofit synthesis of the energy supply system of an industrial site. It is shown that the automated procedure provides a convenient and efficient optimization framework for DESS.

Keywords: Distributed Energy Supply Systems, Synthesis and Optimization, MINLP, MILP, Superstructure generation, P-graph.

1. Introduction

Distributed energy supply systems (DESS) are highly integrated and complex systems. In particular, DESS design principles are fundamentally different from classical chemical plants as the following simple example shows: Consider the total cost optimization of a heating system for a single time-varying heat demand (Fig. 1 a).

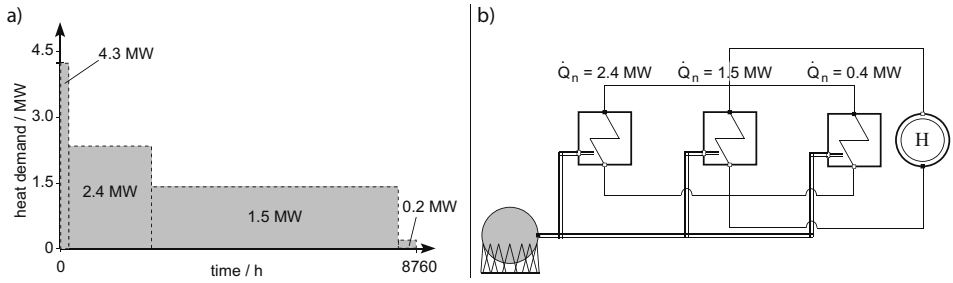

Fig. 1. Time-varying heat demand (a) and optimal heating system (b) covering this demand.

Even if only a single technology such as a simple boiler is considered, the grassroots design problem becomes challenging due to the trade-offs between

- economy of scale of the equipment investments,
- equipment performance in part-load operation, and
- minimum operation loads of the equipment.

On the one hand, the boilers' total capacity has to cover the maximum heat demand, and economy of scale favors large over small equipment; on the other hand, the boilers' efficiencies drop at part-load operation, and thus full-load operation is beneficial. Moreover, boilers must not be operated below their minimum part-loads, and therefore boilers need to be sized small enough to cover the minimum loads. For the considered example, these trade-offs enforce the installation of three redundant boilers in the optimal configuration (Fig. 1 b). This shows that multiplicity and redundancy of energy conversion units should generally be considered for DESS synthesis problems.

The intrinsic properties of DESS have to be reflected in an optimization model. Therefore, both the superstructure generation and optimization are difficult tasks leading to MINLP problems with time-dependent constraints (e.g., demand profiles). For solving these problems, algorithmic approaches rely on the use of mathematical programming techniques [1-2] to optimize a given superstructure. Thus, the designer needs to decide *a priori* which alternatives should be encoded in the superstructure, and thereby runs the risk to exclude the optimum from consideration. Since manual superstructure generation is an error-prone task, automated methods are desirable.

For process network synthesis (PNS) problems, the P-graph [3] based PNS framework has been developed. P-graphs are graph-representations of process networks enabling to employ efficient graph-theoretic algorithms for automated superstructure generation [4] and optimization [5]. Recently, the P-graph approach has been applied successfully to the synthesis of energy systems [6]. However, since the current PNS framework has been developed for synthesizing chemical plants, it does not consider time-varying boundary conditions and part-load dependent equipment performance – features that have a strong impact on the performance of DESS as demonstrated above. Moreover, in case of classical PNS problems, multiplicity and redundancy are often regarded as shortcomings of the problem formulation [7]. The current PNS framework therefore requires manual manipulations to incorporate multiple redundant equipment in the superstructure.

In this paper, an automated superstructure and model generation algorithm is presented accounting for time-dependent boundary conditions, part-load performance, as well as multiplicity and redundancy of energy conversion units as key features of DESS.

2. Automated superstructure and model generation

This section describes the proposed algorithm for automated generation of DESS superstructures represented as MI(N)LP models (Fig. 2). The starting point is a set of simple user inputs defining the synthesis problem: energy demand time series, existing equipment, available new technologies, number of redundant units n to be considered in the superstructure, and topographical constraints. Next, the P-graph based *maximal structure generation* (MSG) algorithm [4] is employed to generate a P-graph superstructure, which contains only one unit of each technology. Then, this superstructure is expanded to incorporate n redundant units: For this purpose, the generated superstructure is represented by a connectivity matrix whose rows and columns represent final energy users (e.g., demands for heating and cooling) and generators (e.g., boilers, absorption and compression chillers), respectively. Absorption

chillers take a special role as they represent both final energy users (driving heat) and generators (refrigeration). The entries of the connectivity matrix represent the connectivity between users and generators: If a generator is connected to a user, the entry in the corresponding row and column is 1; otherwise, it is 0. For superstructure expansion, all columns representing generators are copied *n*-times. The same applies to all rows representing the demand for driving heat of absorption chillers.

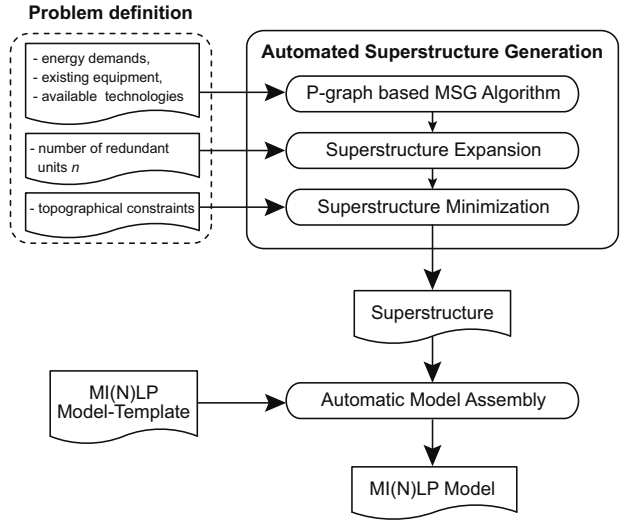

Fig. 2. Flowchart of the algorithm for automated MI(N)LP model generation.

If specified, topographical constraints are taken into account to reduce the generated superstructure by cutting infeasible connections, or more technically, assigning zeros to the corresponding matrix entries. To assemble the final model, the user can use arbitrary MI(N)LP model-templates, which are initialized by the generated connectivity matrix.
In the present implementation, a GAMS model [8] is generated that can be readily optimized using standard solvers. This model employs an MILP formulation [9] based on quasi-stationary energy balances and equipment performance functions accounting for time-varying load profiles and part-load dependent operating efficiencies.

3. Case study: Retrofit extension of an industrial site

The proposed framework is applied to the retrofit synthesis of an industrial site, which is extended by a new production facility. The available energy conversion technologies are listed in Table 1. The optimization is performed maximizing the net present value (NPV) with a cash flow time and discount rate of 10 years and 8 %, respectively.

Table 1. Available energy conversion technologies including their power and price ranges.

Technology	Thermal power range / MW	Price range / 10^3 €
Boiler	0 - 5.0	0 – 160
CHP engine	0 - 3.2	0 – 850
Absorption chiller	0 - 5.0	0 – 360
Turbo-driven chiller	0 - 5.0	0 – 790

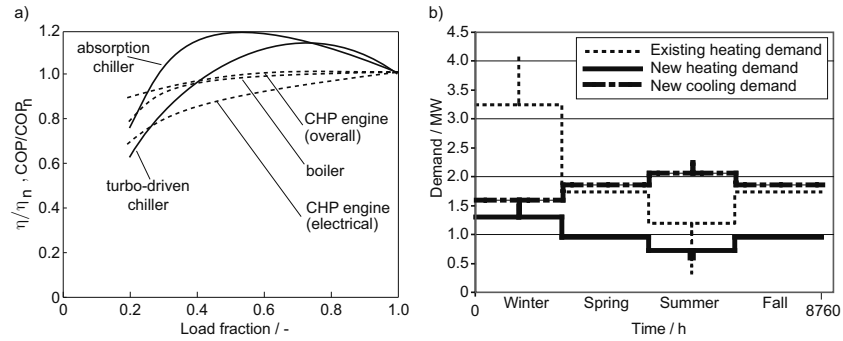

Fig. 3. Part-load performance curves (a) and simplified annual demand profiles (b).

