The depropanizing, debutanizing and deisobutanizing fractionation steps of processing natural gas liquids were improved through studying complex distillation arrangements, including the double dividing wall column arrangement (DDWC), the sequence including a dividing wall column (DWC) and a bottom DWC (BDWC) and the sequence including a DWC and a BDWC with top vapor recompression heat pump. These arrangements offer benefits by decreasing reboiler and condenser power consumption. Reducing the number of columns and their diameters can potentially reduce construction costs. The result also showed that operating cost could be reduced most significantly through novel combinations of internal and external heat integration: bottom dividing wall columns employing a top vapor recompression heat pump.

Keywords: Dividing wall column; DWC; Heat pump; NGL recovery.

1. Introduction

The uses and processing of natural gas (NG) are still evolving since their early twentieth century origins in the United States. Although its primary use is as a fuel, NG is also a source of hydrocarbons for petrochemical feed stocks and a major source of elemental sulfur, an important industrial chemical (Kidnay, 2006). Its clean burning and ability to meet stringent environment requirements ensure demand for natural gas (Elliot *et al.*, 2005). Recovery of natural gas liquids (NGL) has become increasingly economically attractive as a number of its components are often isolated and sold separately. Consequently, numerous methods exist to increase NGL recovery from a feed gas, with potential enhancements involving integrated processes (Elliot *et al.*, 2005; Mak, 2006).

Distillation is the primary separation process used in industrial chemical processing. While it has many advantages, a drawback is its large energy requirement (Schultz *et al.*, 2002), which can significantly influence overall plant profitability. Increasing energy costs deter energy consumption as do tighter environmental regulations regarding fossil fuel use, leading to research into new and more efficient separation methods (Knapp and Doherty, 2005; Malinenand and Tanskanen, 2009).

Ternary separations typically involve either direct or indirect sequences with two conventional columns. Although the control and operation of conventional columns are simple, their use is inefficient in terms of energy due to the mixing entropy by irreversible split (Aspiron, 2010). Therefore, various methods have been developed to improve the energy efficiency of such distillation systems. Many studies confirm that the Fully Thermally Coupled Distillation System (FTCDS) or the Petlyuk column can reduce energy consumption (Halvorsen and Skogestad, 2004; Jiménez *et al.*, 2003). The

Petlyuk column allows reversible splits, with no part of the separation being performed twice (Figure 1), which gives superior separation energy efficiency over other column configurations (Poth *et al.*, 2004).

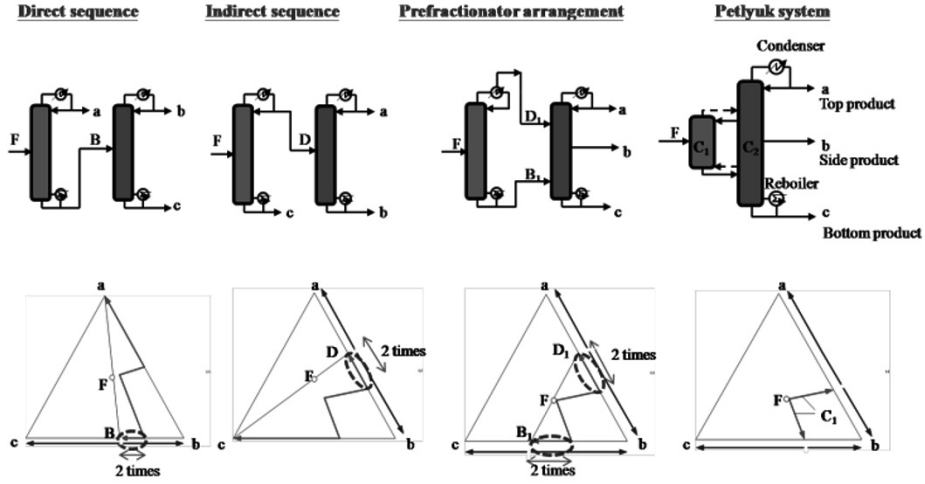

Figure 1. The ternary systems of direct sequence, indirect sequence, prefractionator arrangement, and the Petlyuk system.

Instead of having an external prefractionator, the prefractionator can be incorporated into a single shell arrangement by installing an internal wall, which divides the column into the prefractionator and the main section. This dividing wall column (DWC) is conceptually similar to the Petlyuk column, given their thermodynamically equivalent arrangements (Amminudin *et al.*, 2001), and is expected to give a similar energy saving. However, the dividing wall column requires less capital expenditure and space. Its single shell feature, single reboiler and condenser can typically reduce capital expenditure by 30% compared with conventional two column sequences. The design of the dividing wall column is more complex than a simple column because there are more degrees of freedom that need to be specified. Key variables and parameters such as the number of trays of the column, the liquid and vapor splits each side of dividing wall, and the feed and side tray locations must be established. These degrees of freedom all interact with each other and need to be simultaneously optimized to obtain the best design. Since number of stages is an integer variable, column optimization falls into a class of mixed integer non-linear programming problems (MINLP) (Dejanović *et al.*, 2010), which cannot be solved by commercially available process simulators.

Integrating three columns, whose operating pressures are so different, in such ways is impractical (Long and Lee, 2012). At least two columns are needed. This work aims to find a configuration suitable for improving the performance of the depropanizing, debutanizing and deisobutanizing fractionation steps of NGL processing.

2. Conventional column sequence

Liquid hydrocarbons recovered from NGL are typically separated into relatively pure ethane (C_2), propane (C_3), isobutane (iC_4), normal butane (nC_4), and gasoline products (C_{5+}). This is conventionally done by distilling C_2, C_3 and C_4 from gasoline in sequence

and then distilling iC_4 from nC_4. Because of the large energy consumption, there are numerous configurations and methods known to increase NGL recovery from a feed gas. The difference of operating pressures complicates columns' integration and directly affects energy consumptions and the use of refrigeration.

The depropanizer, possessing 34 theoretical trays, is operated at 17.50 bar as commercial propane can be condensed with cooling water at this pressure, as seen in Figure 2a. The debutanizer and deisobutanizer columns, with 40 and 92 trays, respectively, are operated at 3.50 and 4.40 bar, respectively (Manley, 1997; Amminudin and Smith, 2001). The final distillation of iC4 from nC4 is energy and capital intensive because these compounds' small relative volatility (Manley, 1998). Simulations were performed using the simulator Aspen HYSYS V7.1. The Peng-Robinson equation of state that supports the widest range of operating conditions and the greatest variety of systems was used to predict the vapor-liquid equilibria of these simulations (Aspen Technology, 2009). The base case simulation shows that the energy consumptions of the depropanizer, debutanizer and deisobutanizer are 21.54, 10.48 and 23.80 MW, respectively.

(a) (b)

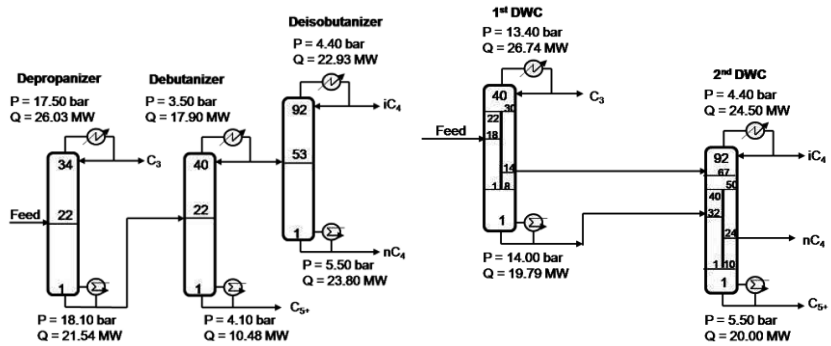

Figure 2. Simplified flow sheet illustrating (a) the separation train of three conventional columns and (b) the DDWC system.

3. Proposed base sequence

3.1. Integration by DWC and bottom dividing wall column (BDWC)

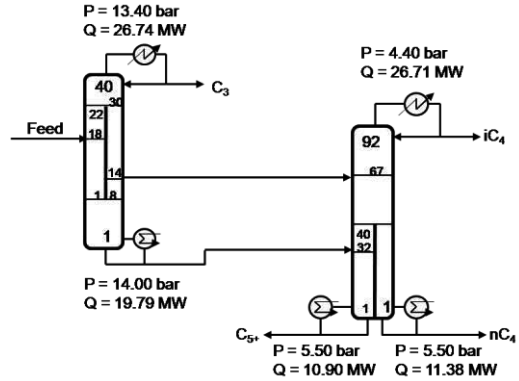

Figure 3. Simplified flow sheet illustrating the DWC and BDWC arrangement.

A double dividing wall column (DDWC) sequence was used to improve energy efficiency in NGL recovery process (Figure 2b) (Long and Lee, 2012). Instead of using the 2nd DWC, a bottom dividing wall column (BDWC) can be used as shown in Figure 3. This BDWC is created by moving the dividing wall down to the bottom of the column to separate the column to three sections: one is prefractionator section for the feeding the mixtures with its own reboiler to produce C_{5+}, another is the top section upper the divided wall, and the last is the divided wall section. Compared to the DWC, the BDWC has one more reboiler causing more investment cost. Using one DWC and one BDWC sequence could save 24.63% in terms of energy consumption. BDWC shows less advantage as compared to DWC because this kind of column could not be adjusted in terms of vapor split ratio (R_v). However, it gives a potentiality with the assistance of heat pump.

3.2. Integration by DWC and BDWC with top vapor recompression heat pump

In the former, instead of using a separate condenser and reboiler, the top product can be compressed to a higher pressure and then condensed in the reboiler of the column. As a result, the condensed vapor provides heat needed for vapor generation at the bottom of the column in the heat exchanger. Then the top outlet stream must be further cooled before being divided to two streams, which including one is recycled back the column as reflux, another is the final top products as shown in Figure 4. Note that the pressure of outlet compressor was adjusted to obtain a minimum approach in the heat exchanger of 5°C. It is possible to save 45.02% in terms of reboiler energy. But that is not the only advantage of this arrangement because, by using a heat pump, the CO_2 footprint could be reduced (Díez *et al.*, 2009). Hence, there is an environmental advantage which could become more important if CO_2 quotas are enforced by governments.

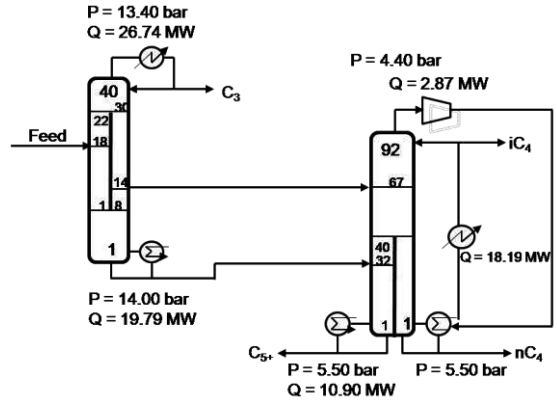

Figure 4. Simplified flow sheet illustrating the DWC and BDWC with top vapor recompression heat pump arrangement.

4. Conclusions

Complex distillation sequences were studied to improve the performance of the depropanizing, debutanizing and deisobutanizing fractionation steps of NGL processing. The sequence including a DWC and a BDWC was shown to reduce energy requirement considerably compared with conventional distillation sequence. Furthermore, operating cost could be reduced most significantly through novel combinations of internal and external heat integration: bottom dividing wall columns

employing either a top vapor recompression heat pump. Furthermore, these sequences, with a decreased number of smaller columns, could reduce investment costs. The reduced numbers of columns and reboilers could also make a plant more compact.

Water condensate collection system by using MINLP model

Anita Kovac Kralj, [a] Jernej Hosnar[a]

[a]*Faculty of Chemistry and Chemical Engineering, University of Maribor, 2000 Maribor, Slovenia*

Abstract

This paper presents a retrofitted procedure for wastewater, or more specifically, water condensate's separate collection, using an intermediate mathematically-programmed heating design based on a MINLP (mixed-integer nonlinear programming) model. The existing separate condensate collection using an intermediate heating system may no longer be optimal; the basic intention being that minimal changes in the system can efficiently improve the separate collections of low and high-temperature condensates, and the use of available heat. This water condensate collection process was tested on an existing methanol process, by using a MINLP model, which allowed for more effective and additional 5 % water condensate collection system for steam generation.
Keywords: water condensate, MINLP-model, energy saving

1. Introduction

Water minimization within the process industry is becoming increasingly important as environmental legislation becomes more stringent, and awareness increases about the impact of industrial activities on the environment. Extensive work was carried out by Bagajewicz (2000) and Foo (2009) on water-minimization during continuous processes. They developed methodologies for wastewater minimization during continuous processes, mainly using pinch-analysis techniques.

Water condensate collection is very important during real chemical processes because it can reduce raw materials, energy-losses, and costs, and can improve the operations of energy and process systems (Richter, 1993). Water is amongst the more important raw materials and utilities, therefore, it is reasonable to collect water during the process industries' activities.

This paper presents the separate collection of low and high-temperature condensates using an intermediate heating by the mathematical techniques - MINLP model.

2. Water condensate collection with an intermediate heating by using MINLP model

Water is amongst the more important raw materials and utilities, therefore it is reasonable to collect water from process industries.

Their goal is to minimize the amount of wastewater, or more specifically reuse condensates by using a MINLP model. Condensate, as produced during a process, could be separately collected, heated, and utilized for steam-generation.

The MINLP approach deals with both continuous and discrete variables, simultaneously (Biegler et al., 1997). Whilst continuous variables are defined for the continuous optimization of parameters (mass flow-q, heat flow rate-Φ, temperatures-T, specific heat capacity-cp costs, etc.). The basic structural binary variable (y) determines the location of an exact condensate (c) into an exact reservoir (r; eq. 1). Each condensate

has the possibility of entering into any reservoir, and this selection can be determined by the binary variables. If the value is one, it means, that the condensate is selected for a particular reservoir, if zero, and then it is not selected (eq. 1).

$$\sum_{r} y_{c,r} = 1 \qquad r = 1. \ldots R \qquad c = 1, \ldots C \tag{1}$$

Different temperature condensates could be collected more efficiently with separated collections for high-temperature and low-temperature condensate collection reservoirs, according to the minimum energy-loss.

When the different temperature condensates are separately collected within a variety of different lower and higher temperature reservoirs and then followed by heating, the allocation choice for various condensates is very important.

This system of separated lower and higher temperature condensates' (c = 1, …C) collection with intermediate heating, includes different numbers of reservoirs (r = 1, …R) and heaters (h = 1,…H) using mass balance equations (Fig. 1). The mass balance for reservoir number 1 (eq. 2) includes all inlet (fresh water - q_{in} and condensates - $q_{c,r}$) and outlet streams (q_r; eqs. 2, 3):

$$q_{in}\, cp_{in}\, T_{in} + \sum_{c}(q_{c,r}\, y_{c,r}\, cp_c\, T_c) = [\sum_{c}(q_{c,r}\, y_{c,r}) + q_{in}]\, cp_r\, T_r \qquad c = 1, \ldots C \quad r = 1 \tag{2}$$

$$q_r = \sum_{c}(q_{c,r}\, y_{c,r}) + q_{in}] \qquad c = 1, \ldots C \quad r = 1 \tag{3}$$

The outlet stream from reservoir number 1 is the same as the stream into heat-exchanger number 1:

$$q_r = q_h \qquad r = 1 \qquad h = 1 \tag{4}$$

Mass balance of reservoir number two is:

$$q_h\, cp_h\, T_h + \sum_{c}(q_{c,r}\, y_{c,r}\, cp_c\, T_c) = [\sum_{c}(q_{c,r}\, y_{c,r}) + q_h]\, cp_r\, T_r \qquad c = 1, \ldots C \quad r = 2 \quad h = 1 \tag{5}$$

$$q_r = \sum_{c}(q_{c,r}\, y_{c,r}) + q_h] \qquad c = 1, \ldots C \qquad r = 2 \qquad h = 1 \tag{6}$$

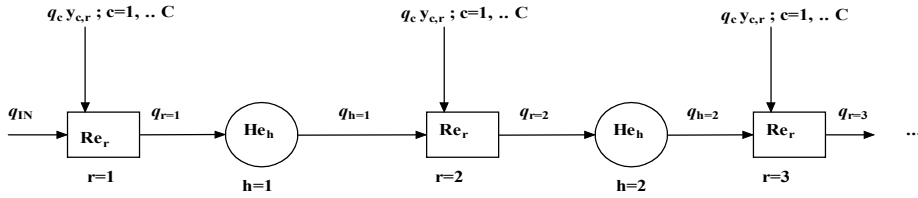

Figure 1: Collection of condensates.

General mass balance of reservoir r is:

$$q_h\, cp_h\, T_h + \sum_{c}(q_{c,r}\, y_{c,r}\, cp_c\, T_c) = q_r\, cp_r\, T_r \qquad c = 1, \ldots C \qquad r = 1, \ldots R \qquad h = 0, 1 \ldots H \tag{7}$$

The energy balance for the heater h is:

$$\Phi_h = q_r \,.\, (cp_r + cp_h)/2 \,.\, (T_h - T_r) \qquad r = 1, \ldots R \qquad h = 1 \ldots H \tag{8}$$

The objective function (OBF, eq. 9) of the MINLP model was to maximize the output temperature from reservoir number 2 by saving (C_{sav} = 100 EUR/K):

$$OBF = C_{sav}\, T_{r2} \tag{9}$$

Many constrained engineering and industrial optimization problems can be modelled as mixed integer nonlinear programming (MINLP) problems.

3. Case study

The existing methanol production had a condensate collection system using two reservoirs. The efficiency of the collection was tested using an MINLP (mixed-integer nonlinear programming) model.

During the methanol process, all the condensates (c=K1−K5) were collected as utilities for 37 bar steam-generation (Fig. 2). The collected condensates were added to the freshly- demineralization water ($q_{FR\text{-}W}$ =19791 kg/h) within the reservoir (R1). The fresh-water and condensates were heated in a heat-exchanger (E111=he-1), followed by another collection of condensates into the reservoir (R2), pumped using a pump (P1) at 50 bar, and then heated in heat-exchangers (E110, E102, REA2, E107, E104, E103). The necessary heat flow rates for the heating of a steam-generation system were obtained from synthesis gases (E111, E110, E107), the furnace-channel (E102, E104, E103), and the REA-2 reactor.

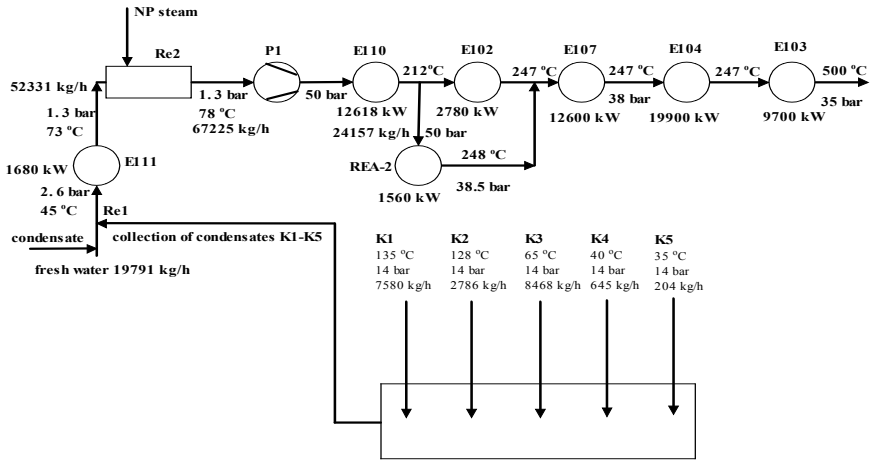

Figure 2: The existing steam-generation.

The existing steam preparation system had been modified by using an Aspen Plus simulator (Aspen Plus, 1996) without a mathematical method. The existing steam preparation system was newly-optimized by using mathematical methods. The optimal modification can be obtained by the mathematical MINLP method by using GAMS optimization tool with execution time of 4.9 s (GAMS with DICOPT, 1992). The MINLP model includes equations from 10 to 18.

Five condensates (c=K1−K5) with different constant temperatures (T_c) and mass flow rates (q_c) were collected within reservoirs (r = R1, R2). Each condensate (c=K1−K5) could be collected in reservoirs 1 or 2, but not in both (eq. 10):

$$\sum_{r} y_{c,r} = 1 \qquad r = R1, R2 \qquad c = K1, K2, K3, K4, K5 \tag{10}$$

Mass balance for the reservoir number 1 is:

$$\sum_{c}(q_{c,r1}\, y_{c,r1}\, cp_c\, T_c) + (q_{FR\text{-}W} + q_{add})\, cp_{FR\text{-}W}\, T_{FR\text{-}W} = [\sum_{c}(q_{c,r1}\, y_{c,r1}) + q_{FR\text{-}W}]\, cp_{r1}\, T_{r1} \tag{11}$$

$$q_{m\,r1} = [\sum_{c}(q_{c,r1}\, y_{c,r1}) + q_{FR\text{-}W}] \quad c = K1, K2, K3, K4, K5 \tag{12}$$

Parameter $q_{FR\text{-}W}$ denotes the heat-flow rate of the fresh water with constant inlet temperature (T_c) and heat-capacity (cp_c), which is only entering reservoir number 1. Parameter q_{add} denotes the additional heat-flow rate of the fresh water with constant

parameters (T_c, cp_c), and with an upper-limit of 3700 kg/h. This is an upper-limit where the system is not too overloaded. All existing units remain the same without additional modifications.