Fig. 3 a) shows the characteristic curves of these technologies, i.e., the boiler efficiency, η, the CHP engine's overall and electrical efficiencies, η_{th+el} and η_{el}, and the chillers' coefficients of performance, COP. While boilers and CHP engines are subject to efficiency losses in part-load operation, chillers have maximum efficiencies in part-load operation. For all technologies, the minimum part-load is assumed to be 20 %. Fig. 3 b) illustrates monthly-averaged existing and new energy demands of the considered industrial site. Peak loads are modeled by spikes on top of the averaged demands.

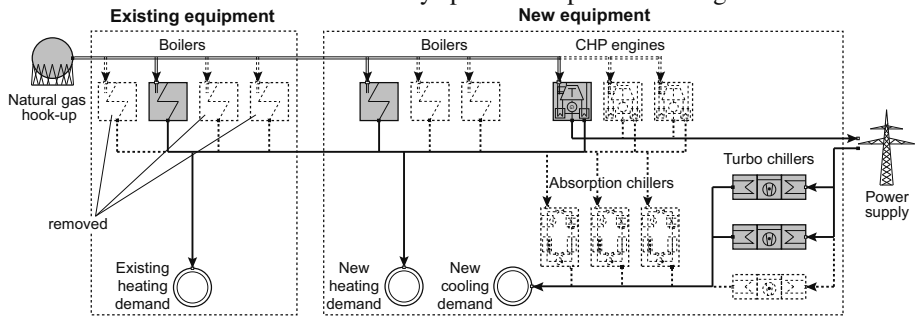

Fig. 4. Superstructure and optimal solution (units in grey) for the retrofit synthesis problem.

Fig. 4. shows the superstructure and the optimal solution obtained when the automated model generation algorithm and an MILP optimization is applied. The superstructure incorporates existing as well as new equipment. The number of redundant units considered is n = 3. In the optimal configuration (NPV = -6.15 Mio. €), three of the existing boilers are replaced by one new boiler and one CHP engine; furthermore, two turbo-driven chillers are installed on-site. Table 2 lists all units of the optimal solution including nominal powers and investments.

Table 2. Nominal thermal powers and investments of the installed equipment.

	Boiler 1	Boiler 2	CHP engine	Chiller 1	Chiller 2
Thermal power / MW	2.0	1.5	3.1	0.9	1.8
Investment / 10^3 €	0 (existing)	70	820	160	300

In optimal operation, the CHP engine covers 88 % of the total heat demand. Except during summer, it constantly runs at full load, and thus generates a considerable amount of feed-in electricity. The new boiler is operated in winter and in summer for the minimum heat loads. The existing boiler is reserved to solely meet the peak load

requirements in winter. The installation of two chiller units in the cooling system allows for load sharing enabling to run both units close to their maximum COP year-round.
Noteworthy, the optimal solution contains both redundant boilers and chillers. Since the superstructure offered even more redundant units than used in optimal configuration, the choice of $n = 3$ redundant units is considered to be sufficiently large for this problem. For comparison, a superstructure prohibiting any redundancy would lead to 10.4 % higher costs.

4. Summary and conclusions

This paper proposes a generic framework for the automated model generation for superstructures of distributed energy supply systems (DESS) incorporating multiple redundant energy conversion technologies. The generated models account for time-varying load profiles and part-load performance as key features for DESS optimization. In the present implementation, a GAMS model is generated that has been successfully applied to the retrofit extension of an industrial site. It is shown that the automated procedure provides a convenient and efficient optimization framework for DESS synthesis problems.

Abstract

The current project focuses on the design and optimization of chemotherapy protocols for Acute Myeloid Leukaemia (AML). AML is a type of blood cancer in which patients are characterized by a weakened blood and immune system due to abnormalities in the bone marrow where the tumour is located. In that respect, there is a high risk that the patient will not withstand the treatment due to life-threatening toxicities of the chemotherapeutic drug mix. Therefore the individualization and optimization of treatment dose and schedule is essential to balance the benefits of higher dose therapy against the tumour with the toxicity to normal tissue. This balance can be achieved by modelling key biological mechanisms as a means to gain insight into the effects of chemotherapy, which can then be used as a predictive tool for patient response during treatment (Dua, 2005; Dua,2008).In this work, we extend our previous model (Pefani et. al., 2011) for the first cycle of chemotherapy for the treatment of AML to include the chemotherapeutic drug action of both anticancer drugs used in current treatment protocols: cytarabine (Ara-C) and daunorubicin (DNR). The simulation and optimization results demonstrate the need for optimal treatment schedule in order to limit the life-threatening toxicities of chemotherapy-induced cytopenia in patients with AML undergoing treatment.

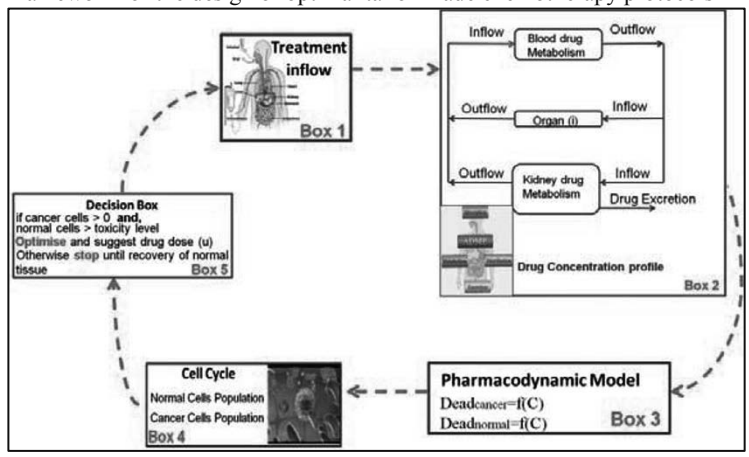
Keywords: Mathematical modelling, chemotherapy optimization, pharmacokinetics, pharmacodynamics.

1. Framework for the design of optimal disease and patient-specific chemotherapy protocols

Most cancers are treated with chemotherapy, anti-tumour drugs which can be equally as toxic to the patient as they are to the cancer and with effects dependent on the characteristics of the patient, the stage of disease and the type, dose and schedule of anticancer drugs used. Current treatment protocols are designed based on empirical rules from the physicians' acquired experience, usually through collection of data from clinical trials. A more systematic and efficient approach for the design of treatment protocols, such as through mathematical modeling, is required. These mathematical models should be able to adequately describe the behavior of the organism under treatment and the tumour being eradicated, leading to an optimal individualized chemotherapy treatment protocol. Such models are lacking in the open literature as most of them fail to include in detail

the above mentioned aspects and are based on empirical assumptions (Afenya, 2001; Fister, 2000; Sherer, 2006).
The models aiming to describe chemotherapy action should consist of mathematical expressions for all steps of treatment, from drug administration through to intracellular drug action. All these parts are described in fig. 1, wherein the general framework for the derivation of such a mathematical model is described.

Figure 1: Framework for the design of optimal tailor-made chemotherapy protocols



To start, the initial dose given to the patient in combination with the administration route and the injection rate will be used for the calculation of the treatment inflow (box 1: fig. 1) that is the main input for the pharmacokinetic model (PK) (box 2: fig. 1). The PK model depends on patient characteristics and is comprised of the set of drug mass balances in patient organs for calculation of the drug concentration profile. This profile is the main input for the pharmacodynamic (PD) model (box 3: fig. 1). The PD model calculates the number of both normal and cancer cells which have died due to drug administration which are then successively subtracted from the starting number of cells in order to calculate the number of each cell type which remain following the chemotherapy cycle (box 4: fig. 1). Thereafter, a new optimization problem will be introduced and solved (box 5: fig. 1) only if there are tumour cells still present (in this model) and normal cells are in sufficient number such that the patient can tolerate another chemotherapy cycle. With this framework, optimal chemotherapy cycles will be designed based on patient characteristics (data input in box 2) and disease characteristics (data input in box 4).