E111 heater (he-1= E111), which heats the outlet from reservoir number one. The energy balance for the heater is:

$$\Phi_{\text{he-1}} = q_{\text{m r1}} (cp_{\text{r1}} + cp_{\text{he-1}})/2 \ (T_{\text{he-1}} - T_{\text{r1}}) \quad (13)$$

The heat flow rate ($\Phi_{\text{he-1}}$) can be calculated using known-values for the inlet and outlet heat capacities (cp_{r1}, $cp_{\text{he-1}}$) and temperatures ($T_{\text{he-1}}$, T_{r1}) of heat exchanger number 1, by using equation 13.

Mass balance for reservoir number 2 is:

$$\sum_{c}(q_{c,\text{r2}} y_{c,\text{r2}} cp_c T_c) + q_{\text{h-w}} cp_{\text{h-w}} T_{\text{h-w}} + q_{\text{m r1}} cp_{\text{r1}}, T_{\text{r1}} = [\sum_{c}(q_{c,\text{r2}} y_{c,\text{r2}}) + q_{\text{h-w}} + q_{\text{m r1}}] cp_{\text{r2}} T_{\text{r2}} \quad (14)$$

Variables T_{r1} and T_{r2} are the denoting outlet temperatures from reservoirs 1 and 2. Parameter $q_{\text{h-w}}$ denotes the heat-flow rate of the hot water-stream with constant inlet temperature ($T_{\text{h-w}}$) and specific heat capacity ($cp_{\text{h-w}}$), which is only entering reservoir number 2. Parameter $q_{\text{m r1}}$ is the sum of all the mass-flow rates, into reservoir 1 (eq. 12), which then further enters the next reservoir number 2. All the condensates (c=K1−K5) have a constant mass-flow rate (q_c), temperature (T_c) and heat-capacity (cp_c) and, therefore, can be multiplied by the binary parameters ($y_{c,r}$).

The specific heat-capacity ($cp_{c,r}$) regarding reservoirs 1 and 2, can be calculated by using linear equation 15, depending on the outlet temperature from the tank (T_r). The parameters of specific heat capacity (a_r b_r) are known values (0.0093, and 1.1067 kJ/(kg K)) for water.

$$cp_r = a_{,r} T_r + b_r \qquad r = \text{R1, R2} \quad (15)$$

Specific heat-capacity ($cp_{c,r}$) after heating in heater he-1, can be calculated by using linear equation 16 depending on the outlet temperature from heater ($T_{\text{he-1}}$).

$$cp_{\text{he-1}} = a_{,\text{he-1}} T_{\text{he-1}} + b_{\text{he-1}} \qquad \text{he} = \text{he-1} \quad (16)$$

An equation similar to the eighteenth can be used for a further heat-exchanger, by considering the additional mass-flow:

$$\Phi_{\text{he}} = (q_{\text{m he}} + q_{\text{add}})(cp_{\text{he-in}} + cp_{\text{he-out}})/2 \ (T_{\text{he-out}} - T_{\text{he-in}}) \quad \text{he} = \text{E110, E102, E107, E104, E103} \quad (17)$$

The objective function (OBF, eq. 18) of the MINLP model maximized additional profit. The reconstruction did not include many modifications, and thus costs. The process did not operate at 100 % capacities, and so the existing process could be used without additional modification. The basic additional cost of reconstruction ($C_{\text{add-fw}}$ = 0.02 EUR/kg) was the cost of additional fresh water mass-flow rate (q_{add}), including the contingencies cost. The additional income accounted for the additional price of steam-generation ($P_{\text{st-gen}}$ = 0.1 EUR/kg). The maximum additional mass-flow rate of steam generated would be increased by 3700 kg/h (an upper-limit), including 40 % efficiency. The operational time (O) was 8000 h/a.

$$\text{OBF} = P_{\text{st-gen}} \ q_{\text{add}} \ 0.4 \ O - C_{\text{add-fw}} \ q_{\text{add}} \ O \quad (18)$$

3.1. Retrofitted system of condensate collection

The existing steam-generation system, including all hot and cold streams (Fig. 3) during the methanol process could be optimized by using MINLP.

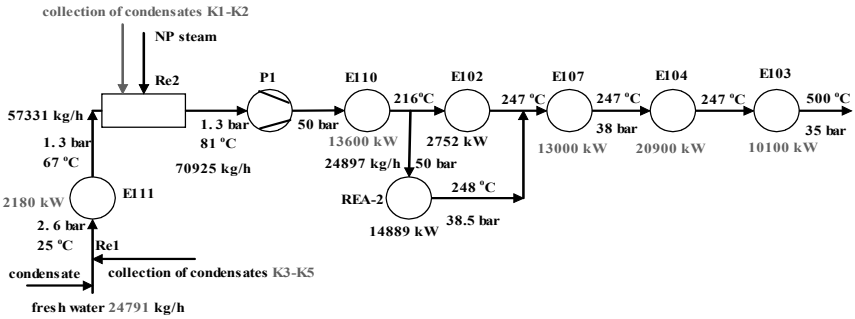

Figure 3: The retrofitted steam-generation.

The optimal result of the objective function was the selection of separate condensate collections (Fig. 3). Low-temperature condensates K3–K5 could be collected within a Re1 reservoir containing fresh-water. The high-temperature condensates K1–K2 could then be collected within a Re2 reservoir. Selection was the same as for the first objective function. The additional heat-flow rate of fresh water (q_{add}) was 3700 kg/h, which was within the lower-bound. The loss of heat-flow rate into the air-cooler was distributed into E111 and E110 heat-exchangers heated with 500 and 1000 kW higher heat-flow rates for the demineralization water, and the inlet temperature of the air-cooler was reduced to 101 °C. The demineralizated water was evaporated in E107 and E104 with additionally-available heat within the furnace-channel, followed by overheating into E103.

The reconstruction of the steam-generation-system could be more effective, as all the available-heat was used during the process. 5 % more steam could be produced by the existing system, which does not work at 100 % capacity.

4. Conclusions

The optimal allocation of condensate collection could be optimized by using a mathematical method, as such the MINLP model. The MINLP model enables both the low and high-temperature condensates to have the possibility of entering into any reservoir, and this choice of selection can be determine by the binary variables.

The existing condensate collection during the methanol process was modified in order to collect low and high-temperature condensates, separately. By modifying the existing process, very little change would be needed for a better preparation of overheated-steam, as used in steam-turbines for producing electricity. The additional profit from the retrofitted steam production system was 590 kEUR/a.

Pressure Drop Consideration in Cooling Water Systems with Multiple Cooling Towers

Khunedi V. Gololo[a,b], Thokozani Majozi[a]

[a]*Department of Chemical Engineering, University of Pretoria, Pretoria, South Africa*
[b]*Council for Scientific and Industrial Research, Advanced Modelling and Digital Science, Pretoria, South Africa*

Abstract

Pressure drop consideration has shown to be an essential requirement for synthesis of cooling water network where reuse/recycle philosophy is employed. This is due to an increased network pressure drop associated with additional reuse/recycle streams. This paper presents a mathematical technique for pressure drop optimization in cooling water systems consisting of multiple cooling towers. The proposed technique is based on the Critical Path Algorithm (CPA) and the superstructural approach. The CPA is used to select the cooling water network with minimum pressure drop whilst the superstructure allows for cooling water reuse. This technique which was previously used in a cooling water network with single source is modified and applied in a cooling water network with multiple sources. The mathematical formulation exhibits a mixed integer nonlinear programming (MINLP) structure. The cooling tower model is used to predict the exit conditions of the cooling towers, given the inlet conditions from the cooling water network model.

Keywords: Cooling water system, Pressure drop, Critical Path Algorithm, Optimization

1. Introduction

Cooling water systems are used in many industries to remove waste heat from the process to the environment. Research in this area has focused mostly on optimization and synthesis of cooling water systems in which the technique of recycle and reuse is explored. In most cases the synthesized cooling water network is more complex thus resulting in a higher pressure drop. Kim and Smith (2001) used the graphical technique to debottleneck a cooling water system with single source. Ponce-Ortega *et al.* (2010) also presented a mathematical model for synthesis of cooling water networks that was based on a stage wise superstructural approach. This work included the cooling tower model and the pressure drop for each cooler was considered. Panjeshahi and Ataei (2008) extended the work of Kim and Smith (2001) on cooling water system design by incorporating a comprehensive cooling tower model. Different approach was taken by Majozi and Moodley (2008) who developed a mathematical model for optimization of cooling water systems with multiple cooling towers. This work was later improved by Gololo and Majozi (2011) by incorporating the cooling tower model.

In all the abovementioned work the topology of cooling water network was more complex thus prone to higher pressure drop than the conventional parallel design. Kim and Smith (2003) presented a paper on retrofit design of cooling water systems in which pressure drop was taken into consideration. The authors used graphical technique to

target the minimum circulating water flowrate and mathematical technique to design a cooling water network. This work was limited to one cooling source.
This paper presents a mathematical technique for pressure drop optimization in cooling water systems consisting of multiple cooling towers. The proposed technique is based on the Critical Path Algorithm (CPA) and the superstructural approach. The CPA is used to select the cooling water network with minimum pressure drop whilst the superstructure allows for cooling water reuse. This technique was previously used by Kim and Smith (2003) to synthesize cooling water network with single source. However in this paper CPA is adapted for a cooling water network with multiple sources. Furthermore, the detailed cooling tower model is also incorporated.

2. Model development

A two-step approach is employed to synthesize and optimize the cooling water system with multiple cooling towers considering pressure drop. The first step involves targeting of the minimum circulating water flowrate and in the second step the CPA is incorporated to synthesize the cooling water network with multiple cooling sources.
The cooling tower model developed by Kröger (2004) is used to predict the outlet conditions of the cooling towers and the overall cooling towers effectiveness. The cooling water network model by Gololo and Majozi (2011) is improved by incorporating the modified heat exchangers and pipes pressure drop correlations of Nie and Zhu (1999) shown in Eq. (1) and Eq. (4) respectively. In this paper the correlation of Nie and Zhu (1999) is expressed in terms of mass flowrate.

$$\Delta P = N_{t1} m^{1.8} + N_{t2} m^2 \tag{1}$$

where $$N_{t1} = \frac{1.115567 \mu^{0.2} n_{tp}^{2.8} A}{\pi^{2.8} \rho N_t^{2.8} d_o d_i^{4.8}} \tag{2}$$

$$N_{t2} = \frac{20 n_{tp}^{3} \rho}{\pi^2 N_t^2 d_i^4} \tag{3}$$

The line pressure drop is calculated from Eq. 4 (Kim and Smith, 2003).

$$\Delta P = N_p \frac{1}{F_p^{0.36}} \tag{4}$$

where $$N_p = \frac{188.318 \rho^{0.176} \mu^{0.2} L}{\pi^{1.8}} \tag{5}$$

The CPA is used to select the cooling water network with minimum pressure drop. Kim and Smith (2003) used the superstructure shown in Fig. 1(a). The superstructure is based on single source cooling water network. By modifying the superstructure for single source cooling water systems, a multiple sources superstructure is shown in Fig. 1(b). The CPA used by Kim and Smith (2003) is based on finding a path from source to sink with maximum pressure drop. The maximum pressure drop path is then minimized during optimization to obtain the network with minimum pressure drop. Eq. (6) is used to identify the maximum pressure drop path between the source and sink.

$$P_m - P_n \geq \Delta P_{mn} \tag{6}$$

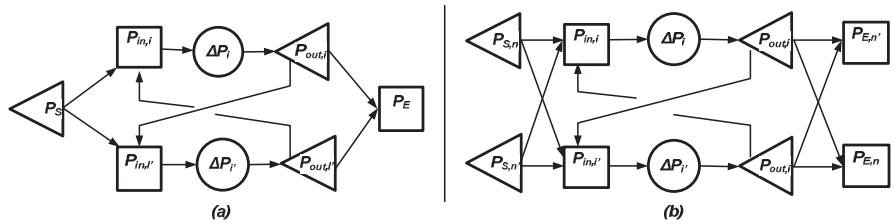

Figure 1: Cooling water system superstructure; (a) Single source (b) Multiple sources

To cater for multiple sources and sinks, the superstructure in Fig. 1(b) is modified by using single imaginary source and sink as shown in Fig. 2. Eq. (7) is then used to define the pressure of source node *n* from the imaginary source node.

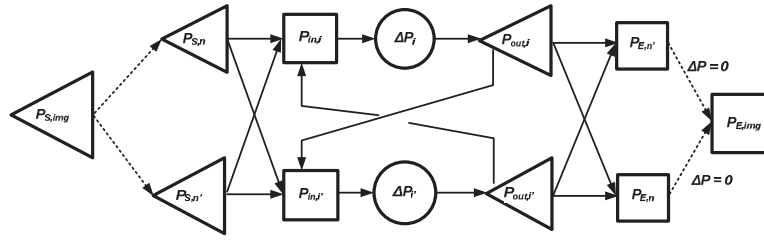

Figure 2: Multiple sources cooling water system superstructure

Eq. (8) to (11) represent the CPA adapted from Kim and Smith (2003). Eq. (12) defines the pressure at the imaginary sink node. From this equation the imaginary sink node will assume a value from all sink nodes with minimum pressure thus identifying a path with maximum pressure drop. The pressure drop of this critical path is then minimized to synthesize a cooling water network with minimum pressure drop.

Sets
$i = \{ i \mid i$ is a cooling water using operation$\}$
$n = \{ n \mid n$ is a cooling tower$\}$

$$P_{S,img} - P_{S,n} = \Delta P_{img,n} \tag{7}$$

$$P_{S,n} - P_{in,i} + LV\left(1 - x_{n,i}\right) \geq \Delta P_{n,i} \tag{8}$$

$$P_{out,i'} - P_{in,i} + LV\left(1 - y_{i',i}\right) \geq \Delta P_{i',i} \tag{9}$$

$$P_{in,i} - P_{out,i} = \Delta P_i \tag{10}$$

$$P_{out,i} - P_{E,n} + LV\left(1 - z_{i,n}\right) \geq \Delta P_{i,n} \tag{11}$$

x, y and z are a binary variables indicating the existence of stream from any source *n*/ operation *i*' *to* operation i/sink *n*. *LV* is a large value.

$$P_{E,n} - P_{E,img} \geq \Delta P_{n,img} \tag{12}$$

The network topology with minimum pressure drop is then synthesized by minimizing the pressure drop between the imaginary source and sink shown in Eq. (13).

$$P_{S,img} - P_{E,img} = \Delta P \tag{13}$$

A case study is considered which involves a cooling water system with dedicated cooling water sources and sinks. This implies that a set of heat exchanger can only be supplied by one cooling tower. No pre-mixing or post-splitting of cooling water return is allowed. However, reuse of water within the network is still allowed (Majozi and Moodley, 2008). The developed mathematical model consists of bilinear terms and binary variable thus rendering the models MINLP.

3. Solution Procedure

The solution procedure involves linearization of nonlinear terms and using results from linearized model as a starting point for the exact MINLP. The bilinear terms in the cooling water network model are linearized using the Reformulation Linearization technique by Sherali and Alameddine (1992) as shown in the paper of Gololo and Majozi (2011). However, a different technique is used to linearize the pressure drop equations. Functions are first plotted within the operating range of the heat exchangers and the piecewise linearization is then used to approximate the nonlinear function (Kim and Smith, 2003).

4. Case Study

Fig. 3 shows a cooling water system consisting of three cooling towers each supplying a set cooling water using operations. The total circulating water flowrate is 31.94 kg/s and the overall cooling towers effectiveness is 90%.

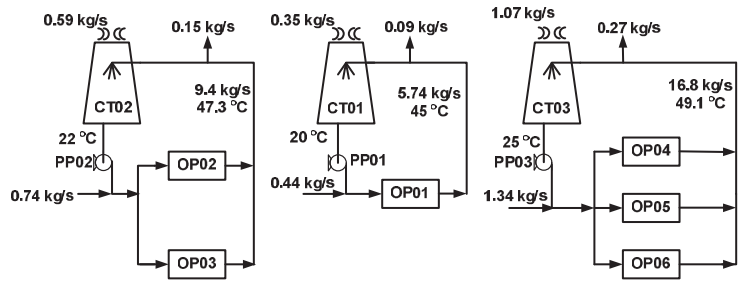

Figure 3: Cooling water system with multiple cooling towers (Majozi and Moodley, 2008)

Fig. 4 shows synthesized cooling water system after the application of the proposed technique. The total circulating cooling water decreased by 22% due to the exploitation of reuse opportunities. The overall increase in cooling tower return temperature associated with decrease in overall circulating water flowrate resulted in a 4%

improvement in effectiveness. The proposed methodology does not only debottleneck the cooling water system but also generate the network topology with the least pressure drop. This has a potential to minimize pumping cost associated with additional reuse/recycle streams. The pressure drop between sources and sinks $\Delta P_{S1,E1}$, $\Delta P_{S2,E2}$ and $\Delta P_{S3,E3}$ is 19 kPa, 31 kPa and 43 kPa respectively.

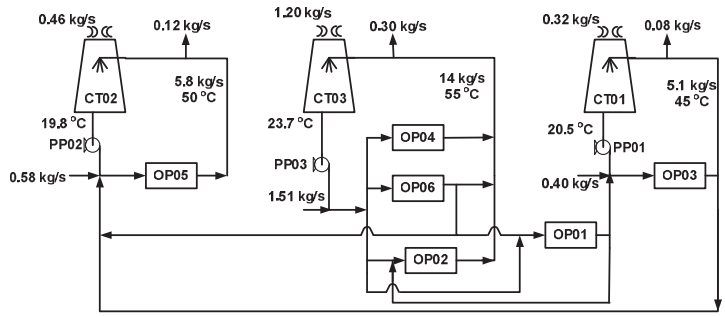

Figure 4: Debottlenecked cooling water system with the minimum pressure drop

5. Conclusion

The mathematical model for synthesis and optimization of cooling water systems with multiple cooling sources which takes into account the pressure drop is presented. The proposed technique is based on the CPA and the superstructural approach. The mathematical formulation developed yields MINLP structure. The case study showed a 22% decrease in circulating water flowrate due to the exploration of reuse opportunities. The return cooling tower temperature was increased which resulted in 4% improvement in the overall effectiveness. The proposed technique offers the opportunity to debottleneck the cooling water system with multiple cooling towers while maintaining minimum pressure drop and maximizing the overall cooling tower effectiveness.

Abstract

For the synthesis of large-scale heat exchanger networks a new method based on a hybrid genetic algorithm is proposed. It uses subnets in order to improve the resulting network structures and the calculation time. The application of the new method on an example from literature yielded a HEN structure with reduced total annual costs by 14% and a decreased calculation time by a factor of 18.

Keywords: heat exchanger network synthesis, genetic algorithm, MINLP.

1. Introduction

Production processes in chemical industry usually come along with a large energy consumption. Therefore, the integration of a heat exchanger network (HEN) can have a major impact on energy consumption and sustainability of a production plant. With increasing heat recovery the energy costs are decreasing whereas the investment costs are increasing. Thus, the design of a cost optimal HEN can be considered as a classical optimization problem.

Due to availability of special software and the strong sequential procedure, the most common used method for HEN synthesis is the well-known pinch design method (Linnhoff & Flower, 1978). Recent research activities have shown that specially tailored genetic algorithms are very capable of finding even better HEN structures (Luo et al., 2009), though. However, because of the large number of optimization variables the computation time is very high especially for large-scale HEN. In order to overcome this disadvantage a new method has been developed by the Institute of Process and Plant Engineering of the Hamburg University of Technology. This new method is based on the idea of subnets. A subnet represents a part of the whole network that does not have any contact to other parts of the HEN. Thus, it can be considered and treated like a single subproblem, which therefore can be easily solved by the genetic algorithm. Further, in order to increase the quality of the result, single subnets are combined and then solved again by the genetic algorithm. The application of this innovative method on industrial relevant problems yielded very promising results.

2. Formulation of the optimization problem

For structural representation of a HEN a simple stage-wise superstructure is used. This method was first introduced be Yee et al. in 1990. With this representation a wide range of theoretically possible network structures is covered. Fig. 1 illustrates the fundamental principle for an example with four hot process streams and three cold process streams.

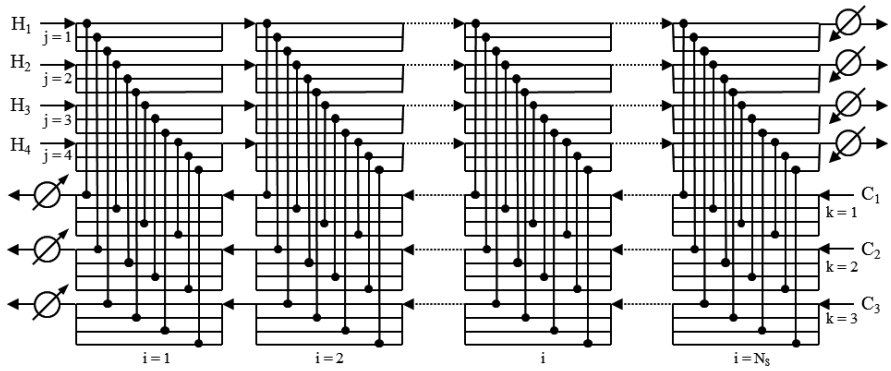

Figure 1: Stage-wise superstructure

Within a stage *i* each hot stream *j* is connected to every cold stream *k* once. The number of stages is proposed as either the amount of hot process streams or the amount of cold process streams, depending which of them is higher (Fieg et al., 2009).
The actual number of series connections of one stream to other streams in an optimal structure is usually rather small. Thus, the number of stages could be smaller. With less amount of stages valuable computational time can be saved.
With a fixed arrangement of the variables *i*, *j*, and *k* every heat exchanger (HX) in the structure has its explicit index that can be calculated by Eq. (1). The HX *ijk* in a given structure connects the hot stream *j* with the cold stream *k* in stage *i*.

$$ijk = (i\text{-}1)N_hN_c + (j\text{-}1)N_c + k \tag{1}$$

The synthesis problem of heat exchanger networks is typically given as a set of N_h hot process streams and N_c cold process streams. These streams are defined by their heat capacity flow rates $\dot{W}$, the overall heat transfer coefficients h and the supply temperatures t_{in} and the target temperatures t_{out}, respectively. For any additional heating and cooling of process streams utility streams are needed. A utility stream is defined by its inlet and outlet temperatures, heat transfer coefficient and a heat load dependent cost factor.
The given task is then to determine the network structure, which produces the minimum total annual costs. Therefore, a HEN is characterized by the heat transfer areas and heat capacity flow rates of the hot and cold streams of each existing heat exchanger within the structure. Thus, the variables to be optimized are the areas A_{ijk} and the heat capacity flow rates $\dot{W}_{h,ijk}$ and $\dot{W}_{c,ijk}$ of the stage-wise superstructure.
The total annual costs are considered as the sum of the investment costs of the heat exchangers and the costs caused by utility usage. In order to avoid binary variables it is stipulated that a positive value for a heat exchanger area indicates an existing HX within the network structure. For the calculation of the investment costs of a HX a typical area dependend approach is used:

$$C_{HX} = a + bA^c \tag{2}$$

This approach considers the fixed costs a of a HX and an area depending part bA^c. For temperature calculation an explicit analytical solution is used (Chen at al., 2007; Fieg et

al. 2009). With this method it is possible to calculate all temperatures within the network as well as the outlet temperatures of the network. In order to meet the postulated target temperatures of the process streams the excessive use of utilities proposed by Lewin et al. in 1998 is applied. A process stream that doesn't reach its target temperature at the outlet of the stage-wise superstructure will be cooled down or heated up by utility anyway. Cold utility is used if the exit temperature of this stream is higher than its target temperature and hot utility is used if its target temperature is below the exit temperature, no matter if it is a hot or a cold process stream. With this method applied the feasibility of any randomly generated HEN is ensured. The necessary heat load for additional heating or cooling is then used to calculate the costs for the utility usage. Therefore, the heat load Q_U that has to be provided by the respective utility U is linked to a cost factor c_U. The costs of each utility are calculated by:

$$C_U = c_U Q_U \tag{3}$$

Thus, the objective function is defined as the sum of the investment costs of all heat exchangers present in the HEN and the costs for the complete utility usage.

3. New synthesis method

3.1. Concept

As mentioned above specially tailored genetic algorithm are very capable of cost optimal HEN synthesis. The combination of heuristic approaches and a genetic algorithm improved the solving characteristics even further (Brandt et al., 2011). Yet, the computational time can get very high for large-scale problems. This is because of the immense amount of structural and continous variables to be optimized. Good large-scale HEN structures consist of many subnetworks, though. The main positive effect is the increasing stability of the process with increasing amount of subnetworks. Occasionally appearing disturbances like temperature changes of single process streams can only effect the respective subnetwork. Therefore, it is not necessary to optimize the whole problem in one single step. Based on this idea the concept of the new method was built up. The new algorithm decomposes the problem into as many subproblems as possible. Each of these subproblems can then be easily solved by the genetic algorithm.

3.2. The new algorithm

In a process without any heat integration each process stream can be considered as a single subnetwork. This is the starting point for the new algorithm. From this set few hot and cold streams are randomly selected to form a new subproblem definition. This subproblem is then optimized by the genetic algorithm presented in the work of Brandt et al. in 2011. From this optimization step the resulting structure is implemented back into the network. Afterwards a novel search algorithm investigates the complete HEN structure for new subnetworks and identifies them. This search algorithm is based on the depth first search method from graph theory. This ensures that all subnetworks will be identified without the need of much calculation time. The result of the search algorithm is a new set of subnetworks. From this set some subnetworks are randomly picked again in order to build a new subproblem definition for the genetic algorithm. This procedure ist carried out until the total annual costs of the complete network can not be reduced over 30 iteration steps. In order to guarantee the HEN synthesis is carried out entirely, two additional constraints are defined. The first constraint ensures that every stream has been used at least once within the optimization procedure. The

second constraint defines the minimum size of a subproblem. Each subproblem formed by several independent subnetworks must consist of more than three process streams.
In order to improve the performance of the new method further, some characteristics of the genetic algorithm are utilized. It turned out that the structural search ability of the genetic algorithm is considerable higher in comparison to the optimization of the continuous variables. Therefore, the new synthesis method runs through two stages, that mainly differs in the parametrisation of the genetic algorithm. In the first stage a rough structural search is carried out. This is to find the most promising combinations of hot and cold process streams. For this task it is reasonable to reduce the population size of the genetic algorithm. Half the size of the population compared to the normal application of the algorithm is enough for finding good first structures. Within the second stage the optimization of the subproblems is carried out more intensively. That means that at this stage the continous variables are optimized as well. Here the parametrisation is the same as for the normal application of the genetic algorithm, see Brandt et al..

3.3. Case study

In this section we demonstrate the improvement of the new method and compare the results to these from literature. For this matter we took one of the largest published examples. It was first presented in the work of Kefeng in 1998 and describes an Ethylene production plant. This example contains 55 process streams and 11 utility streams. In the respective literature a new HEN design was proposed with a claimed total annual cost of 33.1E6 $/a. However, the explicit structure of the HEN was not given. Therefore, this result has to be considered warily.
The HEN synthesis for this example was carried out ten times using the genetic algorithm introduced by Brandt et al. and ten times using the new synthesis method. The results are presented in Table 1. For each calculation run the HEN structure with the lowest total annual costs is considered. For a more practical point of view the process to process heat exchangers and the amount of subnets within these structures are presented, as well.
In order to demonstrate the improvement regarding the calculation effort the average calculation times are presented in Table 1, also. All calculations were carried out on a personal computer with an Intel Xeon 2.8 GHz CPU.

Table 1. Results for case study

	Literature	Genetic Algorithm	New Method
min. costs [$/a]	33,100,000	7,899,968	6,775,277
Number of HX [-]	51	38	32
Amount subnetworks [-]	n.a.	17	23
avg. calc. time [min]	n.a.	1,322	74

Compared to literature the results from the genetic algorithm are considerably better. Especially the costs could be reduced dramatically. On the other hand, the practicability seems also to be improved by the genetic algorithm. Although, the actual structure from literature is unknown, this is strongly indicated by the reduced number of HX. A HEN with less heat exchangers is more likely to have a higher amount of subnetworks. Furthermore, the risk of remixing of process streams due to leakages is reduced by the presence of fewer heat exchangers. Finally, by the application of the new synthesis

method these results could be improved even further. The found structure shows more subnetworks, less heat exchangers and decreased total annual costs by 14 %. A noticable reduction in the calculation time could also be observed. In comparison to the simple application of the genetic algorithm the new synthesis method is about 18 times faster.

4. Conclusion

In this work a new synthesis method for large-scale HEN was introduced. This method uses subnetworks in order to improve the solving characteristics of a genetic algorithm. The application of this method on a large scale problem with 55 process streams yielded very promising results. Compared to the simple application of a genetic algorithm the new method was 18 times faster and a HEN structure was found with 14% less total annual costs. In addition, the practicability could also be improved. The application of the new method yielded a structure with more subnetworks and less process to process heat exchangers.

Dynamic characteristics of self-heat recuperative distillation process

Yasuki Kansha, Akira Kishimoto, Atsushi Tsutsumi

Collaborative Research Center for Energy Engineering, Institute of Industrial Science, The University of Tokyo, 4-6-1, Komaba, Meguro-ku Tokyo 153-8505, Japan

Abstract

Recently, self-heat recuperation technology has been developed. In this technology, whole process heat is recirculated in the process without heat addition, leading to the drastic energy saving for the process. Although the process based on this technology can achieve drastic energy saving at steady state, the dynamics of the process have not been investigated. Therefore, operators of the process have to manually switch the conventional operation mode to the operation mode by self-heat recuperation at reaching steady-state. Two stream lines for each operation mode are required and increase the capital cost. Thus, in this paper, the dynamic characteristics of the self-heat recuperative process for distillation have been investigated to design operation systems such as controllers for further energy saving and stability of this process during operation.

Keywords: Energy, modeling, self-heat recuperation, dynamics, exergy

1. Introduction

Distillation has been widely used for separation in industries owing to the simplicity of their process. Simultaneously, it is well-known process for consuming a large amount of energy, because of large latent heat between liquid and vapor phases. So far, many innovative distillation processes for energy saving purpose have been developed. A vapor recompression (VRC, Annakou and Mizsey, 1995) technology is one of the most famous technologies, in which the top vapor stream is compressed and the heat of the stream is exchanged with the heat of the bottom liquid stream in the column to recover the heat of condensation to the heat of vaporization. Another famous technology is a heat integrated distillation column (HIDiC, Huang et al., 2006). In this technology, the distillation column can be divided into two parts and the condensation heat is exchanged with the vaporization heat between these two parts by using pressure difference. However, both VRC and HIDiC are only focused on heating by the reboiler in the distillation column and are not interested in the heating of feed stream to the distillation. Recently, by incorporating compressors and heat exchangers, the authors have developed another attractive technology to reduce the energy consumption of chemical processes (Kansha et al. 2009) and applied it to the distillation process (Kansha et al. 2010a,b). In this technology, a process unit is divided into functions to analyze the process required heat and all of the self-heat of process stream is recirculated in the process without any external heat source. As a result, the energy consumption and exergy destruction of the process can be greatly reduced in the steady state. Although this technology achieved reduction of energy consumption in the steady state, only few investigations of process dynamics and operation methods for the self-heat recuperative process have been performed. Thus, to apply this technology to actual industrial processes, it is necessary to design the operation system. In fact, there is a pilot self-heat

recuperative distillation process for ethanol production in Japan. This process achieves drastic energy reduction in the steady state. However, operators are switching the operation mode and stream lines when it reaches steady state condition.
Thus, we investigated the dynamic characteristics of the self-heat recuperative process especially distillation, to design the operation systems for the process, achieve further energy savings and investigate the stability of the process during operation in this research.

2. Self-Heat Recuperative Separation Process

To Apply the self-heat recuperation technology to separation processes (Kansha et al. 2010a,b), a system including not only the separation process itself but also the preheating/cooling section, is divided on the basis of their functions, namely separation and heat circulation modules in which the heating and cooling loads are balanced, as shown in Fig. 1. This figure shows the case which has one feed and two products. The enthalpy of inlet stream (feed) is equal to that of the summation of outlet streams (products) in each module. Then, the cooling load in each module is recuperated by compressors and exchanged with the heating load by following the self-heat recuperation technology. As a result, the heat of the process stream (self heat) is perfectly circulated without any heat addition in each module, the perfect internal heat circulation in a whole separation process can be obtained.

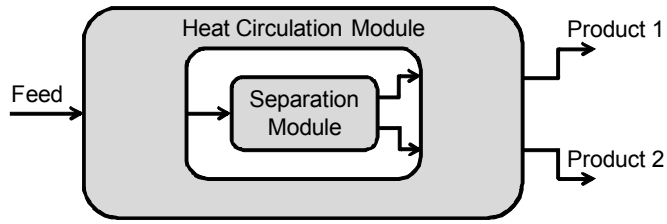

Fig. 1. Conceptual figure of Self-Heat Recuperative Separation

2.1. Self-heat recuperative distillation

To prevent the emission of CO2 by following the self-heat recuperation technology (Kansha et al. 2010b), distillation process can be divided into two sections, namely the preheating and distillation sections, on the basis of their functions. The heating and cooling load are balanced by performing enthalpy and exergy analysis, and the self-heat recuperation technology is applied in these two sections. In the preheating section, one of the streams from the distillation section is a vapor stream and the stream to the distillation section has a vapor–liquid phase. It is necessary to balance the enthalpy of the feed streams and that of the effluent streams in the section, namely heat circulation and distillation module. In balancing the enthalpy of the feed and effluent streams in the heat circulation module, the enthalpy of the streams in the distillation module is automatically balanced. Thus, the reboiler duty is equal to the condenser duty of the distillation column. Therefore, the vapor and liquid sensible heat of the feed streams can be exchanged with the sensible heat of the corresponding effluent streams and the vaporization heat can be exchanged with the condensation heat in each module as shown in Fig. 2.
Figure 2 (a) shows the structure of a self-heat recuperative distillation process consisting of two standardized modules, namely, the heat circulation module and the distillation module. Note that in each module, the summation of the enthalpy of the feed

streams and that of the effluent streams are equal. Figure 2 (b) shows the temperature and heat diagram of the self-heat recuperative distillation process. Both the sensible heat and the latent heat of the feed stream are subsequently exchanged with the sensible and latent heat of effluents in a heat exchanger. The vaporization heat of the bottoms from the distillation column is exchanged with the condensation heat of the distillate from the distillation column in the distillation module. The heat of streams are recuperated by the compressors and exchanged with the heat in the module. It can be seen that all the self-heat is exchanged. As a result, the exergy loss of the heat exchangers can be minimized and the energy required by the distillation process is reduced to 1/6–1/8 of that required by the conventional heat exchanged distillation process. Finally, to examine the feasibility of the simulation when applied to the industrial processes in petrochemical industry, Matsuda et al. (2011) provided it with practical industrial data and modified the stream lines to be suitable for the practical processes. The energy required, exergy destruction and economical efficiency are examined. From these studies, it can be concluded that the self-heat recuperative distillation process is a very promising process for energy saving.

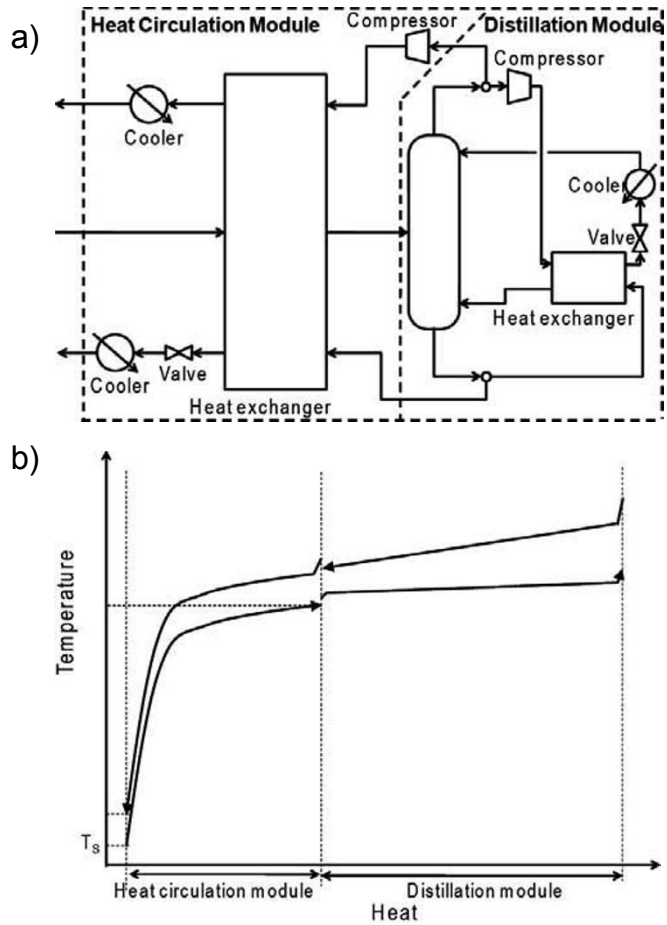

Fig. 2. A Schematic Image of Self-Heat Recuperative Distillation

3. Dynamic Characteristics of Self-Heat Recuperative Process

To investigate the dynamic characteristics of a self-heat recuperative process, step response test was conducted by HYSYS Ver. 7.3 (ASPEN Tech.). The schematic flow diagram for gas stream is shown in Fig. 3. As a real fluid, butane was used for the gas stream. The stream 1 was heated from 25 ^{o}C to a set temperature 100 ^{o}C, and the flow rate of the stream was 100 kmol/h at the initial steady state and ±10 % step changes of the flow rate were introduced to investigate the dynamics. The Soave-Redlich-Kwong (SRK) was used for the state equation. The minimum temperature difference for heat exchange was assumed to be 6 K. The efficiency of the heat exchanger and the adiabatic efficiency of the compressor were 100% (i.e., no heat loss) and 80%. A type of heat exchanger and TEMA type were assumed shell and tube and AFL. Overall heat transfer (UA) in the heat exchanger was 1.216×10^{5} kJ/K^{-1}h^{-1}. The pressure drops of both streams in this heat exchanger are 0.69 kPa. The stream pressures among the compressor are 100.6 and 120.8 kPa. Figure 4 shows the representative response curves of stream temperatures (stream 2 and 4) when the flow rate 10% increase is introduced. It can be seen that the stream temperature of stream 2 cannot reached to the set temperature (100 ^{o}C) due to the increased flow rate. This means that in the case of gas streams, this process cannot naturally keep the equal enthalpy of the feed streams to that of the effluent streams in the module without any adequate operation system under dynamic condition.

As well as the case study with gas stream, the simulation using water as a vapor/liquid stream to close the distillation process was conducted. In this simulation, water must be liquid at standard condition. Thus, it is easy to understand that this process requires the heater to produce vapor initially. Although the heater to initially heat the process stream was introduced, the super heated steam cannot be produced and vapor/liquid mixture was produced in this dynamic simulation. The feed water transforms the phase from liquid to vapor in the heat exchanger in steady state simulation. However, the hold-up in the heat exchanger is required in dynamic simulation and it cannot perfectly transform the phase in this ordinal heat exchanger. Thus, it requires other suitable heat exchanger to produce the super heated steam.

To realize the ideal heat circulation module, it is required to balance the enthalpy of the feed streams to that of the effluent streams. However, this observed phenomena caused by hold-up in the heat exchanger seem to be preferable in respect of design of the heat circulation module in the self-heat recuperative distillation, because the void fraction and enthalpy of feed stream are possible to be controlled by controlling the hold-up level in the heat exchanger.