2. Mathematical Modeling

In accordance with the presented framework in the previous section, the mathematical model should consist of the cell cycle model combined with relevant aspects of PK and PD. The general structure of the mathematical model for the AML patients' behavior (including tumour) during treatment is presented in table 1.

Table 1: Structure of the proposed mathematical model for AML patients' response to chemotherapy

$\inf low_j = \frac{u_j}{rate_j}$	(1)	$inflow_j$:treatment inflow of drug j u_j: dose load of drug j $rate_j$: administered rate of drug j

$\dot{C}_{b,j} = Q_i \cdot C_{bj} - Q_b \cdot C_{b,j} + \inf low_j$	(2)	$C_{b,j}$: drug concentration in blood of drug j Q_i: blood flow of organ i:kidney,liver,heart,marrow e.t.c
$\dot{C}_{M,j} = Q_M \cdot C_{bj} - Q_M \cdot C_{M,j}$	(3)	$C_{M,j}$: drug concentration in marrow of drug j
$Dead_j = \frac{E_{\max} \cdot C_{M,j}^{slope}}{EC_{50}^{slope} + C_{M,j}^{slope}}$	(4)	$Dead_j$: number of dead cells because of drug j action E_{max},EC_{50},slope: drug pharmacodynamic parameters
$CancerCells = S + G_1 + G_2M$	(5)	
$\dot{S} = -\mu \cdot S + k \cdot G_1 - \lambda \cdot S - Dead_j$	(6)	S: cancer cells in proliferating phase μ,k,λ: transition rates between phases
$\dot{G_1} = -\mu \cdot G_1 - k \cdot G_1 + 2 \cdot d \cdot G_2M - Deadj$	(7)	G_1: cancer cells in growth phase d:proliferation rate
$G_2\dot{M} = -\mu \cdot G_2M + \lambda \cdot S - d \cdot G_2M$	(8)	G_2M:cancer cells in the pre-mitotic and mitosis phase
$NormalCells = P + Q$	(9)	
$\dot{P} = (a - m - n) \cdot P + b \cdot Q - Dead_j$	(10)	P:normal cells in proliferating phase a,m,n,b: transition rates between proliferating and non-proliferating phases
$\dot{Q} = m \cdot P - b \cdot Q - Dead_j$	(11)	Q:normal cells in non-proliferating phase

To start, the dose u_j of drug j is used for the calculation of treatment $inflow_j$ (eq. 1) that is the main inflow for the calculation of drug concentration in blood (eq. 2). Successively, the drug concentration in the organs (i.e. kidneys, liver, heart, bone marrow) is calculated and the drug concentration in bone marrow $C_{M,j}$ (eq. 3) (tumour location) is used by the PD model (eq. 4) for the calculation of dead cells. Dead cells are thereafter subtracted from the starting cell number (eq. 5-eq.11) for the calculation of the new state of normal and cancer cells after this dose administration. These expressions form the equations of the optimization problem wherein the objective is to minimize the number of cancer cells and maximize recovery by keeping normal cells above a certain level as required by the patient for survival of normal tissue.

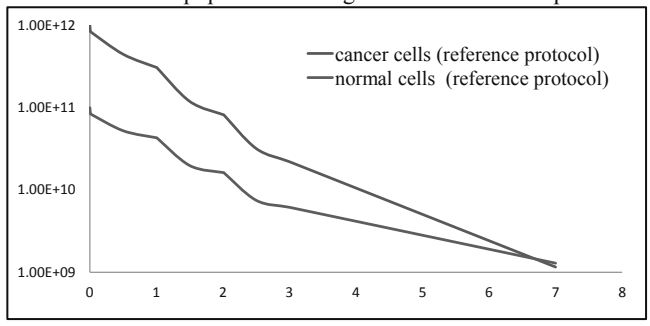
3. Patient case study

A case study of a man weighting 70 kilograms and 1.80 metres in height is presented using Ara-C and DNR combination treatment. Both chemotherapy agents are cell-cycle specific. In particular, DNR is an anthracycline antitumour agent that is metabolized to daunorubicinol, an active metabolite with the ability to prevent DNA and RNA formation by interferring with cells in G_1 and S phase of the cell cycle (Huffman, 1972). Ara-C is an anti-neoplastic drug that is intracellularly activated to Ara-CTP a metabolite that acts on S-phase of the cell cycle to block DNA expression in order to cease cell proliferation (Kufe, 2006). This specificity of the drugs makes the role of cell cycle critical for the validity of the model as the cell cycle phase distribution profile is a parameter required in order to adequately assess the effects of chemotherapy on the tumour. However, this level of knowledge is limited and detailed experimental data are required for system representation. In lieu of this representation, as a first step in the current work we assume a cancer and normal cell population and the case study is solved for some assumed characteristics of these cell populations. To be more specific,

we assume that the initial distribution in the normal cell population is 75% in non-proliferating and the remaining 15% in proliferating phases (Afenya, 2001). Moreover, the percentages used for the cancer cell population are 70% of cell population will be in proliferation phase and 30% in non-proliferating phase (Wilkoff, 1967). The distribution of cells into cell phases is a parameter that varies tremendously between patients (Preisler, 1995) however the assumed distribution shares a certain amount of validity if we consider that cancer cells are characterized by a higher proliferation rate than that of normal cells (Afenya, 2001). The initial AML tumour burden is assumed to be 10^{12} leukaemic blasts with concomitant 10^{11} normal cells within the bone marrow organ at presentation (Williams, 1983). PK parameters for Ara-C are taken from (Dedrick et al., 1972) while PK parameters for DNR are from (Loveless, 1978). Lastly PD parameters for both drugs were found in the work of (Quartino, 2007).

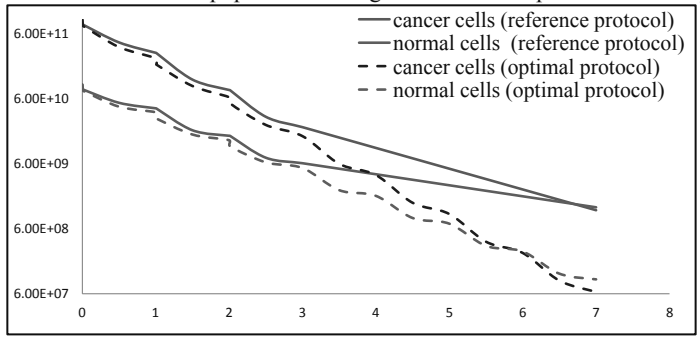
The model is solved for the treatment protocol in (Quartino, 2007) to be in accordance with the PD data used for the two drugs. According to this protocol a total of 700mg/m^2 dose of Ara-C is given as continuous infusion over 7 days and 45mg/m^2 of DNR as daily bolus during the first three days. Simulation results are obtained from this protocol and can be seen in fig. 2 for normal and cancer cells. Normal cell population is decreasing from 10^{11} to $1.29\text{x}10^9$ cells and cancer cells from 10^{12} to $1.16\text{x}10^9$ cells.

Figure 2: Normal and cancer cell population during reference treatment protocol



The minimum accepted level of normal cells during the induction period is set to 3-log cell destruction, which would equate to $1\text{x}10^8$ cells by the completion of induction treatment. Apart from keeping normal cells above this level, the treatment objective is to achieve more normal than cancer cells in the bone marrow. This problem was formed and solved using gOPT (gPROMS, 2003) and the optimal treatment schedule suggests an increase of Ara-C that to total dose of 1400mg/m^2 continuously given over 7 days and DNR dose to 45 mg/m^2 bolus injection during the first three days of treatment.

Figure 3: Normal and cancer cell population during reference and optimal treatment protocols



During the optimal treatment scenario cancer cells are further decreased leading to 6.42 $x10^7$ cells by the end of the treatment, while normal cells reach the minimum accepted level of 10^8 cells. Thus cancer cell population is further decreased making a difference of $1.08x10^9$ cells less comparing to the reference treatment protocol while the resulting bone marrow is of higher level of normal than cancer cells (fig 3).

4. Concluding Remark

In this paper, an optimal control model for the scheduling of AML treatment with Ara-C and DNR is proposed. A case study of an adult man of 70 kg and 1.80 m is analysed. The model is simulated for the induction period of chemotherapy only using combination of 700 mg/m^2 Ara-C continuously infused for 7 days and 45 mg/m^2 DNR given by rapid intravenous injection for 3 days.

Simulation results are obtained showing both normal and cancer cell populations decreasing during the chemotherapy treatment. An optimization problem was formulated and solved using gPROMS with objective to further minimize cancer cell population while obtaining a bone marrow with higher percentage of normal cells. Optimization results suggested higher dose of Ara-C and same dose of DNR and this treatment protocol results in $1.08x10^9$ less cancer cells during the optimal scenario comparing to the reference treatment protocol while normal cell population is higher comparing to the cancer cell population. Optimization results are satisfactory as the AML cell population has decreased enough to debulk the marrow of tumour and the normal cell population is in adequate number to allow for normal tissue recovery prior to the next cycle of chemotherapy to further decrease AML cells. The study demonstrates the clear need for optimal treatment schedule during all cycles of chemotherapy in order to limit life-threatening toxicities of long-term cytopenias in patients with AML undergoing treatment.

Abstract

Achieving calcium homeostasis in the human body, whereby extracellular fluid calcium is maintained within a narrow range (2.4±0.25mM) necessary for normal physiological function, is the task of a biological control system that is still not completely understood. Although general information is available on several of the component processes involved in calcium homeostasis, there is currently no mechanistic understanding of the emergent characteristics of the entire system. To this end, we present an engineering control framework for understanding calcium homeostasis, which is predicated on a configuration of the physiological system in terms of appropriately connected control system components (sensor, controller and actuator). Using information from the literature, we develop mathematical models for each component and integrate them into a holistic, comprehensive dynamic model of the complete system. The framework enables a more systematic study of observable physiological responses such as hypo- and hypercalcemia; it also allows us to interpret pathologies in terms of control system component defects.

Keywords: Calcium homeostasis, mathematical model, calcium control system, parathyroid hormone, Ca-PTH,

1. Introduction

Calcium (Ca) homeostasis is a condition in which, in spite of varying physiological conditions (e.g., lactation, excess or inadequate Ca intake or excretion), the calcium concentration in the human extracellular fluid (ECF) is maintained within a narrow range of 2.45 ± 0.25mM (Parfitt, 1993). This is achieved by a sophisticated biological control system.

Under normal conditions, low Ca levels stimulate the secretion of parathyroid hormone (PTH) from the parathyroid gland (PTG). Subsequently PTH stimulates the production of calcitriol (CTL) from the kidneys, increases renal Ca reabsorption and, stimulates bone cell proliferation, leading to a net bone Ca release. High CTL levels stimulate increased intestinal Ca absorption, inhibit PTH secretion through lowering the PTG capacity, and promote bone cell proliferation. Conversely, high Ca levels cause reduced PTH secretion, increased renal Ca excretion and, net bone formation (Parfitt, 1993).

In this paper, we present a control engineering perspective of plasma Ca homeostasis. The approach provides an efficient structure for organizing the complex and detailed microenvironment information about Ca regulation and the various physiological sub-processes involved. First, we represent the regulatory organs and associated processes involved in Ca homeostasis as a control system comprising sensor (PTG), controller (PTG) and actuators (kidneys, bone and intestines). Here the process is the ECF Ca. Next we develop mathematical models for each of the control system components. Finally, we simulate clinically induced conditions in order to provide quantitative insight into (a) how ECF Ca is regulated within this narrow range, and (b) the meaning of control system component defects in the physiological context.

2. Model Development

Standard conservation of mass principles applied to each component sub-process, lead to mathematical models that represent the dynamic behavior of PTH, CTL, bone cell proliferation, ECF Ca and phosphate. The models are in the form of a system of nonlinear ordinary differential equations. We assume that all hormones and ions are uniformly distributed in the ECF; also their concentrations are similar to those in the plasma. Unless otherwise stated, the following holds: 1) the rate of secretion, production or proliferation and any hormone/ion dependencies are described by the four-parameter logistic function H_{ij} (i is the ion/hormone in the j[th] compartment); 2) in H_{ij}, estimates for the mid-point for half-maximal secretion (S_{ij}) were solved at initial conditions; 3) the literature model refers to that from Peterson and Riggs (2010); 4) Ca refers to ionized Ca; 5) phosphate transfer rates for renal excretion (ν_{23}), intestinal absorption(ν_{24}), bone (ν_{25}) and intracellular (ν_{28}) flux are as described in the literature model; and, 6) parameter were estimated and ODE solved using Simulink in MATLAB.

A detailed description of Ca homeostasis framework as a closed-loop control system with feedback follows. The relevant equations and parameters are listed in Tables 1 and 2.

Sensor/Controller: PTG – For the sensor, direct proportionality is assumed between the detected Ca (u_{12}) and the ECF Ca (x_{11}). In the controller, PTH (u_{31})

production/secretion is dependent on the sensor output (u_{12}) and CTL-stimulated PTG capacity (u_{56}). Their expressions are from the literature. The logistic function (H_{12}) for the Ca-induced secretion is modified to ensure appropriate responses to both hypo- and hypercalcemia and is addressed in the discussion. Finally, PTH decays at a rate of k_{31}.

Actuator: Kidneys (CTL production) – CTL (u_{41}) production is tightly regulated by PTH, the CTL decay rate (k_{41}) and ECF phosphate levels (x_{21}). Parameters for PTH-dependent rate (H_{31a}) and the phosphate-dependent rate (H_{21}) were determined from data by Horwitz et al. (2005).

Actuator: Kidneys (Ca Reabsorption) – A piecewise continuous function (v_{13}) is defined for Ca excretion. Above the Ca threshold, a Ca-dependent linear relationship holds. Below the threshold, Ca reabsorption is distributed between PTH-dependent (H_{31b}) and passive amounts. The Ca threshold is the Ca level at which the PTH dependent excretion is maximum and equal to the linear excretion.

Actuator: Intestines (Ca absorption) –Intestinal Ca absorption (v_{14}) depends on daily Ca intake (Π_{14}) and occurs via both a passive (λ_{14}) and an active (H_{41}) pathway.

Actuator: Bone Formation and Resorption – The bone cell and growth factor proliferation models for osteoblasts (u_{65}), osteoclasts (u_{75}) and RANKL (u_{85}) are unaltered from Lemaire et al., (2004) and the Ca flux from bone (v_{15}) is described by the literature model. Finally, the stoichiometric ratio (λ_{25}) of phosphate to Ca in hydroxyapatite is used to determine the phosphate flux (v_{25}) between ECF and bone.

Process: ECF Ca and phosphate - are determined from the net ion transfer rates from the kidneys, intestines, bone and any disturbance (v_{17}).

3. Results and Discussion

Although we generated more simulation data (e.g. CTL, bone Ca and intestinal Ca) from our model than is published in the literature, due to space limitations, the results presented here focus on comparisons with available Ca-PTH data. Also, for ease of comparison, our results are presented as ratios relative to baseline.

From our proposed framework, we are able to replicate clinical interventions of hypo- and hypercalcemia Fig. 1 [Ca (Sim) and PTH (Sim)]. The infusion protocols, which are the disturbances in our system, are similar to those described for the trials.