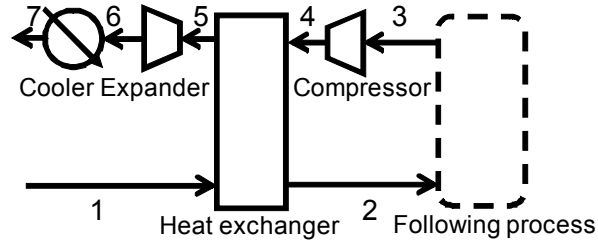

Fig. 3. Flow Diagram for Gas Stream Using Self-Heat Recuperation

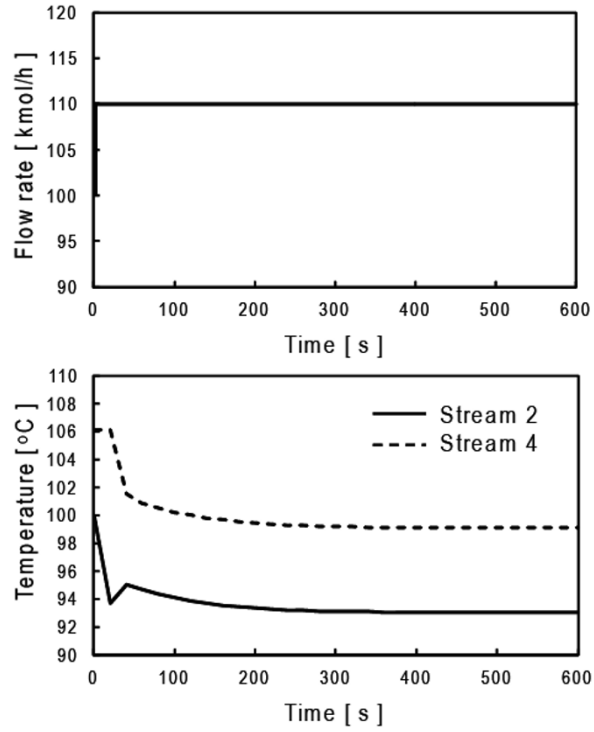

Fig. 4. Step Change of Flow Rate from 100 to 110 kmol/h and Response of Stream Temperature

4. Conclusion

The dynamic characteristics of the self-heat recuperative process to design the operation systems for the process to achieve further energy saving and to investigate the stability of the process during operation are investigated in this paper. To realize the self-heat recuperative distillation, it requires balancing the enthalpy of the feed streams to that of the effluent streams. According to these simulations, it is necessary to design the suitable operation system with further investigation to automatic operation. However, it can also be seen that this process has some potential for further energy saving.

Abstract

A new approach for optimal experimental design has been developed to support the work of chemists and process engineers in determining reaction kinetics of complex reaction networks. The methodology is applied on sub-networks of the hydroformylation process of 1-dodecene with a Biphephos-modified rhodium catalyst in a DMF-decane thermomorphic solvent system (TMS). The isomerization and hydrogenation sub-networks are systematically analyzed with respect to parameter estimability. They are determined in a sequential approach using model-based optimal experimental design via perturbations with respect to temperature and synthesis gas pressure, and subsequently used to build up the reaction network. The focus of this contribution is the parameter estimation procedure at the very early investigation stage where model uncertainties are high. Sensitivities of sensitive parameters are increased while others are suppressed, which are carried over from the estimated sub-networks or structurally more difficult to determine. This subsequently leads to more reliable parameter estimations.

Keywords: optimal experiment design, model discrimination, parameter estimation, hydroformylation, 1-dodecene

1. Problem Statement

The German Collaborative Research Centre/Transregio 63 is engaged in the development of efficient production processes based on integrated chemical processes in liquid multiphase systems (InPROMPT). Currently, the hydroformylation process of 1-dodecene with a Biphephos-modified rhodium catalyst in a DMF-decane TMS-system is investigated. The proposed complete hydroformylation reaction network is quite complex. It is well known, that side reactions can occur in the hydroformylation reaction like isomerization and hydrogenation of 1-dodecene and its isomers. These side reactions have a negative influence on the product distribution. Hower, side or subsequent reactions leading to adols, alcohol and acids have not been observed in all our experiments leading to a reaction network as proposed in Fig. 1:

1: investigated hydroformylation reaction network

The hydroformylation network involves a large number of parameters so that it could not be estimated in an *all-in-one* approach. Therefore, an investigation series of sub-networks is suggested in order to achieve an accurate estimation of the kinetic parameters. The crucial idea is to avoid simply putting the estimated sub-networks together but to regard their estimated parameter sub-sets as uncertainties. Moreover, regarding the parameter estimation of complex reaction networks, it is usually necessary to fix some parameters in order to estimate the free parameters properly. However, most of the experimental design approaches aim at maximizing sensitivities of all parameters. It is rather recommendable to hold the sensitivities of those parameters, which are going to be held constant, as low as possible.

In both cases, the goal is to ensure an acceptable performance of the parameters to be estimated for all possible values of uncertain parameter subsets. A new robust experimental design method is proposed to implement this idea (see 2.2.2).

Notation

c_i	concentration of component i	$c^{L,I}$	g-l-interphase concentration
k_{eff}	effective mass transport coefficient	p	partial pressure
H	Henry coefficient	$\mathrm{H_{ads}}$	adsoprtion enthalpie
r	reaction rate	k_r	reaction rate coefficient
k_{ref}	normalized frequency factor	k_{eff}	effective mass transfer coefficient
c_{Cat}	catalyst concentration	z	state variable (concentrations,…)
s	sensitivity ($\partial z/\partial\theta$)	s^*	sensitivity to be suppressed
u	control variable	h	element length (OC on FEM)
N_e	number of elements(OCFEM)	N_n	number of states
N_θ	number of parameters	N_{sp}	number of sampling points
K	order of OC on FEM	Q	weighting matrix
q_r	diag. element of Q w.r.t. the r-th state	E_a	activation energy

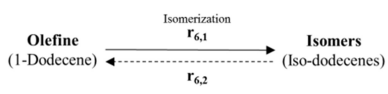
Greek letters

θ_i	i-th parameter	ψ	polynomial base of degree K

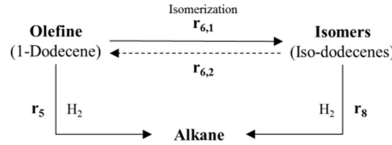
2. Methodology

2.1. Model building

By dividing the main network into sub-networks, one can determine the parameters step by step. The isomerization and hydrogenation sub-networks are shown in figure 2a and 2b.



2a: Isomerization sub-network



2b: Hydrogenation sub-network

The mass transfer of hydrogen through the gas-liquid interface is modeled as:

$$\dot{N}_{H_2} = k_{eff,H_2}\left(c_{H_2}^{L,I} - c_{H_2}^{L}\right)$$

Using the Henry's Law with the Van't Hoff temperature dependency, the interfacial concentration on the liquid side can be described as follows

$$c_{H_2}^{L,I} = \frac{p_{H_2}}{H_{H_2}(T)}, \qquad H_{H_2}(T) = H_{0,H_2}\, exp\left(\frac{H_{ads}}{RT}\right)$$

The ractionrate for the isomerization and hydrogenation reaction are as follows

$$r_{6_1/6_2} = c_{Cat} k_{r,6_1/6_2}\, c_{Doce/IsoDoce}^{L}, \qquad r_{5/8} = c_{Cat} k_{r,5/8} c_{H_2}^{L} c_{Doce/IsoDoce}^{L}$$

The temperature dependency of the reaction rate coefficients are described as proposed by Buzzi-Ferraris et al. [2009]:

$$k_{r,i} = k_{ref,i} ex\, p\left(-\frac{E_{a,i}}{R}\left(\frac{1}{T} - \frac{1}{T_{ref}}\right)\right)$$

2.2. Estimability analysis

If it is not possible to estimate all parameters in an *all-in-one* approach, then one would like to know, which one has to be held constant in the first estimation loops. In this step, the parameter estimability analysis proposed by Franceschini and Machietto [2008] is applied. If the rank of the estimability matrix P_E is equal to the number of parameters N_θ, then all model parameters are estimable. If not, the analysis of the P_E-matrix will give us the information of which parameter sensitivity must be taken out of the analysis. This is equivalent to identify those parameters, which must be held constant in the subsequent parameter estimation. The idea is to push the sensitivities of those parameters to zero. This aims for ensuring an acceptable performance of the "estimable" parameters for all possible values of the discarded parameters.

2.3. Optimal Experimental Design

The main idea of maximizing the divergence of competing model candidates for model discrimination or maximizing the information content of designed experiments for precise parameter estimation are the main methods of the model based experimental design community. In this work, a simultaneous approach for optimal experimental design is proposed based on the simultaneous optimization approach of Biegler et al. [1991]. Moreover, a new A_R-criterium for robust parameter estimation is discussed.

2.3.1. Problem Formulation

The defined problem (Espie and Macchietto, [1989]) can generally be written as an optimal control problem consisting of the objective function:

$$\varphi(z(t), s(t), u(t), \theta) = \sum_{l=1}^{N_{sp}} \Phi_l(z(t_l), s(t_l), u(t_l), \theta)$$

which is to be maximized, subject to a process model:

$$0 = f(z(t), s(t), u(t), \theta), \qquad 0 = g(z_{t0}, s_{t0}, u_{t0}, \theta)$$

where $0 = g(\ldots)$ is the general formulation of the initial state conditions. Furthermore the system has to follow the constraints of states and controls:

$$z_L \le z \le z_U, \qquad u_L \le u \le u_U$$

2.3.2. Robust Experimental Design Criterion

Applying the simultaneous approach with orthogonal collocation on finite elements on the A_R-criterion, one obtains:

$$\max_{u_{ik},z_{ik},s_{ik}} \varphi(u_{ik},z_{ik},s_{ik}) = \sum_{m=1}^{N_{sp}} \left(\frac{\sum_{r=1}^{N_n} \sum_{s=1}^{N_\theta} q_r \cdot (s_{ik}^{rs})^2}{\exp\left(\sum_{r=1}^{N_n^*} \sum_{s=1}^{N_\theta^*} q_r \cdot \left(s_{ik}^{*,rs}\right)^2\right)} \right)_m$$

Where x_{ik} are the fully discretized state variables, $x := [z, s]$. The equality and inquality constraints of the process model are:

$$0 = \sum_{k=0}^{K} x_{ik} \dot{\psi}_k(\tau_j) - h_i f(x_{ij}, u_{ij}, \theta), \qquad i = 1, \dots, N_e; j = 1, \dots, K$$

$$x_{10} = x_{t_0}, \qquad x_{l0} = x_{l-1K}, \qquad l = 2, \dots, N_e$$

$$x_L \leq x_{ij} \leq x_U, \qquad u_L \leq u_{ij} \leq u_U$$

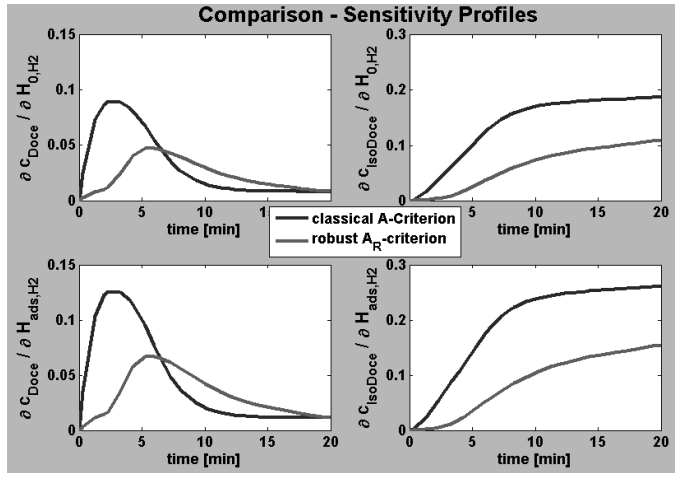
In order to maximize the objective function φ, the sensitivities of the discarded parameters $s_{ik}^{*,rs}$ are suppressed.

3. Results

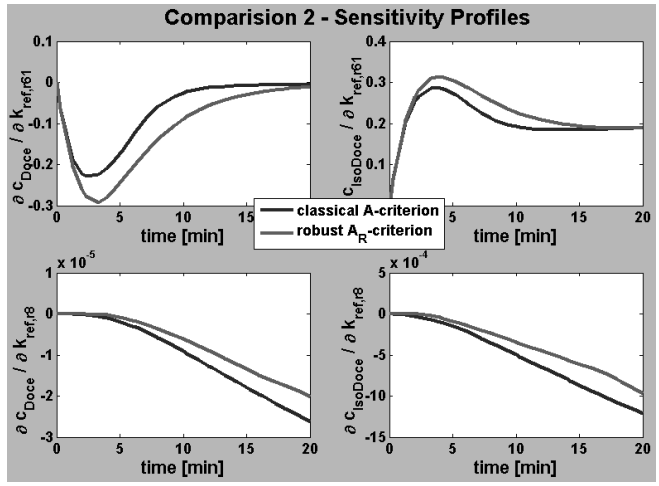
The methodology is described by an experimental design example for robust parameter estimation of the hydrogenation sub-network.

It is very common to identify the solubility of the gas educts separately without the reactions. Those thermodynamic parameters are fixed afterwards for the determination of the reaction kinetics parameters. Nevertheless they still represent uncertainties because of their high sensitivities towards the reaction rates and so make the kinetic parameter estimation unreliable. Now, one would like to have an experimental design which suppresses the sensitivities of the solubility parameters making the kinetic measurements more robust towards mass transfer effects.

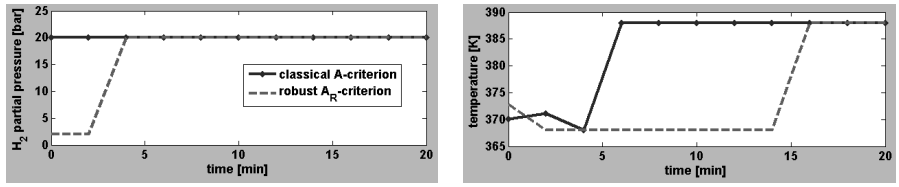
As shown in figure 3a the sensitivity of solubility parameters could be reduced upto 50%. On the other hand the designed experiment still yields high sensitivities for the wanted kinetic parameters (fig. 3b). The difference with respect to control trajectories between classical and robust experimental design can be seen in figure 4.



3a: sensitivities with respect to solubility parameters



3b: sensitivities with respect to kinetic parametres



4: sensitivities with respect to kinetic parametres

4. Conclusion

The solution strategy aims at dividing a complex reaction network into sub-networks, in particular, if an *all-in-one* parameter estimation approach is not possible. The determination of the sub-networks provides parameter subsets which are transfered to the main reaction network and treated as uncertainties. The new method aims for a robust optimal experimental design which ensure an acceptable performance of the new parameters for all possible values of the carried over parameter-subsets. This subsequently leads to more reliable kinetic parameter estimations.

Abstract

A novel process concept for the hydroformylation of long chain olefins in micro emulsions is investigated and developed within the framework of a Collaborative Research Centre in Germany. In this process, the liquid feed material (C12 olefin) is brought in contact with a hydrophilic rhodium-ligand-complex, which is dissolved in an aqueous phase while forming a micro emulsion system under the use of non-ionic surfactants. The hydroformylation reaction is started by adding syngas (H_2&CO) into a continuously stirred tank reactor (CSTR). Due to phase separation into an aqueous phase (catalyst-rich) and an organic phase (product-rich), the valuable rhodium catalyst can be retrieved and recycled. This key separation step is challenging and crucial for the technical and economic feasibility of the overall process concept and plant design.

Depending on the temperature the mixture decomposes into two or even three liquid phases. Preliminary investigations have shown that product and catalyst separation in a continuous process is only attainable in the three phase state, given the required separation time and quality. However, due to the lack of thermodynamic data for micro emulsion mixtures, the design of the phase separation unit strongly depends on experimental data. Consequently, a systematic experimental approach has been developed to identify potential operating conditions and relevant design parameters. In order to classify and find these, a set of systematic experimental set-ups have been investigated to characterize impact factors on the phase separation such as type of surfactant, different concentrations of surfactant, olefin, product, and water. With the information gained through the observations the relevant composition of the investigated mixture and the separation temperature are determined for the operating conditions. Finally, necessities with regards to plant and process design are revealed.

Keywords: Hydroformylation, micellar catalysis, phase separation, process design

1. Introduction

Hydroformylation represents an important application in the field of homogenous catalysis. For short olefins, hydroformylation has already been established as a standard process in order to produce aldehydes. Due to the decreasing solubility of alkenes with an increasing length of carbon chains in the aqueous phase, hydroformylation of higher olefins is not yet performed in industry. Therefore, non-ionic surfactants are applied to

increase the miscibility of the oil- and the catalyst-containing water phase. In order to increase yield and selectivity even under mild reaction conditions, a water-soluble, hydrophilic rhodium-ligand-complex is employed. The resulting multiphase system offers the possibility to separate the valuable rhodium catalyst comparatively easy from the organic product (Bode et al., 2000). Figure 1 shows the novel process concept for the hydroformylation of long chain olefins in a micellar multiphase system.

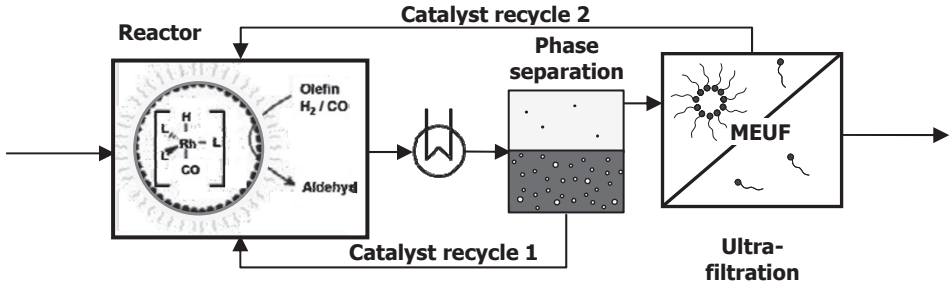

Figure 1: Novel process concept for the hydroformylation of long chain olefins

The first step is the hydroformyltion reaction of C12 olefins in a CSTR according to Figure 2. Secondly, the valuable catalyst is retrieved by means of phase separation and subsequently recycled to the reactor. Due to high catalyst costs a second separation step through ultra filtration is required to reduce the catalyst loss to a minimum (lower 1ppm) and to ensure economic feasibility.

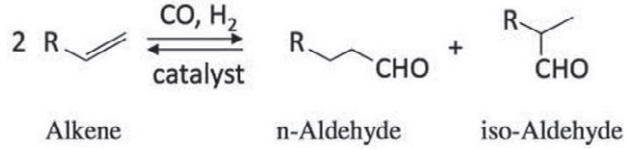

Figure 2: Basic concept of the hydroformylation reaction equation (Kupka, 2006)

The initial catalyst removal takes place in the phase separation unit (decanter), in which most of the rhodium is drawn into the aqueous phase. Preliminary investigations have shown that this is quite challenging. Phase separation itself as well as separation quality and time strongly depend on the type of surfactant and its concentration (γ, Eq. 1), on temperature, on the amount of water (α, Eq. 2), and product (λ, Eq. 3). The following three equations are employed to represent the respective concentrations after the reaction.

$$\gamma = \frac{m_{\text{surfactant}}}{m_{\text{olefin}} + m_{\text{water}} + m_{\text{surfactant}}} \tag{1}$$

$$\alpha = \frac{m_{\text{olefin}}}{m_{\text{olefin}} + m_{\text{water}}} \tag{2}$$

$$\lambda = \frac{m_{\text{aldehyde}}}{m_{\text{aldehyde}} + m_{\text{olefin}}} \tag{3}$$

2. Systematic analysis of the micro emulsion mixture for process and equipment design

Due to the lack of thermodynamic data for micro emulsion mixtures and a lack of reliable simulations, the design of the phase separation unit strongly depends on experimental data. Therefore, a systematic experimental approach is developed so as to identify potential operating conditions and relevant design parameters.

2.1. General phase separation behavior

In a first step, the general phase separation behavior is determined. There are four potential states, which depend on temperature and conversion rate. These are depicted in Figure 3 in the form of Kahlweit´s fish (Kahlweit et al., 1983) for a given composition.

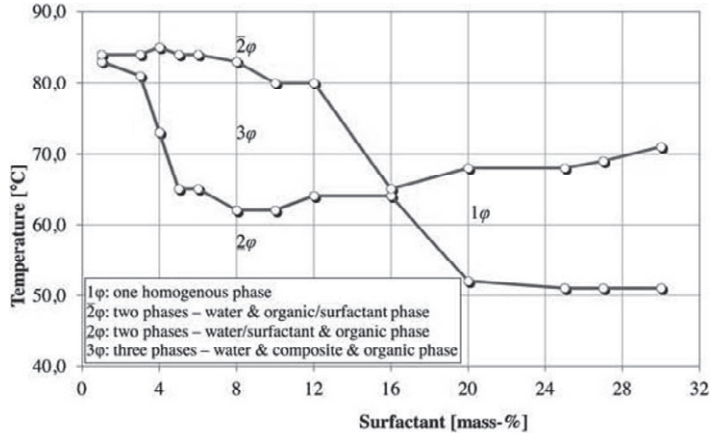

Figure 3: Kahlweit's fish for Marlophen NP9, α=0.5 and λ=0.5 conversion

Preliminary investigations of a mixture consisting of Marlophen NP9, water, and dodecene show that product and catalyst separation in a continuous process are only attainable in the three phase state, given the required separation time and quality. Hence, the initial aim is to identify the three phase region to find potential operating conditions.

2.2. Dynamics of phase separation & quality classification

In a second step the separation dynamics and quality of the three phase state has to be determined. Therefore, the mentioned composition is mixed in a tempered measuring glass and the separation progress of each single phase is recorded. In Figure 4 two graphs are shown for the dynamic separation behavior at 71°C and 74°C.

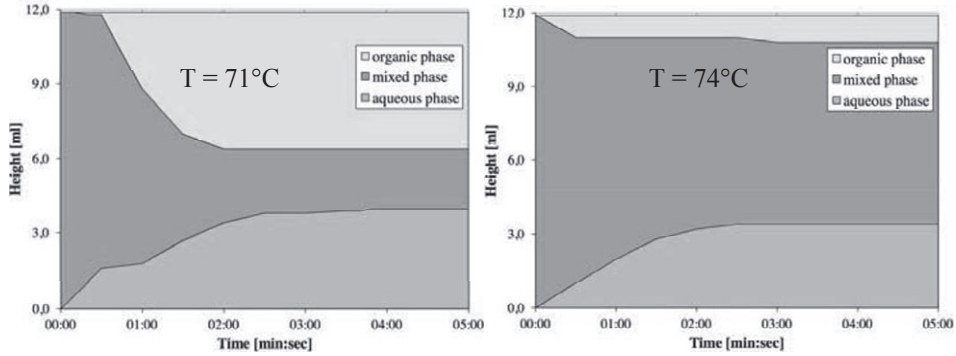

Figure 4: Dynamic phase separation behavior for γ=0.05, α=0.5, λ=0.5 at 71°C and 74°C

For 71°C the separation occurs comparatively fast, reaching a quasi steady state after around three minutes. All of the three phases appear transparent, which signifies a complete separation of the micro emulsion. A further quality criterion is a small mixed phase in comparison to the other two phases. These observations imply a qualitatively good separation. On the other hand, the graph for 74°C shows that the separation of the organic phase is poor and most of the product remains in the mixed phase. This is an example for an undesired phase separation behavior. The comparison of these two examples illustrates the difficulty in handling this multiphase system, because of the strong temperature dependency. Even within the three-phase-state, the separation quality of each phase differs strongly for small temperature changes, in this case, 3 K. This necessitates a flexible and fast temperature control.

2.3. Continuous separation

Since adequate and potential process parameters were found by means of the dynamic investigations of the mixture, the next step is the demonstration of the general applicability in a continuous separation process. Figure 5 shows the PFD-diagram and a picture of the applied experimental test set-up. The mixture consisting of γ=0.05, α=0.5, λ=0.5 is heated and stirred in the composite storage tank and pumped into the heated glass decanter, which is designed referring to the required retention time. Here, both of the heavier phases, the catalyst rich aqueous and the surfactant rich middle phase, are removed together. The lighter organic product phase is removed separately. The experimental results show that the separation of a three phase micellar multiphase system is possible for a continuous process.

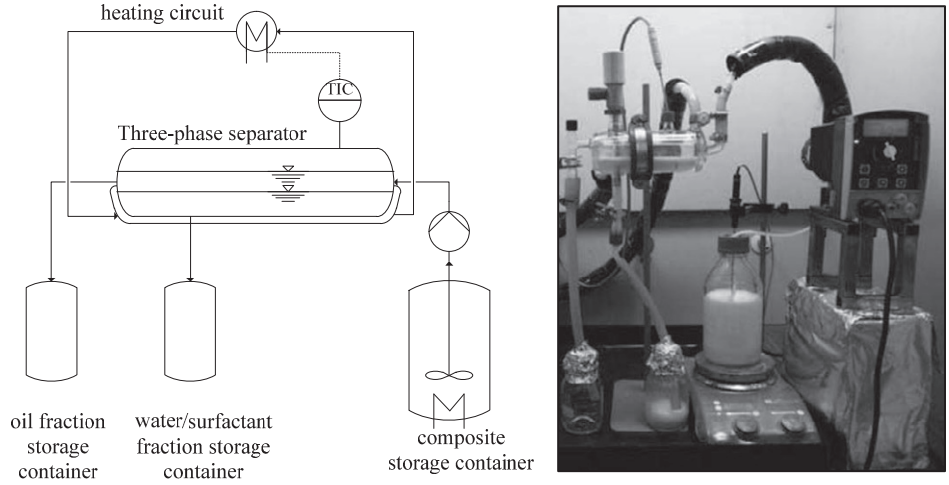

Figure 5: PFD diagram and a picture of the experimental test set-up for the continuous separation of a three phase micellar multiphase system

3. Mini-plant Design

The systematic approach discribed so far aids in designing a mini-plant to test the viability of the process concept and at the same time shows opportunities to optimize the yield of the almost pure organic product phase. The observations of the dynamic separation behavior highlight the necessity of a temperature control system in both

reactor and decanter of the mini-plant. Thus, the temperature for an optimal phase separation with respect to quality and time can be maintained. Furthermore, the results obtained during the continuous separation allow for the sizing of the actual decanter in relation to the reactor volume. The instability of the phase separation dynamics with regards to the temperature influence imply the implementation of an additional quality control of the product phase to ensure and ascertain the composition. This is achieved through an online HPLC which can be used to modify and control feed and recycle streams of the mini-plant.
To proceed, the afore mentioned investigation of the phase separation dynamics may aid in improving the control concept through the development of a short-cut model predicting the phase sizes in the decanter. This requires extensive experimental investigations of the stand-alone decanter for various temperatures and concentrations.

4. Conclusion

The removal of the valuable rhodium catalyst for recycling by means of phase separation is vital for the economical and technical feasibility of the proposed novel process concept for the hydroformylation of long chain olefins. To identify potential process and design parameters for a micellar multiphase system, a systematic approach has been successfully developed and established in three steps. First of all the general phase separation behavior was determined. Then, the dynamics of the phase separation were investigated, which basically provide information to evaluate and classify potential process parameters and to enable the design of a decanter. In the last step, the applicability of a continuous phase separation was demonstrated by means of an experimental test set-up. This systematic approach now offers the possibility to adapt the decanter operation of the mini-plant towards new developments concerning the micellar multiphase mixture and contributes to improve and develop the novel process design systematically.

Abstract

In the work reported here, a conceptual generic continuous process *template* for pharmaceutical production is presented. The template is demonstrated on a nitro reduction case study that should in principle be generic such that it can handle a series of substrates with similar molecular functionality. To assist in adoption of different substrates, a systematic substrate adoption methodology (SAM) has also been developed. The objective of the generic process *template* together with the SAM is to provide flexibility as well as increased efficiency to continuous processes while reducing inventory for safer operations (from 50 to 100 L in batch or 3 to 5 L in continuous processes). It is shown that the use of the template together with SAM can lead to potential savings in product development times through flexible and efficient production of Kg amounts of product material for clinical trials and other analyses.

Keywords: process template, API, substrate adoption, methodology, pharmaceutical.

1. Introduction

Identification of an effective and safe pharmaceutical product is based on success in clinical trials. Often, several candidate APIs (active pharmaceutical ingredients) targeting the same disease area are tested in order to identify efficacious products. This involves the manufacture of small quantities of compounds in early delivery campaigns. Of these candidates only a few are successful for which, further development is required to scale–up the process. Conventionally, for each candidate API, a whole new manufacturing system (process, reagents, process conditions etc.) needs to be developed, which is costly in terms of time and resources. One solution is to develop a generic process 'template' (a common manufacturing platform) that can be adapted for the production of a series of similar APIs for their early delivery campaigns, resulting in a reduction of time, early manufacturing cost and resource consumption.

2. A conceptual generic nitro reduction process template

A conceptual generic nitro reduction process *template* has been designed (see Figure 1). The template consists of several route alternatives as well as generic process equipments. The nitro compound (C_N) is dissolved in a solvent (S) in a stirred tank, prior to filtration to remove any un-dissolved material before feeding to the reactor. The reducing agent (R_A) can be mixed with C_N, with the catalyst or fed directly to the reactor. The suspension of catalyst may also be prepared in a stirred tank prior to being

continuously fed to the reactor. A slurry plug-flow micro-reactor is used to perform the reaction in continuous mode. The outlet stream from the reactor contains product (P_N, representing, for example, an amino compound), catalyst, any un-reacted R_A and by-product(s), P_B. The subsequent steps are to separate catalyst, reducing agent, products (P_N and P_B) and solvent.

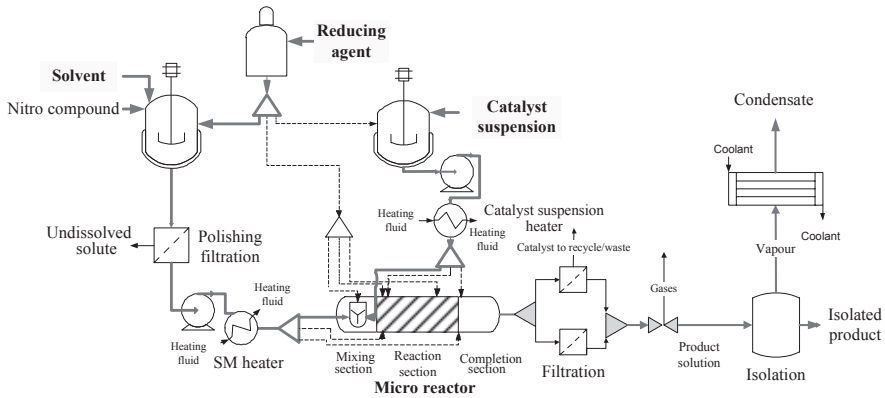

Figure 1. Nitro reduction process template (one route is highlighted)

A generic form of the nitro reduction reaction is given in Scheme 1. Through this reaction, an aromatic nitro compound (C_N) is reduced to the corresponding amine (P_N). The reducing agent, solvent and catalyst are the key materials which need to be selected for a given substrate. By-product(s) depend on the type of reducing agent used. The number of alternatives because of R and reducing agent is potentially very high.

$$R\text{-}NO_2 \quad + \quad \text{Reducing agent} \quad \xrightarrow[\text{Solvent}]{\text{Catalyst}} \quad R\text{-}NH_2 \quad + \quad \text{By-product(s)}$$

Scheme 1. Generic nitro reduction forming an amine

3. Substrate Adoption Methodology (SAM)

To adopt any new substrate in the generic process template, SAM employs 6 hierarchical steps as shown in Figure 2. In step-1 the aim is to check whether the substances involved in the process are hazardous. In step-2 a preliminary solvent list, suitable for dissolving the substrate and product is generated. The reducing agent and catalyst are selected in step-3 through reactivity and selectivity assessments. In step-4, an appropriate process flowsheet is generated from the process template and the corresponding process conditions are identified. The feasibility of the generated process is analyzed in step-5. On the basis of the outcomes of steps-1 to -5, reducing agent, catalyst, solvent, process flowsheet and the process operating conditions necessary for a new product synthesis are summarized (step-6). These can then be further validated through experiments. The data sources needed and the corresponding output from the methodology are also given in Figure 2. Each step of the methodology is described in a publication by Singh et al. (2011) – the SAM related work-flow is new.

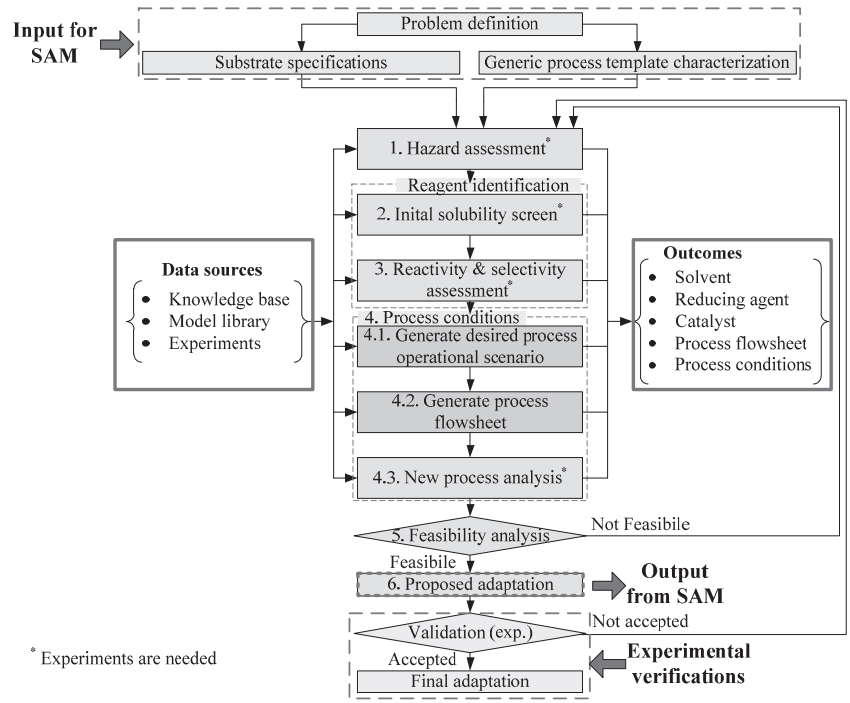

Figure 2. Substrate adoption methodology (SAM)

4. Conceptual case study

Problem definition: To adapt a generic nitro reduction process template for the production of P_N (a multi-functional organic chemical with C, H, N & O atoms) through transfer hydrogenation (for reasons of confidentiality, the actual names of the chemicals cannot be disclosed). The reaction scheme is similar to that shown in Scheme-1.

Substrate specifications: The reactant (substrate) is CN (also a multi-functional organic chemical with C, H, N & O atoms).

Generic process template characterization: Based on experimentation and analysis of several nitro compounds and the nitro reduction process template, some common information & data is generated, which are expected to be applicable to a series of nitro compounds. For example potential reducing agent candidates (e.g.: triethylammonium formate and ammonium formate), catalyst candidates (e.g. Pd/C, Pt/C) and solvent candidates (THF, IPA, NMP) are identified.

4.1. Hazard assessment (step-1)

The substrate is subjected to a hazard assessment methodology. For the purpose of this example, we will assume that based on experimental results, it was concluded that this substrate could be considered for adoption with appropriate safety measures.

4.2. Initial solubility screen (step-2)

The solubility of reactant and product in different solvent candidates is predicted using the UNIFAC group contribution model to select the appropriate solvent. For the purpose of this demonstration, the solubility order found is THF >IPA>NMP.

4.3. Reactivity and selectivity assessment (step-3)

A number of reducing agents and catalyst candidates can be used to carry out this reaction. Based on our existing knowledge, only one reducing agent candidate (for example, triethylammonium formate), one catalyst candidate (for example, Pd/C) and three solvent candidates (THF, IPA and NMP) are considered for further analysis (see Figure 3). Figure-3 shows an example of the type of information that could be generated in this step of the methodology. In the case of THF as solvent, the yield increases rapidly at first but after a certain reaction time the yield decreases, meaning that the reaction is fastest in this case but it also leads to the highest over-reduction. However, the maximum yield achieved with triethylammonium formate, Pd/C and THF is satisfactory meaning that these could be considered as reagents. Furthermore, the use of continuous reaction technology allows a better control of reaction time compared to batch operation and therefore an adaptation is proposed for this reaction with these reagents.

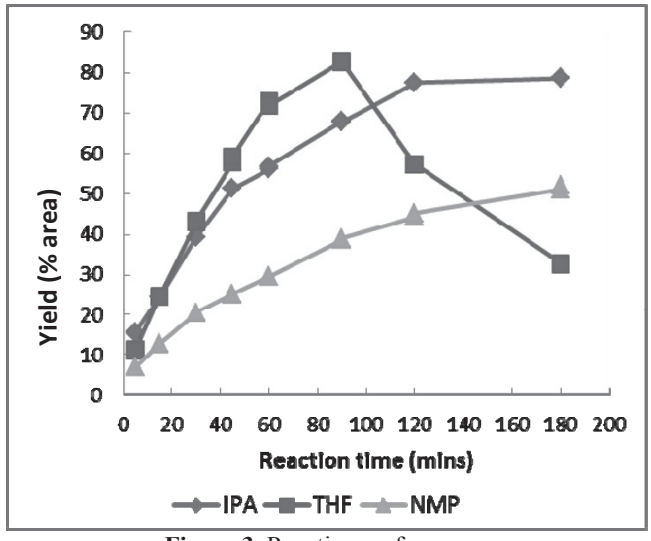

Figure 3. Reaction performance

4.4. Process conditions (step-4)

For the purpose of this demonstration, a process flowsheet is generated (indicated by the highlighted part of Figure 1) from the generic process template. The process is then analyzed and operating conditions are generated. The reactor operating window is shown in Figure 4 as an example.

4.5. Feasibility analysis (step-5)

In this step plant feasibility, operational feasibility and reagents feasibility are analyzed and could be considered satisfactory for the purpose of this demonstration.

4.6. Proposed adaptation (step-6)

On the basis of the outcomes of steps-1 to -5, the necessary reagents, process flowsheet and operating conditions are proposed as a demonstration example.

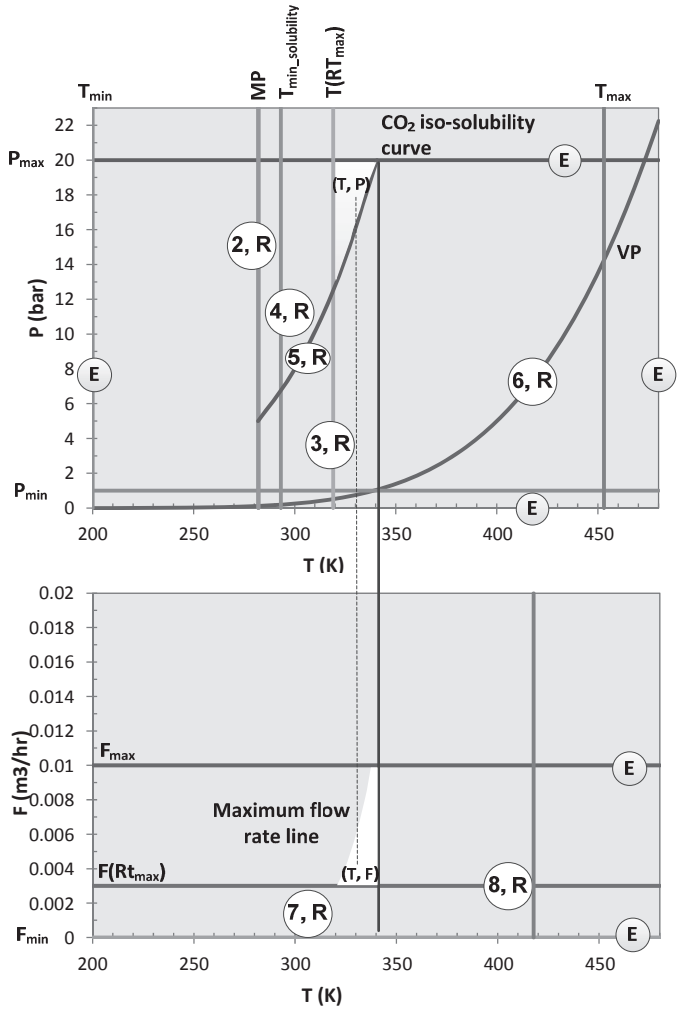

Figure 4. Reactor operating window (R: reaction dependent, E: equipment dependent)

5. Conclusions

In this paper, a generic nitro reduction process template has been reported. To assist in adaptation of the process template, a systematic substrate adoption methodology (SAM) has also been developed. The scope and significance of the process template and SAM has been demonstrated through a conceptual case study. The practical implementation of the template will now follow. The rapid and easy adaptation of the process template results in potential savings of time and resources.

Abstract

Flexibility in manufacturing processes is essential not only to handle a variety of feed stocks or to produce multiple product grades but also to accommodate process or catalyst inventions to improve productivity or quality. While designing in litheness we should ensure the robustness of the process output. In this paper, through a case study of biodiesel manufacturing, we summarize a novel technique which uses a probabilistic design approach using meta-models to evaluate the process intensification/integration scheme in a bio-refinery context.

In our methodology first we develop individual process models for a number of processes intensification alternatives where waste or non-edible vegetable oil are converted to biodiesel. These alternatives include the use of reactive distillation and a supercritical process. We integrate these process intensification schemes along with other necessary process steps to establish a plausible manufacturing process. Simultaneously we formulate high fidelity meta-models to describe the various responses of the reactive distillation column w.r.t the changes in the process conditions (or decision variables) in a given design space as an example. This simplification allows us to setup a probabilistic design using commercially available meta-heuristic optimization tools.