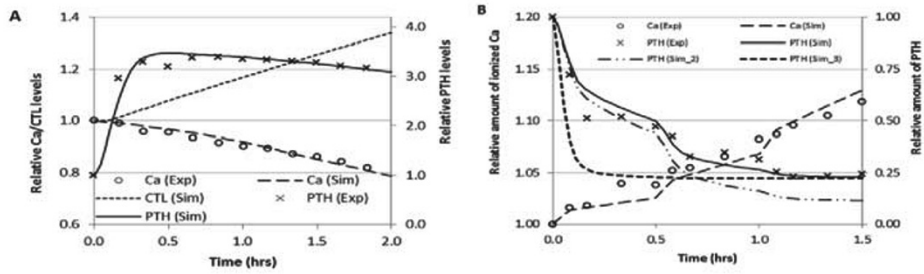

Fig. 1. Simulation of (A) hypocalcemia (Ramirez et al, 1993) and (B) hypercalcemia (Haden et al; 2000)

We estimated the parameters for H_{12} by fitting the model to data for induced hypocalcemia as shown in Fig. 1A. Using these parameters, we simulated hypercalcemia; however, we noticed that the PTH had a faster response and reached steady-state much sooner than the clinical data, [PTH (Sim_3)] in Fig. 1B.

These observations are consistent with those in Shrestha et al. (2010). Although their model was not a fully integrated Ca homeostatic model, they noted that model parameter estimates developed from hypocalcemia data could not predict hypercalcemic PTH response. This phenomenon has also been observed in clinical studies and can be attributed to hysteresis in the PTH response between hypo- and hyper-calcemia (Diaz et al., 2010). To account for this, we modeled H_{12} as an asymmetric logistic function, where the constant exponent was replaced by a Ca-dependent logistic function. This modification significantly improved the PTH response [PTH (Sim)].

We also observed that the minimal and maximal PTH secretory rates (A_{12} andB_{12}) were sensitive to different datasets. PTH (Sim_2) in Fig. 1B shows the result when the minimal secretory rate from one dataset is used to simulate another. Here, the final PTH level for PTH (Sim_2) is 50% lower than PTH (Sim) and the experimental data.

These findings are comparable to clinical observations, which suggest that there are in-group variations in Ca-PTH dynamics. Haden et al. (2000) found that ageing was associated with an increase in PTH secretory response to Ca changes. They also showed that, there were wide variations in the maximal and minimal PTH levels within the same age and ethnic groups. In the data used for comparisons, the subjects were young white men aged 26.6 ± 1.3yrs (Haden et al., 2000) and, a mix of young men and women aged 21 ± 2yrs of unreported ethnicities (Ramirez et al., 1993).

The utility in the proposed framework lies in the insight it provides with changes to control system components. To test this hypothesis, we introduced a gradual decrease in sensor gain (λ_{12}) (from 1 to 0.9) over a one-month period, and then held it steady for an additional 11 months. In Fig. 2, there is a gradual increase in the Ca level, up to a maximum of 1.1 above baseline. Likewise, the PTH level reaches a maximum of 1.1; however, this is attained over the 1-yr period rather than one month for Ca increase. As the excreted Ca is partly PTH-dependent, there is a concurrent gradual but significant 25% reduction in renal Ca with increase in PTH.

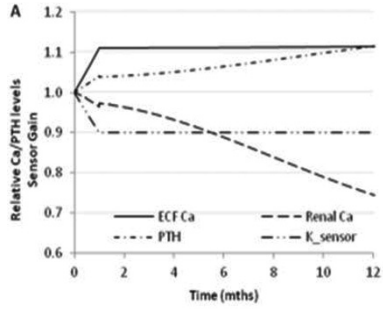

Fig. 2. Ca homeostatic response to sensor gain reduction

Again, these outcomes are in accordance with pathological cases. Familial hypocalciuric hypercalcemia (FHH), an inherited genetic condition, is characterized by mild hypercalcemia, normal-to-slightly elevated PTH levels and low urinary Ca excretion. More than two-thirds of families with FHH have inactivating mutations in the Ca-sensing receptor (CaR) gene, which result in varied levels of receptor inactivation (Yano and Brown, 2005). Therefore, this reduction in sensor gain mimics the behavior of a form of genetic mutation of the CaR.

4. Conclusions

This paper focuses on an engineering control system framework proposed for understanding Ca homeostasis that is based on developing/assembling appropriate computational models for each of the control system components. We have shown that we can simulate clinically induced hypo- and hypercalcemia with our model and account for hysteresis in the Ca-PTH secretory response. Furthermore the results show that variations in in-group demographics affect Ca-PTH response. Finally the results indicate that a gradual reduction in sensor gain is consistent with a type of genetic mutation in the CaR, which causes FHH.

Abstract

In this paper we present a novel technique for 3D micro capillary bed model reconstruction and computational fluid-dynamics (CFD) calculation to simulate morphological and blood perfusion parameters. Major arterial and venous cerebral blood vessels were reconstructed from scanning electron microscope (SEM) images and vessels whose diameters are beyond the resolution of modern imaging techniques were grown from this base structure using our novel directed interactive growth algorithm (DIGA). 3D voronoi networks were used to represent the microvasculature capillary network that joins arterial vessels to adjacent draining veins. The resulting network is morphologically accurate to *in vivo* measurements of the functional unit with accurate measurements of vessel density (3.17%) and surface area to tissue volume ratio (5.84%). Perfusion patterns of supply to the functional unit and systemic pressure drops match those expected in living tissue and indicate the model is a good candidate for exploring the hemodynamic phenomenon of autoregulation.

Keywords: micro vascular, functional blood unit, hemodynamics, cerebral vasculature

1. Introduction

Many questions regarding cerebral hemodynamics and control of cerebral blood flow remain unanswered due to the complex architecture of the cerebral vascular network. Clusters of a single draining vein surrounded by a ring of three to six arterioles were discovered to provide the blood supply to the cortex [1]. The separate independents units appear to form a functional blood unit (FBU) serving a critical physiological role in the micro vascular network of the human brain by facilitating the efficient distribution of oxygen and nutrients to their associated clusters of neurons of the cerebral cortex. Each FBU consists of single central draining vein with a diameter of 80μm to 120μm. The ring arterioles are approximately 40μm in diameter [2-3]. To better understand the ability of the brain to maintain adequate blood perfusion over a wide range of blood pressures - a phenomenon known as autoregulation - many researchers have suggested detailed fluid dynamics analyses of the micro vascular flows. However, most studies have been performed on one or two dimensional models that did not preserve the morphologic and spatial dimensions of the FBU. To accurately describe the blood flow patterns in the capillary microcirculation in the brain, a three-dimensional representation of the FBU is necessary. In this paper presents for the first time a complete three-dimensional model of a FBU in the human cortex. We will illustrate how we constructed with computer algorithms a network of micro vessels matching the morphology of the FBU (Figure 1). We also demonstrate computational results of blood flow patterns, which are a strong function of the network architecture.

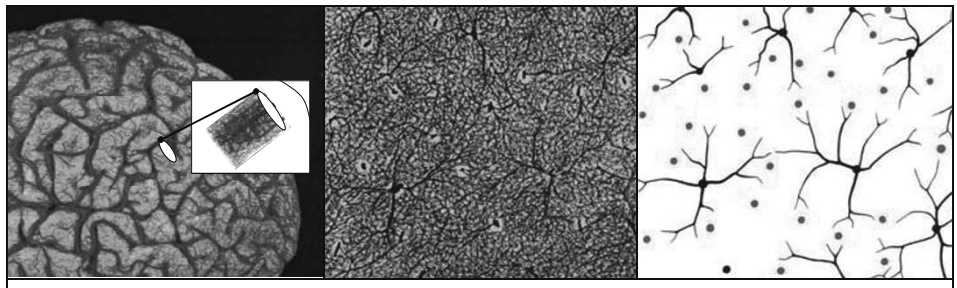

Figure 1 Morphological context of FBU. From left to right; the position of the FBU in the entire brain, SEM of micro vessel structure of the cortical surface of the brain[1], medical illustration of pattern of a draining veins surrounded by feeding ring arterioles[1].