Keywords: process integration, reactive distillation, meta-model, probabilistic design

1. Introduction

There have been various efforts worldwide for more efficient conversion of biomass into syn-gas, chemicals, fuels etc. to overcome certain technical challenges leading to better process economics and operations. Biomass is a promising resource having lower carbon footprint compared to the existing non-renewable energy sources such as coal or petroleum based feedstocks. The areas of ongoing research include biomass pre-treatment e.g. biochemical or thermochemical routes such as biomass gasification or pyrolysis, gas treatment and cleaning, biogas to liquid conversion such as Fischer-Tropsch synthesis, transformation of bio-oil or vegetable oil into biodiesel by transesterification and esterification, fermentation of biomass to ethanol or other products, use of biogas in fuel cell for electric power. Each process or technology has its own advantages, for example, in a thermochemical path-way most of the biomass including lignin can be converted into added value chemicals, which is difficult using biochemical treatment. With the availability of many technologies and the ongoing

developments for converting variety of biomass to more useful products, integrating these technologies or processes in the most economical way has become equally important. Generally bio-refinery is referred as a facility capable of converting various types of bio-feedstock into biofuels, chemicals and energy in a sustainable way. In such a scenario, flexibility of the manufacturing unit is essential not only to handle multiple feed stocks or multiple products but also to accommodate process inventions to improve overall economics and sustainability of an integrated scheme. Our work mainly focuses on developing a tool which will enable to assess various process integration alternatives for biomass conversion. In our previous paper (Gondkar *et al.*, 2011) we discussed various types of uncertainties encountered in process engineering problems. Probabilistic design allows to quantify the fitness of a given process or component by providing a probability (likelihood) that the same will survive the operating conditions. In this paper first we discuss a case-study *i.e.* a process integration alternative for manufacturing of biodiesel and then derive a framework for probabilistic design. For this purpose we used the literature reported kinetics as mentioned in the next section. We demonstrate the power of this design with an example where the meta-model is used for optimization of a reactive distillation case.

2. Case Study

A case study for manufacturing of fatty acid alkyl esters (FAAE) of non-edible or waste vegetable oil feedstock containing higher amount of free fatty acids is investigated. In a typical heterogeneous catalytic transesterification and esterification process a fixed bed reactor is fed with a mixture of oil and methanol at a given molar ratio. Excess methanol and water formed due to esterification is removed at the exit of the reactor by partial evaporation. Esters and glycerol are separated in a settler. The reaction products are further purified and methanol can be reused after removing water. Solid acid catalysts and amphoteric metal oxides based on zinc or lanthanum are promising candidates. It is a well-known fact that heterogeneous catalyst for such reactions result in much slower volumetric reaction rates as compared to homogeneous catalysts. There is also a possibility of significant catalyst deactivation, leaching or blocking of porous solid catalyst because of its use. It is possible to overcome such limitations by further optimization of the reaction conditions, by minimizing mass transfer limitations or by carefully designing the catalyst architecture.

First we investigated the possibility of a process intensification alternative for fatty acid methyl esters (FAME) manufacturing comprising a reactive distillation using a heterogeneous catalyst. Here the oil containing higher fatty acid is continuously fed in the upper section of the distillation column containing a heterogeneous catalyst and the methanol is fed at a location a few stages above the reboiler. The bottom product obtained from the reboiler contains FAME, unreacted oil *i.e.* mixture of glycerides, glycerol and water. It is not necessary to have catalyst in the bottom stages to avoid hydrolysis. Methanol is distilled at the top which is either refluxed or recycled to the column. This concept avoids the use of a separate column to separate water and methanol and also possibly helps to improve mass transfer because of the presence of vapors bubbling on each stage. We developed Aspen Plus steady-state models for these processes. Dortmund modified UNIFAC property method is used. For the reactive distillation case we used the pseudo-homogenous catalytic reaction kinetics for tranesterification and esterification, as an approximation to demonstrate the concept. We derived the apparent kinetics from the published work of Qing *et al.,* (2011) for carbon

based solid acid catalyst as an example. Simulation results suggest that the reactive distillation alternative is useful to convert free fatty acids into esters and partial conversion of triglycerides at moderate process conditions (<125^0C). At higher temperatures the reaction would be more sensitive to solid-liquid mass transfer and requires a higher operating pressure for the reactive distillation column.

The other process intensification option we considered is a heterogeneous catalytic supercritical process. It uses CO_2 as a solvent along with methanol in a fixed bed catalytic reactor at elevated temperatures (approximately 200^0C) which needs much shorter residence times. For this case, the pseudo homogenous kinetics are derived from the reported experimental results (Macaira *et al.*, 2011) for a solid acid catalyst, Nafion SAC-13. One of the advantages of this process is that liquid to solid mass transfer under super-critical condition is so high that the reaction is still in the kinetically controlled regime. The downside of such a process is a need to separate water from the recovered solvents, which makes it energy intensive. Our simulation results suggest that if there is no water present in the recovered mixture of CO_2 and methanol, the energy requirement can be considerably reduced. So this process requires either using a feed free from fatty acids or a solvent dewatering scheme such as molecular sieves.

In order to leverage the best of both processes, it is possible to integrate the reactive distillation with the supercritical process. Reactive distillation is useful to convert free fatty acids into esters and realize partial conversion of triglycerides at moderate process conditions. The supercritical methanol and CO_2 based catalytic process is suitable for further conversion of glycerides at reasonable energy consumption. The flow-sheet of the integrated scheme is shown in Figure-1. When such processes are integrated the design and operation of individual unit are critical to obtain the optimum performance of an integrated shceme. In the next section the design philosophy is discussed using reactive distillation as an example.

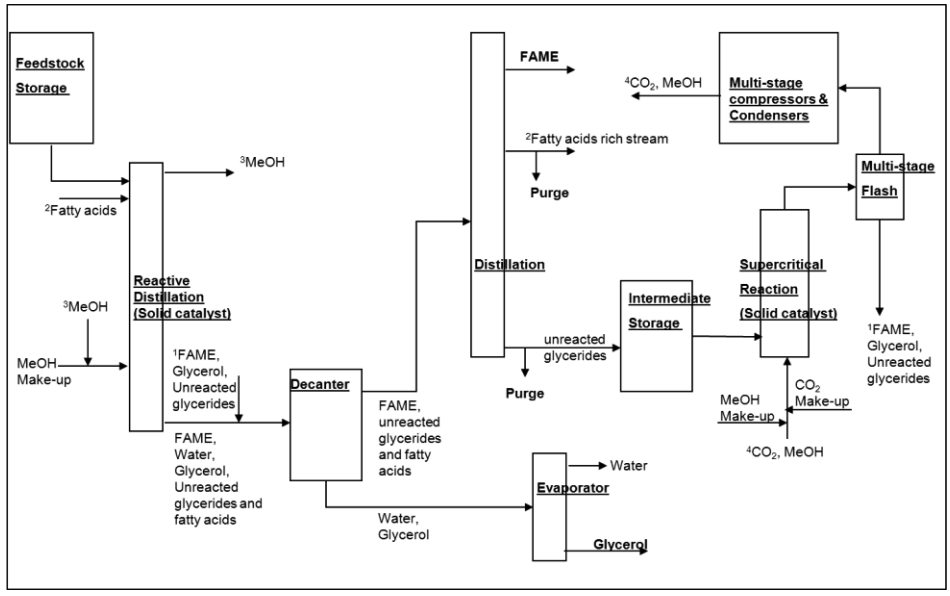

Figure-1: Integrated process (simplified block diagram)

3. Probabilistic Design

In our previous work (Gondkar *et al.,* 2011) for optimization of process intensification, we attempted the use of classical response surface methodology (C-RSM) based on a center composite design (CCD), but the errors associated with these simplified models (linear or quadratic) were resulting in wider error range on the predictions. We also directly coupled a commercially available meta-heuristic optimizer with a process simulator such as Aspen Plus. The results were satisfactory but the simulations were computationally intensive, i.e. long CPU times. This prompted us to look for an alternative methodology for model simplification. The use of meta-models is reported in structural engineering or mechanical design, but their application is very limited in process engineering (Palmer & Realff, 2002; Caballero & Grossmann, 2008; Henao & Maravelias, 2011). In the following section we will discuss the results from C-RSM and the meta-modeling exercise and the subsequent optimization of the reactive distillation for the kinetics derived from recent work by Qing *et al.,* 2011. In this example for illustration purposes, we selected 2 variables (methanol feed rate and reflux ratio), 7 responses (FAME rate, reboiler duty, condenser duty, methanol losses, liquid flow rate, gas flow rate and liquid hold-up) and the objective was set to maximize the product rate i.e. FAME rate with certain design requirements or constraints derived from the other responses.

C-RSM simulations were run at CCD design points (i.e. factorial points, center point and star points – alpha=1.41421)suggested by Design Expert software. As expected from our previous work (Gondkar *et al.,* 2011) the models suggested have very poor R^2. The diagnostic plots (*e.g.* Actual vs. Predicted) for two of the responses are shown in Figure 2. Such large residuals of the model predictions do not justify further optimization.

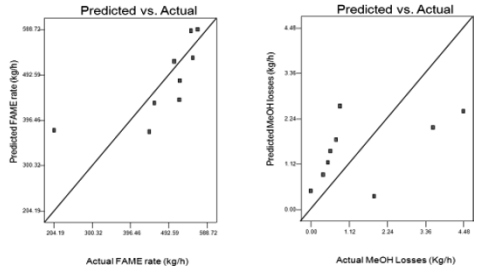

Figure 2: C-RSM model predictions (for CCD design) for reactive distillation

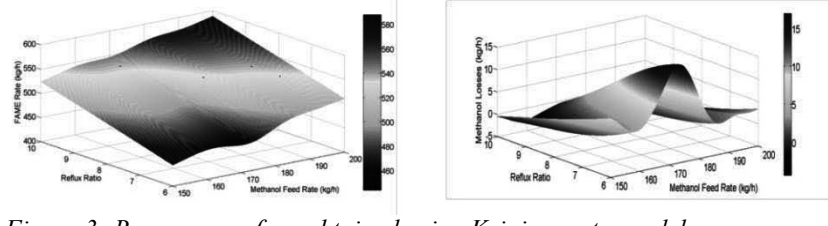

Figure 3: Response surface obtained using Kriging meta-model.

For the purpose of meta-modeling a Latin Hypercube sampling technique was preferred by keeping the same sample size as that of C-RSM and simulations were run at these points. For the fitting of the meta-models for all the responses, the Kriging toolbox implemented by Lophaven, Nielsen and Sondergaard (Nielsen, 2002) was used. The

meta-model parameters are estimated to minimize root mean squared error (RMSE). The response surface obtained using Kriging interpolation are given in Figure-3 for FAME rate and methanol losses.

For probabilistic optimization we developed a framework as follows: Crystal Ball, a spreadsheet based application is used for sampling probability density functions of decision variables as well as running simulations using above mentioned meta-models. For optimization OptQuest a meta-heuristic commercial optimization software is used. In this example for the decision variables i.e. methanol feed rate and reflux ratio standard deviation of 2% and 3% are specified to obtain the distribution of these variables at a given point. For the objective function defined and the design requirements specified the results obtained from this optimization exercise are given in Table 1. These results are further validated using Aspen Plus model.

		Objective	Requirements					Decision Variables	
		Maximize P99.87 Percentile	Certainty of 2.75-3.75 >= 95%	Certainty of 250.00-425.00 >= 95%	Certainty of 0.00-0.75 >= 95%	Certainty of -0.75-0.00 >= 95%	Certainty of 0.00-20.00 >= 95%

4. Conclusions and Path Forward

In our case study for evaluating a possible process intensification alternative it was found that highly non-linear responses can be described by high fidelity meta-models. This simplification allowed us the probabilistic design, which otherwise was difficult using classical response surface methodology because of large error, or by integrating process model with an optimizer. The methodology discussed here can be used to design an industrial system comprising of multiple processes and products. This will be accomplished using a multi-layer hierarchical framework (Zondervan *et al.,* 2008).

Abstract

In this work the adsorption and desorption parameters for the separation of theaflavins from tea are determined. The obtained data is used for a preliminary selection of the resin with the best adsorption capacity and desorption ratio. From the four tested resins the hydrophobic A-DVB resin has the best characteristics. In addition, the data was used to fit the adsorption isotherms at different temperatures to two theoretical models. The isotherms form the basis of a more extensive model that can be used to optimize the sorption separation yield. The selected resin will be used in a follow up study to determine the optimal operating conditions of the system, using design of experiments and analysis of variance.

Keywords: macroporous resin, adsorption, food industry, polyphenols, tea.

1. Introduction

Tea polyphenols are associated with many health benefits, such as prevention of heart, inflammatory and neurological diseases, as well as cancer prevention. While in green tea mostly catechins can be found, black tea is the source of several types of polyphenols formed by enzymatic polymerisation of catechins, including theaflavins, which can only be found in black and oolong teas [1,2].

The conventional approach for large-scale polyphenols separation is solid-liquid extraction followed by column adsorption chromatography as a purification step. Although this process is not very efficient from an energy requirement and reagents consumption point of view [3], today there is no established alternative to it. Macroporous adsorption resins are economically attractive and have a large surface area combined with a hollow and layered structure [4]. The purification mechanism is based on differences in polarity, hydrophobicity, molecular size and the shape of the different solutes for adsorbent resin. While the literature reports some investigation about suitable resins for green tea polyphenols adsorption [5], information about black tea polyphenols (namely theaflavins) adsorption is scarce.

The first step in designing any adsorption system is to acquire knowledge about adsorption equilibria, kinetics and capacity for target compounds on the selected ligand. The capacity of the adsorbents is usually characterized by isotherms, where Langmuir [6] and Freundlich [7] isotherms are most often applied for phenolic compounds:

Langmuir: $$Q_e = \frac{K_L C_e}{1 + a_L C_e} = \frac{Q_m a_L C_e}{1 + a_L C_e} \quad (1)$$

Freundlich: $$Q_e = K_F C_e^{1/n} \quad (2)$$

where K_L(l/g) is the solute adsorptivity, a_L(l/mg) is a Langmuir constant that represents the ratio between the adsorption and desorption rate constants, Q_m(mg/g) is another Langmuir constant that represents the maximum adsorption capacity, K_F (l/g) is the

Freundlich constant that represents the adsorption capacity and $1/n$ (dimensionless) is an empirical constant that represents the magnitude of the adsorption driving force [8,9].

In this study both the adsorption and the desorption parameters for the separation of theaflavins from black tea were determined. Adsorption data has been analyzed with both types of isotherms to determine the best experimental fit. The results obtained will be used further as a basis for characterization and optimization of a suitable system for purifying the theaflavins from the black tea on the large scale.

2. Experimental

2.1. Reagents and adsorbents

Acetonitrile and ascorbic acid were analytical grade obtained from Sigma – Aldrich. Glacial acetic acid (HPLC grade) and ethanol absolute were purchased from Merck KGaA. Individual theaflavins standards were obtained from Unilever NV. The deionized water (< 18,2 MΩ) used in the experiments was Milli-Q gradient (Millipore). Freeze-dried dry black tea powder was supplied by Unilever R&D.

The resins used in this work and their characteristics are presented in Table 1. Prior to the adsorption-desorption experiments, all resins were pre-treated to remove the monomers and preservative agents. The resin was subsequently dried at 70°C in the oven during 24 hours. Weighted amounts of resin where then washed with ethanol and subsequently a second thorough wash with deionized water was done [10,11].

Table 1: Screened macroporous resins physical properties (manufacturer data)

Resin matrix	Surface area (m^2/g)	Particle size (mm)	Pore volume (ml/g)	Polarity
Polymethacrylic acid ester (AAE)	370	0.25-0.84	1.14	Moderate polar
Aromatic divinylbenzene copolymer (A-DVB)	700	0.6-0.75	1.4	Non polar
Styrene-divinyl benzene (S-DVB)	600	0.25-0.85	1.30	Non polar
Formophenolic (F-PHE)	150-250	0.56-0.76	0.95-1.18	Polar

2.2. Static adsorption and desorption experiments

The tea solutions used for the resin screening and for the adsorption isotherms were prepared by dissolving tea powder in 20% aqueous acetonitrile solution. The starting concentration of theaflavins used in the resin screening tests was around 0.4 mg/ml and for the isotherms experiments the theaflavins concentration range was 0.11-0.62 mg/ml.

For the desorption on the A-DVB resin at different water ethanol solutions, the tea solutions were prepared by dissolving tea powder in water (with stirring). This change in the solution preparation method was made to achieve similar properties to the tea at the process level. All future tests will be done using tea aqueous solutions.

For the static adsorption tests, the hydrated resin (with a dry weight of 1.5 g) was placed in an Erlenmeyer with a lid and 25 ml of black tea solution was added to it. The Erlenmeyer was shaken at 100 rpm at 25°C in a temperature controlled IKA KS 4000i Control Orbital Shaker, during 4 hours. After achieving the adsorption equilibrium, a desorption test was initiated by placing the resin in another Erlenmeyer and adding 25 ml of eluent. The Erlenmeyer was again shaken at 100 rpm and 25°C during 4 hours. Based on the results obtained by Huang *et al.* [12] we decided to use a 50 % (v/v) ethanol solution in this preliminary screening study. In another experiment the ethanol-water ratio was varied to study it's effect in the desorption ratio.

The adsorption capacity (Qe, in mg/g) and adsorption ratio (E, in %) of the theaflavins in the tested resins were calculated according to the following equations:

$$Q_e = \frac{(C_0 - C_e)V_i}{W} \quad (3)$$

$$E = \frac{(C_0 - C_e)V_i}{C_0} \times 100\% \quad (4)$$

where C_0 (g/l) and C_e (g/l) were the initial and equilibrium concentration of the solute in solution, respectively, V_i (l) was the volume of initial solution and W (g) was the weight of dry resin. Desorption ratio (D, in %) was calculated according to:

$$D = \left[\frac{C_d V_d}{(C_0 - C_e)V_i}\right] \times 100\% \quad (5)$$

where C_d (g/l) is the concentration of the solute in the desorption solution and V_d (l) is the volume of desorption solution.

2.3. Analytical methods: HPLC analysis of theaflavins

Individual theaflavins concentrations were determined by HPLC analysis on a Varian HPLC equipped with a Varian Prostar 310 UV Detector and on a Waters 2695 equipped with a 2487 wavelength detector. The analysis was performed in a C18 column, by isocratic elution with acetic acid/water/acetonitrile solutions. The exact method was supplied by Unilever R&D. The total amount of theaflavins was determined by a summation of the four theaflavins (theaflavin, theaflavin 3 monogallate, theaflavin 3' monogallate and theaflavin digallate).

3. Results and discussion

3.1. Static adsorption

The adsorption process during the first hour exhibits an almost linear increase (Figure 1) for all tested resins, followed by a slow increase until the equilibrium plateau was reached. The maximum adsorption capacities, adsorption and desorption ratios at room temperature can be found in Table 2. The polar F-PHE resin consistently showed

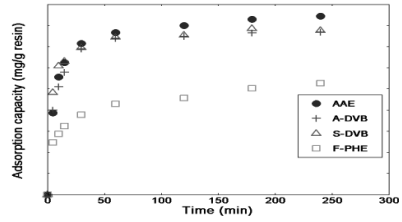

Figure 1:Adsorption kinetic curves for total theaflavins

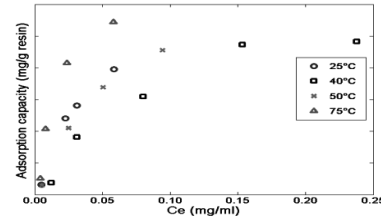

Figure 2: Adsorption isotherms of theaflavins on a A-DVB resin

lower adsorption capacity, probably due to slightly hydrophobic nature of theaflavins. Gogoi *et al.* [5] noticed a completely opposite trend when testing tea catechins adsorption capacities of different resins, where the most polar resin had the best performance. Similar results were reported for polyphenol adsorption on microporous non-ionic aliphatic ester resin by Silva *et al.* [12], where hydrogen bonding between studied polyphenols and resin active sites was the most probable adsorption mechanism. This is not surprising as the theaflavins, which are dimers of green tea catechins, are expected to have a reduced polarity compared to their monomers, i.e. hydrophobic interactions are expected to have a predominant effect for adsorption. However, a straightforward conclusion why a certain resin behaves better than the other is difficult to make at this stage, as their active surface areas (Table 1) are quite different: Although the F-PHE resin has approximately three times lower surface area when comparing to both DVB resins, it only has a ~50 % lower adsorption capacity (Table 2).

Table 2: Adsorption capacity and ratio of adsorption and desorption for theaflavins at 25 °C

Resin	Q_e (mg/g resin)	E (%)	D (%)
AAE	8.44	82	38
A-DVB	7.69	81	71
S-DVB	7.76	71	61
F-PHE	5.26	49	78

According to Table 2 the resin with the best combined adsorption and desorption characteristics was the highly hydrophobic A-DVB resin. This resin was further used to determine parameters for both isotherms. Figure 2 shows the adsorption isotherms for the theaflavins on A-DVB resin at four different temperatures. To calculate the values for both adsorption models, Eq. 1 and Eq. 2 were re-written into their linear forms:

$$\frac{1}{Q_e} = \frac{1}{K_L C_e} + \frac{1}{Q_m} \quad (6)$$

$$\log Q_e = logK_F + \left(\frac{1}{n}\right) logC_e \quad (7)$$

The parameters of the two isotherms are summarised in Table 3. The correlation coefficients are very high for the Langmuir isotherm model at all the tested temperatures and for the Freundlich isotherm model at 25°C and 50°C, suggesting that both models fit very well to the experimental data. The Langmuir model shows a better fitting than the Freundlich model and the highest correlation coefficient is obtained at 25°C for the Langmuir equation (R^2 = 0.9961). The constant (1/n) in the Freundlich equation is the degree of favorability in the adsorption. Since the value is always between 0.1 and 1, the adsorption of theaflavins on the A-DVB resin was considered to be favorable. For a value above 1 it would be very difficult for the adsorption to occur [13].

Table 3: Langmuir and Freundlich adsorption values for theaflavins on A-DVB resin

Temperature (°C)	Langmuir model	R^2	Freundlich model	R^2
25	Ce/Qe=0.0745 Ce+0.0016	0.9961	Qe= 50.81 $Ce^{0.5520}$	0.9872
40	Ce/Qe =0.0693 Ce+0.0013	0.9925	Qe= 26.91 $Ce^{0.4908}$	0.9598
50	Ce/Qe=0.0713 Ce+0.0019	0.9873	Qe= 38.48 $Ce^{0.5058}$	0.9954
75	Ce/Qe=0.0607 Ce+0.009	0.9914	Qe= 65.83 $Ce^{0.5284}$	0.9202

3.2. Static desorption on A-DVB resin

Theaflavins are soluble in water, ethanol, methanol, acetone and ethyl acetate [14]. Since the possibility of food grade operations is to be tested, the desorption study was performed with different concentrations of ethanol-water solutions.

According to Figure 3, the normalized desorption ratio (to 100% ethanol) of theaflavins increases with increasing ethanol concentrations until it reaches a maximum at 70% (v/v). At higher ethanol concentrations the desorption ratio decreased again.

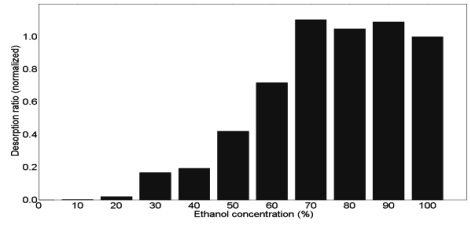

Figure 3: Normalized desorption ratio of theaflavins on A-DVB resin with different ethanol–water solutions

This ethanol-water desorption ratio is in accordance with the result obtained by Yi *et al.* [15] for eluting purified theaflavins. This is explained by a higher hydrophobicity of the theaflavins when comparing to other components present in black tea, e.g. catechins or caffeine, which have higher desorption rates at lower ethanol concentrations.

4. Future work

The selected resin will be used in a follow up study to identify the operational conditions (temperature, flow, etc.) that significantly affect the adsorption and desorption behavior of the resin. To capture the nonlinear behavior between the influence factors and the response factors a surface response methodology will be used. In addition, polynomial models can be generated from the data which can be used for optimization purposes.

5. Conclusions

Four commercial macroporous resins ranging from polar to non-polar were tested for their theaflavins adsorption characteristics from real aqueous black tea extracts. Among all resins studied, the most apolar A-DVB resin was found to have the best adsorption and desorption characteristics, probably due to chemical nature of the adsorbent. The desorption process was strongly influenced by the water content of the alcoholic solvent, as theaflavins will partition in the alcoholic phase only if their energy requirement for that phase is lower than for their sorption on the resin. The adsorption equilibrium exhibited a slightly better fit with the Langmuir model for all resins studied.

This work is the first step for a more detailed characterization and modeling study of the theaflavins adsorption process.

Influence of the organic phase fraction in the biphasic organic-aqueous reactor feed stream on the enzymatic hydrolysis of FAME in a packed bed

Przemyslaw Krause, Georg Fieg

Hamburg University of Technology, Institute of Process and Plant Engineering, Schwarzenbergstrasse 95 C, 21073 Hamburg, Germany, p.krause@tu-harburg.de

Abstract

The behavior of a differential packed-bed reactor element was investigated regarding the impact of the organic phase fraction on the reaction rate of an enzymatic hydrolysis with biphasic reactant flow. Wetting of the catalyst particles played an important role for this reaction system, and an assumed packed-bed flow pattern was examined. To cover the entire operation range varying from biphasic flow with high water excess to singular organic phase flow an integrated approach consisting of experiments and simulation was chosen. With the developed method wetting of the catalyst particles only by one liquid phase could be confirmed for the entire operation range.

Keywords: packed bed, enzyme, multiphase reactors, modeling

1. Introduction

For the development of production processes in the biochemical industry quantitative information about the behavior of reaction systems is decisive. Their knowledge enables the transfer of imaginable processes, already working in laboratory scale, to concepts suitable for production scale. The present work deals with a systematic investigation of a biotechnological reaction system. To ensure practical relevancy the procedure was developed on the basis of a model system, so that this work may be seen as an exemplary case study. The findings were obtained from knowledge-based assessment and modeling of the enzymatic hydrolysis of short-chain fatty acid (C_6–C_{10}) methyl esters using *Candida antarctica* lipase B (Novozym®435). The reacting methyl esters and water formed two liquid phases. The reaction was performed as batch run in a recycle packed-bed reactor assembly containing swollen catalyst particles. Fatty acids and methanol were obtained as products.

2. Theoretical Approach

The reaction behavior of the packed-bed element was determined from experiments and their model based analysis. For this purpose the usage of a phenomenological model based upon a decomposition of the observed reaction behavior into singular contributions was required. A mathematical model for the aforementioned hydrolysis reaction was developed by Krause and Fieg (2011) and utilized for the present study. This model assumed a pseudo-homogeneous reaction in the organic phase, whereas the kinetic expression used thermodynamic activities. The approach applied a UNIQUAC model for description of the liquid-liquid phase behavior. The biochemical reaction occurring at the active sites of the catalyst depended on the transport of the reactants and products between the bulk phase and the particles. The bulk phase composition was obtained from macroscopic balances of the entire experimental assembly. The

macroscopic balances constituted the connection between the actual (intrinsic) reaction and the observed reaction behavior. To limit the complexity of the modeling approach simplifying assumptions were made. All simplifications were justified by choosing adequate reaction conditions, e.g., to warrant ideal mixing or excluding mass transfer limitations by choosing appropriate superficial velocities.
The examination of the flow patterns showed that both liquid phases occupied the same pores of the particle bed, whereas the particles were enclosed by the organic phase. Hence, wetting of the catalyst particles only by the organic phase was assumed. The schematic representation of the determined flow pattern at biphasic flow is depicted in Fig. 1. Fig. 1 shows a strong simplification of the observed flow pattern, which exhibited a dynamic change of the flow channel positions and geometries.

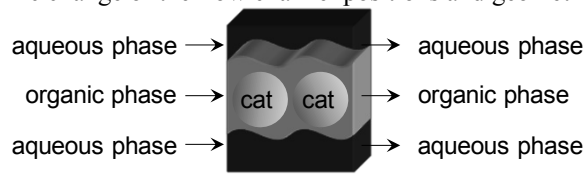

Figure 1: Schematic representation of the determined flow pattern in the packed-bed reactor at biphasic flow. (cat = catalyst particle)

At absence of mass transfer limitations a differential reaction step in the assembly can be subdivided in two separate imaginary steps (Krause and Fieg (2012)): (1) differential reaction progress in the bed element, and (2) attainment of the phase equilibrium. Assuming that for step 1 only the organic phase is required, both imaginary steps can be sterically separated from each other without the change of the observed global reaction behavior in the apparatus. From this decomposition two operation modes resulted, which could be compared: the two-phase flow operation mode in which both phases were passed through the packed bed vs. the singular phase flow operation mode with only organic phase flow through the reactor, in which the liquid-liquid phase mass transport exclusively occurred outside the reactor. In both operation modes only differential conversion per pass through the reactor was presumed.

3. Experimental Procedure

The kinetic experiments were performed in a so-called batch recycle packed-bed reactor assembly (Krause and Fieg (2011)). The schematic representation is given in Fig. 2. A similar setup was used, for example, by Kosugi and Tomizuka (1995), however without following the above described differential reactor concept. The assembly exhibited one circuit to provide the feed stream from the mixing vessel to the packed-bed reactor. To realize the decomposition of the reaction steps the experimental assembly could be run in two operation modes: either biphasic flow through the packed bed or singular phase flow. In the biphasic flow operation mode a homogeneous emulsion generated in the mixing vessel was passed through the reactor circuit. In the singular phase flow operation mode only the organic phase was passed from the mixing vessel to the reactor circuit. The liquid-liquid phase equilibrium was subsequently achieved in the mixing vessel. Within the experiments the impact of high water excess was investigated in the two-phase flow operation mode, whereas the singular phase flow operation mode was additionally used to confirm the model validity. The experimental assembly operated in the singular phase flow operation mode is depicted in Fig. 3. Fig. 3 shows that at the appropriate stirrer speed it was possible to achieve an o/w-emulsion in the aqueous phase while a clear organic phase layer on top of the emulsion was obtained.

4. Results and Discussion

4.1. Operation at low organic phase fractions

All kinetic parameters were determined on the basis of experimental conversion courses X_i obtained in the two-phase flow operation mode with organic phase total mass fractions of approximately 0.3, corresponding to an initial water to methyl ester mass ratio of $A_{H2O} = 2.3$. The determination of the kinetic parameters in this operation range provided advantages in the experimental procedure and a simplified mathematical evaluation. The main benefit was that the entire assembly could be treated as a stirred tank because of the comparatively small conversion per pass through the reactor, while still a sufficiently high final total conversion of the methyl esters was obtained despite the strong limitation by the reaction equilibrium (Krause et al. (2010)). From experimental runs it was found that the initial reaction rate was independent of the aqueous phase fraction and constant for a constant organic phase to catalyst ratio.

For decreasing organic phase fractions in the emulsion the conversion per pass through the packed bed increased when flow velocity and bed length remained unchanged. This caused an increasing deviation of the assembly behavior from the stirred tank assumption. The reason for not reducing the bed length was to maintain exactly the same catalyst bed throughout one experimental series. Hence, for low organic phase fractions the packed bed could not be treated as a differential reactor in the modeling

approach. To consider the integral character of the bed it was treated as a plug flow reactor.

Measuring the conversion courses X_i on the basis of the organic phase compositions was impossible at low organic phase fractions without significantly interfering with the observed system behavior. However, the reaction could be tracked by following the methanol mass fraction in the aqueous phase $w_{MeOH,aq}$, which was an adequate method to compare the experimentally determined and modeled reaction courses. For this purpose the absence of mass transfer limitations and a reliable description of the methanol distribution between the phases were required. The comparison of the obtained experimental and calculated courses is given in Fig. 4. For the cases (1) to (4) the overall methyl ester conversion increased from $X \approx 0.5$ to 0.8 (the temperature had no decisive influence). Because of the decreasing total amount of methyl ester and the increasing water excess the methanol content of the aqueous phase decreased.

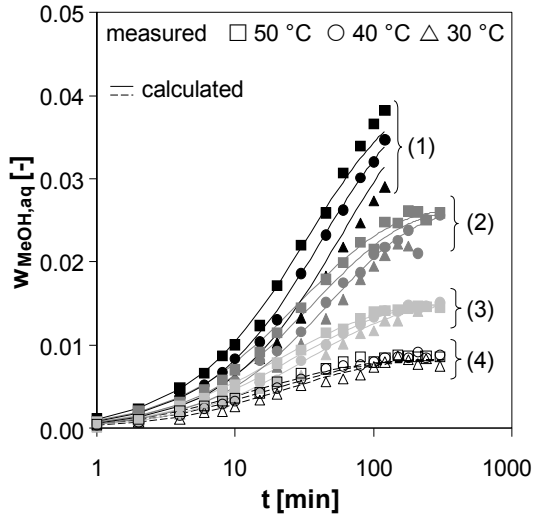

Figure 4: Influence oft the initial water to methyl ester (A_{H2O}) and catalyst to methyl ester (A_{cat}) mass ratios on the conversion course during the hydrolysis of methyl octanoate at constant total reactant mass and a packed bed superficial velocity of 0.07 m/s. (1) $A_{H2O} = 2.3$, $A_{cat} = 7\times10^{-3}$; (2) $A_{H2O} = 4.4$, $A_{cat} = 12\times10^{-3}$; (3) $A_{H2O} = 9.8$, $A_{cat} = 23\times10^{-3}$; (4) $A_{H2O} = 20.6$, $A_{cat} = 46\times10^{-3}$. Comparison of calculated and measured methanol mass fractions $w_{MeOH,aq}$ in the aqueous phase.

Within the mathematical model wetting of the entire particle bed by the organic phase irrespective of A_{H2O} and direct proportionality between the reaction rate and the catalyst mass were assumed. From the good agreement between the calculated and measured courses shown in Fig. 4 it can be concluded that the modeling assumptions were correct up to a water excess of 20:1 g/g for temperatures ranging from 30 to 50 °C.

4.2. Direct comparison of the operation modes

In section 2 the decomposition of the reaction in two steps was suggested. The purpose of the decomposition was to prove the validity of the assumptions regarding the catalyst wetting applying the sterical separation of reaction and liquid-liquid mass transfer. A direct comparison between calculated and measured courses for both operation modes is shown in Fig. 5. The calculated courses were based upon the parameter determination from two-phase flow experiments as described in section 4.1. The successful separation of both elementary steps enabled the examination of the impact of the catalyst wetting on the reaction rate from the direct comparison of experiments performed in both

operation modes for a fixed value of A_{H2O}. From the comparison it can be concluded that both operation modes gave nearly identical conversion courses, which confirmed that in both cases the same amount of catalyst was active. Thus, wetting of the entire particle bed by the organic phase at two-phase flow could be assumed.

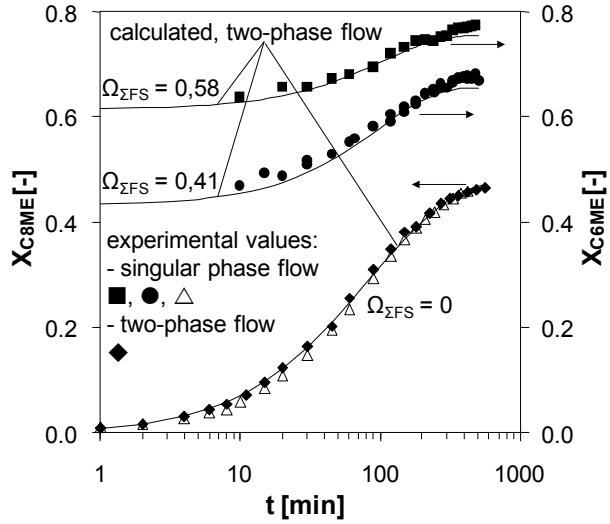

Figure 5: Comparison of experimental and calculated conversion courses obtained in the singular and two-phase flow operation mode at A_{H2O} = 2.3 exemplarily given for four independent experimental runs. (X_{C6ME}, X_{C8ME} = methyl hexanoate or methyl decanoate conversion; $\Omega_{\Sigma FS}$ = initial fatty acid to (fatty acid + methyl ester) mass ratio).

5. Conclusions

For this type of equilibrium limited reactions multistage extractive-reaction processes provide an alternative concept for shifting the equilibrium conversion toward the products (Krause et al. (2010), Samant and Ng (1998)). Either high water to methyl ester mass ratios resulting in a comparatively small number of equilibrium stages, or a moderate water excess resulting in a comparatively high number of stages are applicable. Both strategies lead to different requirements in respect of the process design. Using the suggested examination method a reliable calculation model necessary for the simulation of process alternatives was obtained.

Statistical Monitoring of Water Systems

Marco Cedeño Viteri,[a] Leandro Rodriguez Aguilar,[a] Mabel Sánchez[a]

[a]*Planta Piloto de Ingeniería Química (UNS- CONICET,) Camino La Carrindanga Km 7, (8000) Bahía Blanca, Argentina*

Abstract

In this work a new statistical control methodology that works in the original variable space is presented. The study is focused on the performance of the detection stage, which applies the 2-order Mahalanobis distance as statistical test. Its critical-value is estimated using a kernel density estimation technique. The identification stage uses the concept of the nearest in control neighbor to calculate the variable contributions to the inflated statistic and employs the same distance measure. Application results are provided for a waste water treatment plant.

Keywords: Statistical Process Control, Mahalanobis Distance, Waste-Water Treatment Plants.

1. Introduction

Multivariate Statistical Process Control (MSPC) techniques have been widely applied for turning data into information since they are suitable to develop empirical descriptions of the process behavior based on measurements. Most of them work in latent-variable spaces. In the spirit of developing new approaches that could provide new features and capabilities to those techniques, little attention has been paid to the fact that some strategies which work in the original measurement space could also perform well when monitoring a process (Alvarez et al., 2010).

From the monitoring standpoint, determining whether the process can be considered as in-control at a given time t is just one step in the procedure, called the detection stage. The MSPC approaches that work in the space of measurements make use of the Hotelling (T^2) statistic, which is a measure of the linear Mahalanobis Distance (MD), for this purpose. Whenever one observation is believed to show an abnormal behavior, all the effort must be oriented towards finding what the root cause of the deviation is. The activities related to isolating the variable(s) that indicate(s) the faulty state conform what is known as the identification stage, which is frequently performed by calculating the variable contributions to the inflated statistic. The main purpose of evaluating those contributions is to compare the relative influence of each measured variable on the final T^2-statistic value. It is considered that those having the largest contributions reveal the faulty state. In this sense, Mason and Young (2002) presented a combinatorial strategy to decompose the T^2-statistic into the contributions of each variable. It has the limitation that a great number of possible decompositions are obtained, increasing the complexity of the identification procedure. Then a straightforward method to decompose the T^2 statistic as a unique sum of variable contributions, called OSS, was developed by Alvarez et al. (2007). Recently, Alvarez et al. (2010) proposed a new MSPC strategy for batch process monitoring, called OSSBP, based on that decomposition. For the analyzed case studies, the proposed strategy has comparable abilities regarding the detection of process failures with respect to the ones presented by the most popular latent variables-based approaches (Westerhuis et al., 2000; Ramaker et al., 2005; Yoo et al., 2004).

Moreover, identification performance indexes show better results for the OSSBP. Its satisfactory behaviour may be attributed to the fact that the number of variables involved in this type of processes is moderate and the strong non-linear relationships among them prevent the measurements from being linear combinations. These facts prevent the data correlation matrix to be singular.

When the T^2-statistic is applied for the detection stage of a MSPC procedure, it is generally assumed that measurement vectors are independent and follow a multivariate normal distribution. In this case, the T^2-statistic follows a $[J(I^2-1)/(I^2-IJ)]F_{J,I-J,\alpha}$ distribution where, $F_{N,I-N,\alpha}$ is the value of the F distribution for a level of significance α with J and $(I-J)$ degrees of freedom, I represents the number of samples in the reference population and J is the number of measurements. No assumption about the probability density function (*pdf*) is required when the threshold value T^2_C is determined as the $(1-\alpha)$ quantile of the T^2 *pdf*, which can be estimated using well-known kernel density estimation (KDE) methods. Although the computational effort increases, the extra calculations are performed offline, thus no application restrictions during the online monitoring stage arise due to the extra computational burden (Alvarez et al, 2010).

Because the OSS methodology has a comparable ability for fault detection with respect to the existing latent-variable procedures, the use of a different distance measure to indicate the out of control state is analyzed in this work. The same type of distance between the nearest in control neighbour (NICN) and the current observation (Alvarez et al., 2009) is used to determine the contribution of each variable to the out of control state. Those variables whose distance measures exceed a certain threshold value are considered as suspicious. The coordinates of the NICN are obtained by solving a minimization problem. In this work, the Polynomial Mahalanobis distance of order 2 is selected for both stages of the proposed MSPC.

The rest of the paper is structured as follows. In Section 2 the methodology is presented. Results corresponding to its application for the detection of faults in a waste water treatment plant (WWTP) benchmark are provided in Section 3. A Conclusion section ends this work.

2. Methodology

The Mahalanobis distance is a common metric that attempts to capture the non-isotropic properties of a J-dimensional feature space. It weights the distance calculation according to the statistical variation of each component using the covariance matrix of the observed sample. Grudic and Mulligan (2006) have shown that the MD may not tightly follow a learning data set, and substituted it by the Polynomial Mahalanobis distance (PMD), which is obtained by mapping the measurement space into high order polynomial terms. They use the PMD for classifying path regions in images of natural outdoor environments.

Those authors formulated the q-order PMD (q-PMD) as follows. Given a set of $\mathbf{x}_k$ observation vectors (k=1,..,I) of dimension J, the q-PMD between vectors $\mathbf{x}_i$ and $\mathbf{x}_j$ is calculated by first mapping each $\mathbf{x}_k$ into all polynomial terms of order q or less, which are included in vector $\mathbf{z}_k$, and then calculating the MD between $\mathbf{z}_i$ and $\mathbf{z}_j$ using the covariance matrix obtained from the reference population of polynomial term mappings. In this way they attempt to describe more sophisticated and nonlinear relations among feature vectors.