2. Methods

We first generated a three-dimensional network representing the morphology of the FBU. The momentum equations were solved to compute pressure and flow field throughout the network. The transition times of a tracer injected into the ring arterioles were computed. The computed transition times match well with clinical values. The network construction and the computations are presented here for the first time.

2.1. Vascular network generation

Since cerebral micro blood vessels are smaller than the resolution provided by the most powerful angiography imaging techniques, the micro vascular network geometry must be generated artificially. Analysis of SEM images of cortical capillary micro vessel bed yielded the dimensions of the functional unit and the vessel diameter of the central draining vein and three ring arterioles that supply the functional unit. The draining vein and ring arterioles penetrate the cortex surface at a normal angle, then proceed to bifurcate as they enter deeper into the cerebral cortex. Artificial networks composed of cylindrical segments were generated to emulate the micro vessel structure with physiologically accurate morphometric parameters. Initially, a cylindrical domain was constructed using commercial mesh generation software (MIMICS); the surface mesh was created via the marching cubes algorithm, where an iso-surface is detailed by the voxels that enclose the domain. The volume mesh serves as a reference frame for the generation of the bifurcating trees networks of the arterial and venous systems. Large vessel backbone segments (above 50μm) were obtained manually from SEM micrographs [4]. Binary acyclic trees were generated using the novel DIGA developed by our group, which uses elements from a constrained constructive optimization perfusion algorithm used previously for synthesis of coronary arteries [5]. DIGA spawns multiple vessels within a user selected domain from a reconstructed backbone. An acyclic binary graph composed of cylindrical elements is then created by adding the segment in such a way that the total network volume – the lumen of the blood it would contain – is minimum. The addition of each new segment was the computed as the solution of a repeated global minimization problem for the entire tree volume. At each step, the volume of the network is minimized and solved as a constrained optimization problem which solves for the bifurcation coordinate (Eq. 1).

$$\underset{\vec{x},\, r_i,\, l_i}{Min}\ V = \sum_{i=1}^{N} \pi r_i^2 \cdot l_i(\vec{x}) \qquad \text{Eq. 1}$$

$$\text{s.t. } \Delta P = \alpha_i F_i \quad \forall \text{arcs on Network}$$

The relation between the diameters of parent and daughter segments obeys Murray's Law[7]. The microvasculature is not a tree and mesh-like structures were generated in a

morphologically consistent manner. Mesh-like structures were based Voronoi meshes with a vessel density of about 10542 segments per mm^3 [Table 1]. These setting achieved capillary lengths, diameters and vessel density consistent with SEM micrographs of the FBU [2]. The resulting network was constructed at physiological scale, and contained 12,292 vessels.

2.2. Hemodynamic simulations of the FBU

Network simulations were carried to solve the mass and simplified momentum balances. For each vessel, pressure and flow were computed as functions of length *L*, diameter *d* and viscosity μ by the Hagen-Poiseuille equation (Eq. 3).

$$\nabla u = 0 \qquad \text{Eq. 2}$$

$$\Delta P = \alpha u A \qquad \text{where } \alpha = \frac{128\mu L}{\pi d^4} \qquad \text{Eq. 3}$$

Where u is the average velocity through and ΔP is the pressure drop, A is the cross sectional area and α is the resistance.

2.3. Dye Infusion

To assess the validity of the model in comparison to clinical values, we dynamically simulated the infusion of dye into ring arterioles. For the network and each segment we computed the dye washout times, know in medical literature as the transient times through the functional blood unit. The dye transport was modelled by the dynamic species balance of *C* with convection as in Eq. 4 in which diffusion was neglected.

$$V\frac{dC}{dt} = u\nabla C \qquad \text{Eq. 4}$$

In this equation, *C* is the species being transported and *V* is the volume of the conservation envelope.

3. Results

3.1. Network morphology

By following the morphological patterns as described extensively in medical literature, DIGA was employed to generate a physiologically accurate function blood unit model whose morphological parameters (Table 1) agree reasonably with the characterization presented in literature[1-2, 4, 8]. Flow patterns were calculated as a function of cortical depth of the supply of arterial blood as it enters the micro vessel capillary bed. The model predicted a distribution of oxygenated blood to the neuronal capillaries that is consistent with medical understanding of grey matter organization, in which the internal granular layer, at 60% cortical depth [2] is the location of the highest activity neurons with the highest metabolic requirement (Figure 2).

	Model Parameters	Clinical Parameters
Volume Density	5.40%	3.02% [2]
Vessel Count/ Tissue Volume	10887.6/mm^3	10542.02/mm^3 [2]
Vessel Surface Area/ Tissue Volume	13.60 mm^2/mm^3	12.85 mm^2/mm^3 [2]
Mean Capillary Length	56.16 μm	52.95 μm [8]
Mean Capillary Diameter	6 μm	6.47 μm [1]
Diameter of Functional unit	0.71 mm	0.5 - 2 mm[1]
Depth of Functional unit	3.3 mm	2 – 4 mm [4]

Table 1 Morphological comparison between model and literature values.

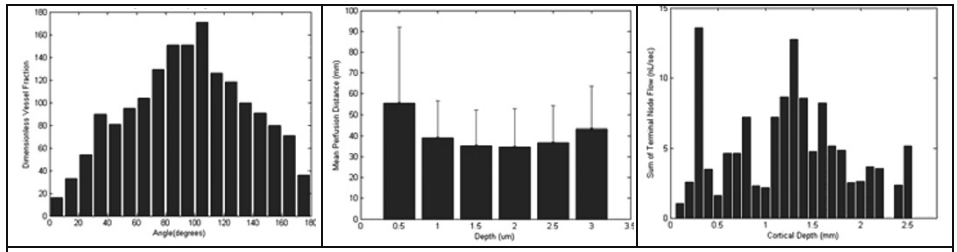

Figure 2 Functional blood unit morphological characterization. From left to right, Angle spectrum of vessels, mean perfusion distance as a function of cortical depth, and terminal node count as a function of cortical depth.

3.2. Results of Hemodynamic simulations

Fluid flow throughout the system was conserved in the arterial graph and decreased monotonically before reaching the capillary bed, than increased steadily until the venous outlet. Vessel pressure decreased monotonically from inlet to outlet (Figure 3). Simultaneous pulse injections of a dye into the three ring arterioles was computed dynamically and concentration trajectories for each vessel were recorded at each time point (Figure 4). The sharp inlet pulse of dye into three inlet arteries is attenuated as it traverses the capillary micro vessels, and the signal is much wider as it leaves the draining vein.

From left to right; structure of the entire functional blood unit with flow values mapped from 20 uL/sec (red) to 1 fL/sec (blue), flow through network with only large vessels shown, pressure map network rendered from 45 mmHg (blue) to 25 mmHg (red) with only large vessels shown.

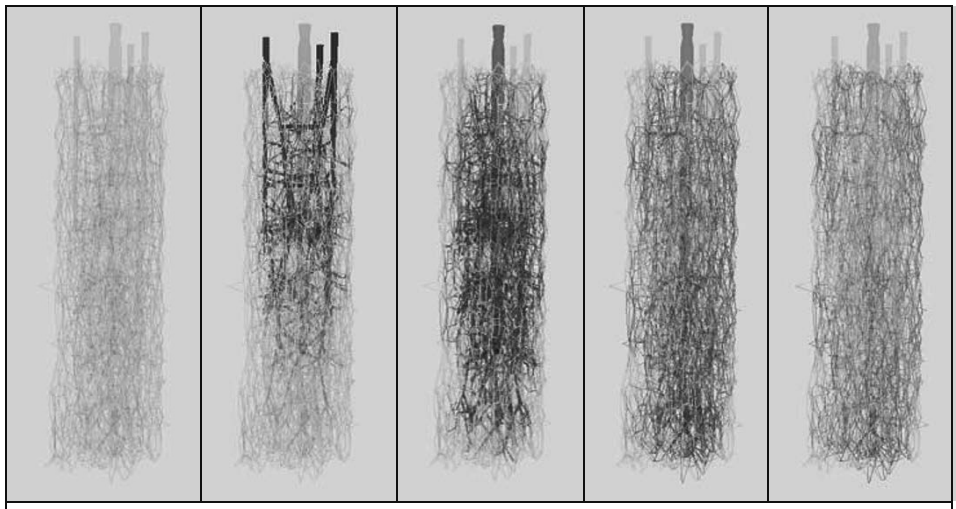

Figure 4 Dynamic dye dilution from feeding ring arterial to draining vein. Time dependent renderings of concentration profiles in the functional blood unit, from left to right. Inlet pulse of dye into three inlet arteries is flattened as it traverses the capillary micro vessels, resulting in a wider signal as the dye leaves the draining vein.

4. Discussion and Conclusions

Morphological comparisons between the functional unit and the model constructed by DIGA show favourable results in the vessel density of the model, vessel surface area to tissue volume ratios and volume density. This paper has presented an analysis of a automatically generated functional blood unit which provides insight into the morphologic and hemodynamic properties of a micro vascular network in the human cerebral cortex. Implementation of DIGA imbues the network with micro vessel architecture beyond the scope of modern reconstruction techniques and gives a fluid transition from arterioles to capillaries to veins. Future applications of this model include the effects of pulsatile flow on hematocrit distribution through a micro vessel network, investigating the biochemical transport of oxygen or the implementation of autoregulation as a response to ischemic biochemical signalling pathways.

Abstract

Gene silencing therapies have succeeded in controlling expression levels of a desired gene in animal models. By infusing short-interfering RNAs (siRNA), these molecules target particular messenger RNA (mRNA) in the cells through sequence-specific binding, suppressing the translation for the target protein. These therapies hold great promise for treating numerous disorders of the central nervous system (CNS) including novel approaches to chronic pain management. While novel siRNA targets are being discovered rapidly, difficulties in siRNA delivery such as anatomical accessibility of the target tissue, slow diffusion and non-specific uptake make achieving a precise degree of protein downregulation nearly impossible. We propose to design optimal infusions integrating medical imaging with systems engineering principles. A novel pain management therapy is designed to suppress the expression of pain-transducing NMDA receptors in the subject's spinal cord. The coupling of biotransport equations with intracellular siRNA kinetics enables the design of siRNA gene silencing therapies. The accurate prediction of dose-response and the computation of optimal infusions are expected to accelerate clinical implementations of gene silencing therapies.

Keywords: RNA interference, medical imaging, patient-specific medicine, siRNA.

1. Introduction

Gene silencing therapies are the next generation of treatments for CNS disorders. siRNA molecules bind and destruct target mRNA in the cell, changing the expression levels of the target protein at the cellular level. This promising technique induced down-regulation of NMDA receptor subunit NR2B in the spinal cord of rats, temporarily inhibiting pain transmission.[1] The NMDA receptor mediates sensitized pain in chronic pain subjects. A design method is proposed in this article to precisely control the expression of disease-related proteins in the human CNS. High resolution medical imaging can capture fine anatomical details. The integration of medical reconstruction with mathematical models may provide quantitative answers to issues that currently delay the clinical implementation of human gene silencing therapies.

The infusion of therapeutics into the human CNS is particularly challenging due to the blood brain barrier, which prevents macromolecules from leaving the cerebrovasculature. To reach the brain or spinal cord tissue effectively, therapeutics can be instead infused into the cerebrospinal fluid (CSF), which surrounds the entire CNS. After infusion, the biodistribution and reactions of these therapeutic molecules are unknown. What is the distribution of these molecules along the spine? What percentage of the infused molecules reached the target? Can we quantify the biochemical interaction of siRNA with the tissue, such as binding, internalization, or enzymatic activation of other intracellular proteins? We provide quantitative answers to these open questions using medical image-based computational fluid dynamics, termed miCFD.

2. Methodology

2.1. Three dimensional reconstruction of the human CNS

A patient-specific model was reconstructed from magnetic resonance (MR) images of the patient's CNS through a process termed image reconstruction (Figure 1).[3] Automatic and manual segmentation were used to reconstruct the CSF, the brain and spinal cord tissues in three dimensions. This patient-specific model was converted into an unstructured computational mesh as described in Somayaji et al.[4]

2.2. Functional regions in the spinal cord

The human spinal cord is composed of the grey and white matter. Within the grey matter, our target regions are within the dorsal horns where the NMDA receptors are densely populated (Figure 1). Neurons within these target regions specialize in pain signal transduction through these receptors. Neurons outside of the dorsal horns have little or no target receptors. Therefore, siRNA molecules have no effect in neurons outside of the target regions due to the lack of NMDA receptor-encoding mRNA. The bioreactivities of siRNA molecules differ in different functional regions in the spinal cord. The application of transport and reaction equations allows the computation of infusion, biodistribution, and reactions of siRNA within different cell types.

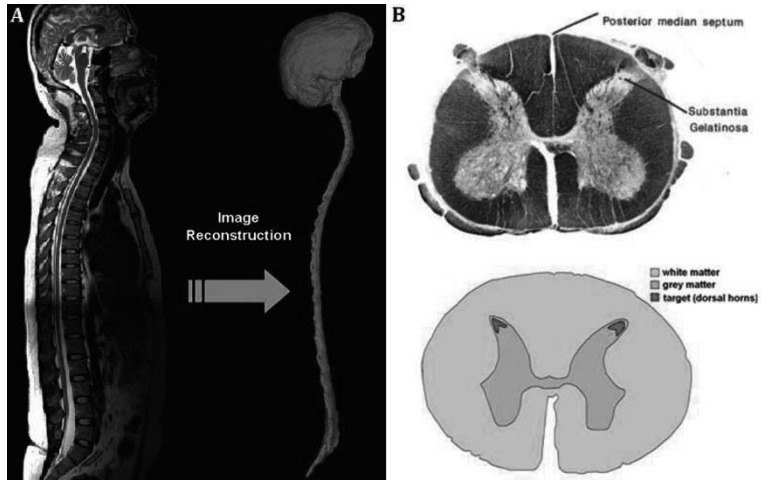

Figure 1. (A) Image reconstruction of the subject's CNS. (B) Image of the human spinal cord[2] (top frame) and the reconstructed model with different zones (bottom frame). The target zones are the dorsal horns, densely populated with NMDA receptors.

2.3. Gene silencing therapies for chronic pain

The goal of this therapy is to silence 70% of the pain-transducing NMDA receptors in the subject's spinal cord to suppress chronically heightened pain. We estimate the siRNA infusion concentration that would achieve this precise demand. NMDA receptor down-regulation in the spinal cord is computed for four different siRNA concentrations in the CSF, simulating continuous spinal infusions. The continuity (1) and species transport (2) equations compute the biotransport of siRNA.

The cells in grey and white matter of the spinal cord actively uptake siRNA molecules in the extracellular space. In untargeted cells lacking NMDA receptors and their corresponding mRNA, siRNA molecules accumulate and are merely degraded. Inside

the target cells, the activation of the gene silencing cascades is initiated by the binding of siRNA to an intracellular protein termed RNA-induced-silencing-complex (RISC). The activated siRNA binds to the NMDA receptor-encoding mRNA with high affinity and specificity. The RISC-siRNA cleaves the bound mRNA, and the translation of the receptor is suppressed for as long as an effective siRNA concentration is present in the cell. These biochemical reactions are computed for extracellular siRNA (3), intracellular siRNA (4), RISC (5), activated RISC-siRNA complex (6), bound RISC-siRNA-mRNA (7), target mRNA (8), and NMDA receptors (9).

$$\frac{\partial \rho}{\partial t} + \nabla \cdot (\rho v) = 0 \tag{1}$$

$$\frac{\partial}{\partial t}(\rho Y_i) + \nabla \cdot (\rho v Y_i) = -\nabla \cdot J_i + S_i \tag{2}$$

$$\frac{\partial \mathrm{C_{siRNAex}}}{\partial \mathrm{t}} = -\mathrm{k_1} \cdot \mathrm{C_{siRNAex}} - \mathrm{k_2} \cdot \mathrm{C_{siRNAex}} \tag{3}$$

$$\frac{\partial C_{siRNAin}}{\partial t} = +k_1 \cdot C_{siRNAex} - k_3 \cdot C_{siRNAin} \cdot C_{RISC} \tag{4}$$

$$\frac{\partial C_{RISC}}{\partial t} = \mathrm{P_{RISC}} - k_3 \cdot C_{siRNAin} \cdot C_{RISC} + k_6 \cdot C_{RISC \cdot siRNA} - k_{10} \cdot C_{RISC} \tag{5}$$

$$\frac{\partial C_{RISC \cdot siRNA}}{\partial t} = k_3 \cdot C_{siRNAin} \cdot C_{RISC} - k_4 \cdot C_{RISC \cdot siRNA} \cdot C_{mRNA} + k_5 \cdot C_{RISC \cdot siRNA \cdot mRNA} - k_6 \cdot C_{RISC \cdot siRNA} \tag{6}$$

$$\frac{\partial C_{RISC \cdot siRNA \cdot mRNA}}{\partial t} = k_4 \cdot C_{RISC \cdot siRNA} \cdot C_{mRNA} - k_5 \cdot C_{RISC \cdot siRNA \cdot mRNA} \tag{7}$$

$$\frac{\partial C_{mRNA}}{\partial t} = \mathrm{P_{mRNA}} - k_4 \cdot C_{RISC \cdot siRNA} \cdot C_{mRNA} - k_7 \cdot C_{mRNA} - k_8 \cdot C_{mRNA} \tag{8}$$

$$\frac{\partial \mathrm{C_{receptor}}}{\partial \mathrm{t}} = \mathrm{k_8} \cdot \mathrm{C_{mRNA}} - \mathrm{k_9} \cdot \mathrm{C_{receptor}} \tag{9}$$

In these equations, C is species concentration; $P_{RISC} = 5 \cdot 10^8$ is the RISC production rate, and $P_{mRNA} = 5 \cdot 10^9$ is the mRNA production rate. Reaction rate constants used were derived from experimental data by Bartlett and Davis.[5]

3. Results and Discussion

Prior to siRNA treatment, the NMDA receptors and their encoding mRNA in the target cells maintain constant levels. These steady state levels are responsible for the stable receptor expression in these cells. The number of 'cells' per cm^3 is estimated based on the extracellular volume fraction and the average cell volume. This allows us to estimate the number of molecules per cell from computed concentrations.

At steady state, there are 55,543 NMDA receptors and 900 receptor-encoding mRNA per cell. The quantities of mRNA and protein are within reported range for mammalian genes.[6] As expected, the amount of receptors per cell is much greater than its encoding

mRNA,[6] due to translational amplification. Each mRNA transcript is used for translation multiple times before its natural degradation.

After the start of a continuous siRNA infusion, the system in steady state experiences a dynamic transition. siRNA molecules diffuse into the tissue from the spinal cord surface. Cellular uptake of siRNA molecules occurs simultaneously. A small amount of siRNA molecules reach the dorsal horns and initiate gene silencing. siRNA concentration inside dorsal horn cells is several orders of magnitude smaller than the infusion concentration due to the diffusion resistance and non-specific cellular uptake.

Intracellular siRNA in a cross section of the spinal cord is shown for four hours of continuous infusion at the concentration of 10^{-6} M (top panel of Figure 2). The receptor down-regulation in the dorsal horns is shown in the bottom panel (Figure 2).

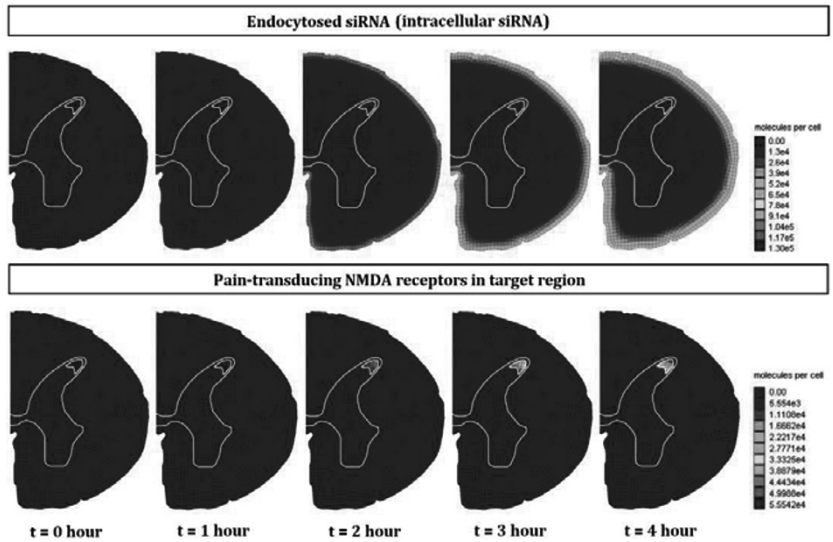

Figure 2. Intracellular siRNA (top) and NMDA receptors in the dorsal horns (bottom) in a cross section of the spinal cord over four hours of continuous siRNA infusion at 10^{-6} M. (Top panel) siRNA molecules are uptaken by cells during their diffusion. Slow diffusion and non-specific uptake of siRNA are principle barriers for effective delivery of siRNA into a targeted region in the CNS. (Bottom panel) gene silencing of pain-transducing NMDA receptors induced by intracellular siRNA molecules in the dorsal horns.

Four different infusion concentrations were compared for gene silencing efficacy using this patient-specific model. NMDA receptor down-regulation for continuous siRNA infusions into the CSF over 9 hours is shown in Figure 3. After gene silencing, the target receptors were 92.9%, 85.9% 57.6% and 29.4% of the steady state level for siRNA infusion concentrations of 10^{-7}M, $2 \cdot 10^{-7}$M, $6 \cdot 10^{-7}$M and 10^{-6}M, respectively. The therapy goal of 70% NMDA receptor suppression was met using an injectate with 10^{-6}M siRNA concentration.

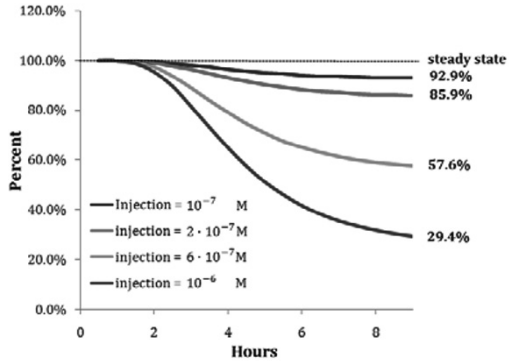

Figure 3. Pain-transducing NMDA receptor down-regulation for 9 hours of continuous siRNA infusion. The infusion concentration of 10^{-6}M induces 70.6% of receptor suppression, meeting the therapy goal. The optimal infusion concentration is determined.

4. Conclusions

Controlling the expression of disease-related genes in the CNS using gene silencing therapies is the next generation of CNS treatments. However, delivering an exact concentration of siRNA molecules to a targeted region in the CNS presents multiple challenges. CNS therapy design also poses stringent requirements. For example, a precise percent of protein down-regulation may be desired in the target region, while maintaining unaltered protein levels elsewhere. In many cases, it is not desirable to completely suppress the expression of a target gene. The use of sub-optimal infusion parameters may cause either no effect on the gene expression or the complete suppression of a gene, leading to unwanted outcomes.

The traditional trial and error animal infusion experiments do not provide quantitative answers for the optimal dosing of a human subject. This article addresses the challenge of optimal human dosing by integrating medical imaging with systems engineering principles. siRNA biochemical kinetics coupled with biotransport are fused with subject-specific anatomy to estimate drug action in vivo. The systematic design of human gene silencing therapies can generate optimal infusion parameters to precisely suppress protein expression levels as desired. Future direction includes the coupling of this patient-specific model with spatially distributed kinetic inversion technique for the determination of unknown siRNA reaction parameters.