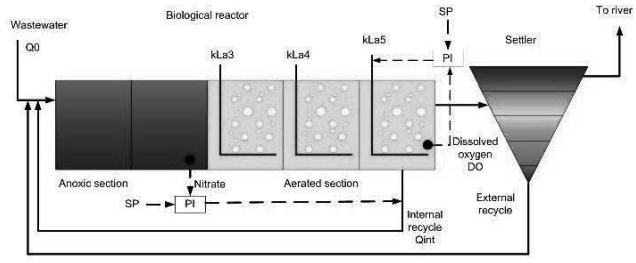
The T^2- statistic applied in MSPC procedures is a measure of the MD between an observation and the population mean. An out-of-control state of the process is indicated

if the T^2- statistic value exceeds the critical one. This is calculated using a KDE technique when the OSS procedure is used.
In this work a new MSPC procedure is devised whose detection stage makes use of the 2-order PMD (PMD^2) between an observation and the population mean as statistic test. That PMD^2 is formulated following the work by Grudic and Mulligan (2006) and the critical value of the statistic PMD^2_C is calculated using the KDE technique.
Regarding the identification stage, the knowledge about how far the faulty observation is from an in-control allocation gives us an idea of the directions whose distances explain the anomalous situation. This information is obtained by finding the nearest neighbour of the observation point that is in statistical control ($\mathbf{x}_{NICN}$). An optimization problem is formulated whose objective is to minimize the PMD^2 between $\mathbf{x}_{NICN}$ and the measured point $\mathbf{x}$, subject to the constraint that the PMD^2-value for $\mathbf{x}_{NICN,}$ is equal to the critical one (PMD^2_C). The comparison of the absolute difference between x_{NICN} and x for each variable j with a threshold value τ, which is obtained by simulations for a given Number of Precise Identifications (Alvarez et al., 2010), allows to identify the suspicious measurements.

3. Application Results for the WWTP Benchmark

In this section application results of the proposed strategy for the detection and identification of faults associated to a WWTP benchmark are presented. The plant layout, model equations and control strategy are not included for the sake of brevity but they are described in detail online [http://www.ensic.u-nancy.fr/COSTWWTP]. For the present study, plant layout combines nitrification with predenitrification, which is the most commonly used method for nitrogen removal. The plant is designed to treat an average flow of 20,000 m^3/day with an average biodegradable chemical oxygen demand concentration of 300 mg/l. The plant is made up of five-compartment biological tanks and a secondary settler. The first two compartments of the bioreactor are not aerated whereas the others are aerated. The nonreactive secondary settler is modeled with a series of 10 layers. There are two internal recycles: the nitrate internal recycle from the last tank to the first tank, and the activated sludge recycle from the underflow of the secondary settler to the front end of the plant. In Figure 1 a schematic diagram of the simulation benchmark is shown.

Fig 1: WWTP Layout



The training model is based on a normal operation period of 1-week of dry weather and a 1-week data set is used for validation. The sampling time is 15 min; therefore 96 samples are taken each 24-hour period. The data used are the influent file and outputs with noise suggested by the benchmark. The following eight variables are selected to build the monitoring system: influent ammoniac concentration, influent flow rate, total

suspended solids in reactor 4, effluent total suspended solids, dissolved oxygen concentration in reactors 3 and 4, oxygen transfer coefficient in reactor 5, and nitrate concentration in reactor 2.

In this work, three scenarios describing real situations are considered for the analysis. The first external disturbance takes the form of a storm event. It originates that the influent flow rate exceeds the maximum standardized value for normal operating conditions, which is equal to 2.67, during the following time intervals (848-857), (1049-1086), (1095-1103). The second external disturbance is the increment of the influent flow rate due to rain. This flowrate exceeds its maximum normal-operating value from samples (807-906). The third fault is a mean change in the nitrate concentration sensor noise. This fault is introduced at the beginning and maintained until the end of the simulation.

Regarding the detection capabilities of the proposed strategy, the evolution of T^2-statistic and PMD^2-statistic in time is analyzed. Both statistics are compared to their corresponding critical values obtained using a KDE technique. For a significance level α= 0.06, their values are: 16.85 for T^2, and 120.11 for PMD^2. A failure is declared after three consecutive warnings.

For the storm disturbance, the T^2-statistic gives alarms at samples 849 and 1051, and the PMD^2-statistic indicates a fault condition at samples 849 and 1049. Both statistics point out the abnormal situation for a long time. This shows the effect of the influent flowrate increment on internal variables persists in time. The evolution of the influent flowrate, the T^2-statistic and PMD^2-statistic in time is displayed in Figure 2 for the storm event.

Fig 2: Storm Events

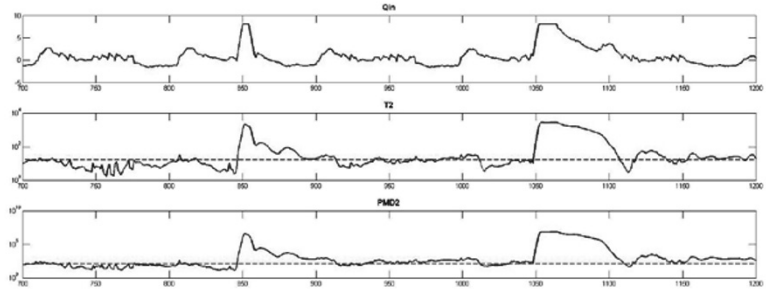


Fig 3: Rain Event

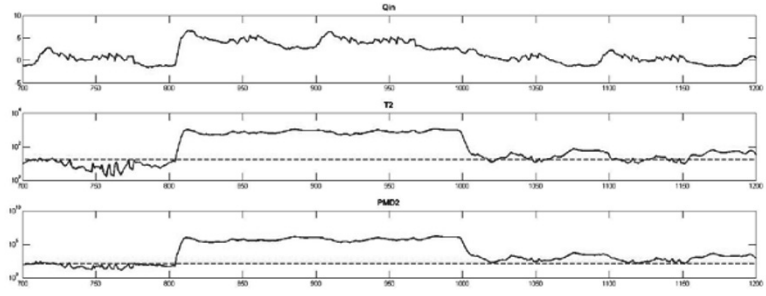
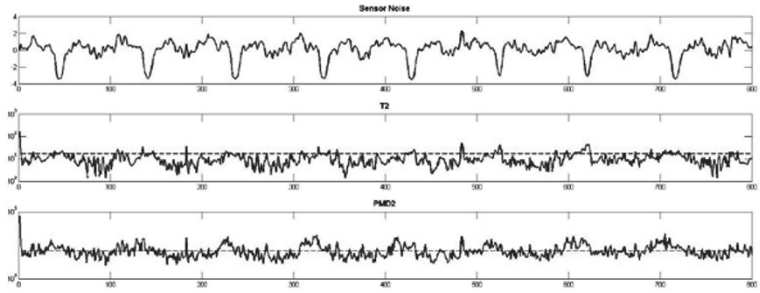


For the rain event, both the T^2-statistic and PMD^2-statistic give an alarm at sample 807, that also persist in time. The time evolution of the statistics for this event is shown in Figure 3. The next figure reports the same information for the third fault, which is

associated with a mean change of the concentration nitrate sensor noise. The T^2-statistic gives an alarm at sample 47, after 3 consecutive warnings are obtained. In contrast the PMD^2-statistic provides the first alarm signal at sample 3 and it is repeated many times during the operation. Variable contributions to the inflated statistics are obtained that properly indicate the faulty variables. Contribution plots are not included for the sake of brevity.

Fig 4: Mean change in sensor noise



4. Conclusions

In this paper a new MSPC methodology that works in the original variable space is presented and applied for WWTP fault diagnosis. A different distance measure, the *q order-PMD*, is used as test statistic for the detection stage and to determine the variables that signal the fault.

For the fault scenarios of the WWTP analyzed in this work, the PMD^2 has shown better capabilities for fault detection with respect to the T^2-statistic. Also it has a rewarding performance with respect to the statistics used in the latent variable space methodologies reported in literature when the action to signal time is considered for comparison purposes.

The computational load of the identification stage ensures real-time results for the tested faults. Future work involves the selection of the polynomial order.

Next-Generation, Integrated Fire Detection and Diagnosis Built Upon the Recent Advances in the Abnormal Situation Management

Kijun Lee[a], Seong-Hwan Han[a], Tae-Ok Kim[a], Dongil Shin[a]

[a]*Department of Chemical Engineering, Myongji University, Yongin 449-728, Korea*

Abstract

Process fault monitoring, detection and diagnosis, and fire detection and isolation technologies have many common characteristics between them, and the amount of technological overlapping is being increased. This paper compares and discusses our works in the areas of conventional abnormal situation management (ASM) as well as fire alarm generation management, as a try to show how the ASM technologies would contribute in developing next-generation fire detection and management technologies and improve the safety of process plants and the public. And the lessons from the fire detection research that could be applied for better monitoring, detection and diagnosis of processes are also discussed.

Keywords: Fire Detection, Process Monitoring and Diagnosis, Industrial Applications, Process and Public Safety, Computational Methods

1. Introduction

Fire is one of the oldest hazards and has been around the human beings with the start of the history. Process fault monitoring, detection and diagnosis and fire detection and isolation technologies have been developed separately and have rich histories individually, but there has been no study of the commonality of the both. There are many sharing characteristics between them and the amount of technological overlapping is being increased: Mitigation of sensor failures, context sensitivity, and minimization of Type I, II errors are important problems. Use of wireless sensors and merge of heterogeneous information are getting the focus en route to the next-generation technologies. This paper discusses how the abnormal situation management technologies, studied in the process systems engineering perspective, would contribute in developing next-generation fire detection and management technologies and improve the safety of process plants and intelligent buildings as well. The next sections show our works in the area of conventional abnormal situation management as well as fire alarm generation management.

2. Fault Detection, Monitoring and Diagnosis System for CNG Stations

2.1. Necessity of the Research

The compressed natural gas (CNG) among the eco-friendly energy sources already accounts for more than 10 percent of domestic energy consumption of Korea. CNG vehicles and also the gas stations are being increased. However, more than nine large and small accidents of CNG vehicle and gas stations have occurred in the past five years, which makes us aware of the need for the study for the safety and safe operations of CNG stations. A lot of non-repetitive transition sections exist during the ordinary operation of CNG gas stations. Therefore, fault detection and diagnosis are limited with

the current monitoring methods, and the advanced maintenance before failures is almost impossible and even the alarms exceeding the specified upper and lower thresholds are ignored as nuisant [1,2].

2.2. Using PCA

In this study, we developed a system (see Fig. 1) to build a monitoring model for the CNG station and perform the real-time monitoring and diagnosis using Principal Component Analysis (PCA), which is suitable for processing large amounts of multi-dimensional data for multivariate statistical analysis [3].

2.2.1. Filtering and Scaling

Filtering and scaling processes are conducted prior to the model construction and application. As shown in Fig. 2, data during the start-up and shut-down are removed from the 7 pressure sensor and 5 temperature sensor data collected per second, and the remaining data of ordinary charging operation are used for model development [4,5,7].

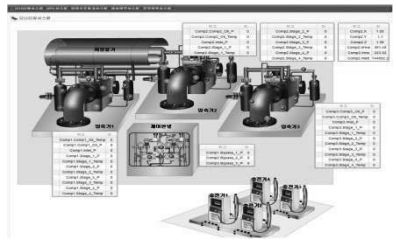

Fig. 1. Screenshot of the developed system

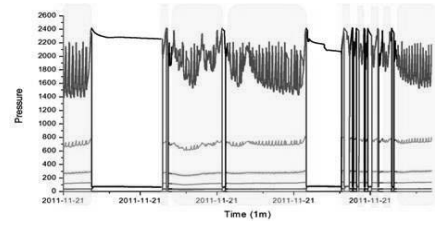

Fig. 2. Filtering of the pressure data

2.2.2. Modeling

We built the PCA model in Fig. 3 by the calculation of the new characteristics variables, called as the major component, finding the factors representing the trend of unsteady process operation. Fig. 4 represents Q residuals of model data [6].

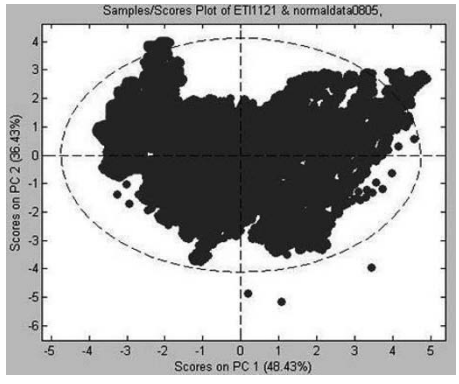

Fig. 3. Score plot of PCA model

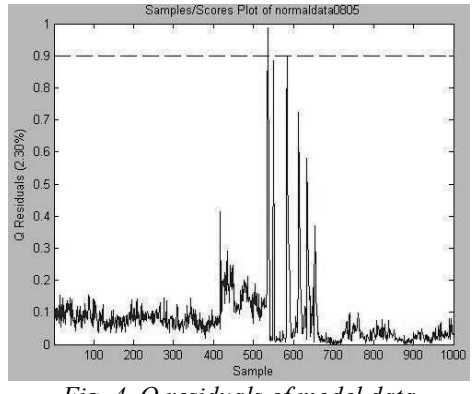

Fig. 4. Q residuals of model data

2.3. Result

The performance of real-time monitoring was measured against the data of process operations already stored in the real-time database. As a result of conducting the off-line monitoring in order to improve the accuracy of the system and verification, all data in the normal operation were distinguished as normal. And when an abnormal

phenomenon was tested by reflecting the abnormal process data, the cause of abnormality could be refined by detecting abnormality as in Fig. 5 and by tracking main contributing variables as in Fig. 6.

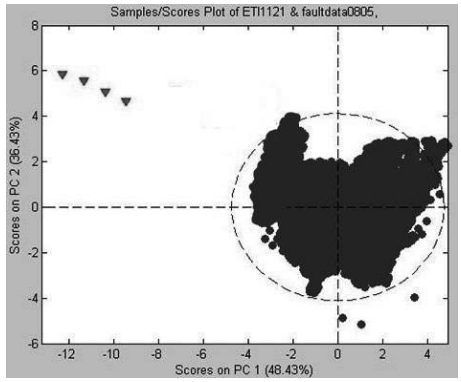

Fig. 5. Plot of detecting abnormality

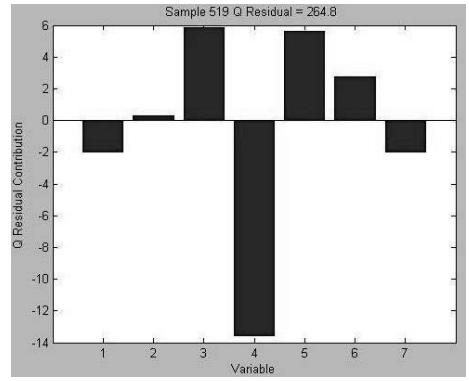

Fig. 6. Diagnosing cause of abnormality

Even though the training data of abnormal operations are rare, the proposed system is able to efficiently cope with the abnormality in process through fault detection and diagnosis with the development and building of the monitoring system for CNG gas stations using PCA. It is estimated that the optimized operation of the facility would be possible by the real time comparison of the current state of facility to the normal state of the past.

3. Fire Detection System Design Based on Multi-sensor Information for Improved Reliability

3.1. Necessity of the Research

The fire detector is used to sense and alarm the danger in an emergency, and the time it takes from the outbreak of fire and detecting the danger and its accuracy are considered critical [8]. For existing detectors, such as mechanical method (on-off), single sensor-based (heat, smoke, or flame), or dual sensor (HR combination system), malfunctions as false-positive alarms not going off in case of fire or false-negative alarms ringing when there is no fire occur frequently [9].

3.2. Improved Detection Algorithm

This study suggested an improved algorithm that senses fire by using three types of information of heat detector, smoke detector, and concentration detector, and has established a fire detecting testbed on LabVIEW, and verified algorithm by using the testbed [12]. Simulation was carried out by using the measured sensor data according to the experiments provided by Fire Research Division of NIST, and was able to verify if a fire occurs or not for a given set of data [10,11].

3.2.1. Fire Detection Algorithm

This study determined whether the temperature, smoke, or carbon monoxide values exceeded the critical value, and suggested an integrated fire detecting algorithm that determines cases of emergency based on the results as shown in Fig. 7.

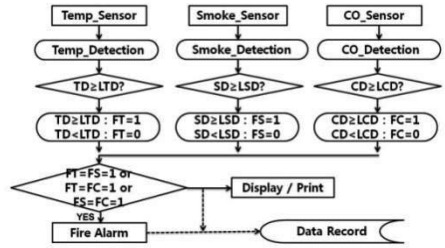

Fig. 7. Fire detection based on multiple information

3.2.2. Simulation

As shown in Fig. 8, the testbed was established on LabVIEW, implementing the suggested algorithm, and simulation was carried out by using the sensor measuring data according to the situation of Home Smoke Alarm Tests performed by the Fire Research Division of NIST from 2004 to 2008. A test scenario among Home Smoke Alarm is as shown in Table 1, and the simulation process is as shown in Fig. 9 [12].

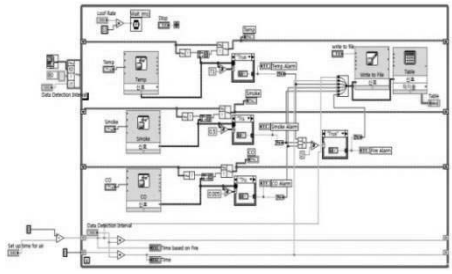

Fig. 8. Testbed implemented

Table 1. Fire place and a source of ignition [12]

Situation	Test	Ignition	Fuel Package	Fire Location
Fire	SDC02	Flaming	Chair	Living Area
	SDC05	Flaming	Mattress	Bedroom#2
	SDC08	Smoldering	Mattress	Bedroom#2
	SDC11	Smoldering	Chair	Living Area
	SDC15	Flaming	Chair	Living Area
	SDC39	Flaming	Mattress	Bedroom#2
	SDC41	Heating	Cooking Oil	Kitchen Area
Non-fire	MHN30	14 g (1 tbls) butter, cast iron pan, fan on		
	MHN31	14 g (1 tbls) butter, cast iron pan, fan off		
	MHN40	Smoldering PU foam block, fan off, (flamed)		

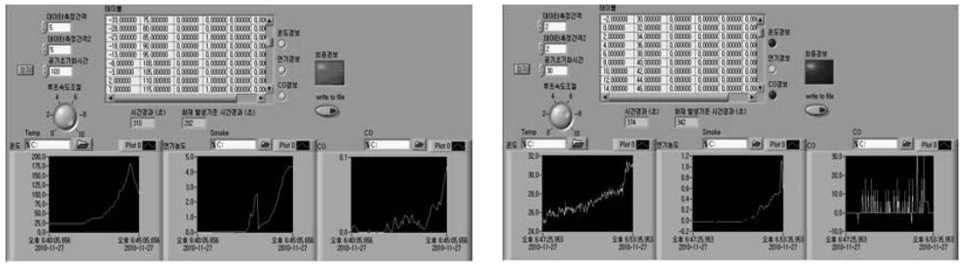

Fig. 9. Simulation: Minimization of false negative and positive errors (Scenario SDC05 at 202sec : Detected false positive / Scenario SDC05 at 342sec : Detected false negative)

3.3. Result

As a result, the elapsed time until the very first integrated generation of warning and alarm operation was identified as shown in Tables 2 and 3. Every fire emergency except for Test SDC41 was detected, and the integrated alarm method worked successfully for all non-fire situations.

The integrated fire detection system based on multiplexed information of three independent measuring data improved the accuracy of diagnosing the real and non-fire situations than the existing fire detecting systems based on single or dual information.

Improvement in more collection of quantitative data, which consider both accuracy and time of detection, and advanced algorithm built upon the recent advances in the abnormal situation management are considered to make contribution in a development of next-generation fire detection system. Performance evaluation of fire detection system which was actually restricted other than actual fire experiments is considered to be possible by expanding the suggested testbed.

Table 2. Detected all fire situations

Test	Ignition	Fuel Pkg.	Fire Location	Fire Alarm (s)	Temp Alarm (s)	Smoke Alarm (s)	CO Alarm (s)
SDC02	Flaming	Chair	Living Area	110	146	110	0

Table 3. Detected all non-fire situations

Test	Nuisance Sources	Fire Alarm (s)	Temp Alarm (s)	Smoke Alarm (s)	CO Alarm (s)
MHN30	14 g (1 tbls) butter, cast iron pan, fan on	-	-	324	-
MHN31	14 g (1 tbls) butter, cast iron pan, fan off	-	-	310	40
MHN40	Smoldering PU foam block, fan off, (flamed)	-	-	-	470

4. Conclusion: Integrated fire detection and diagnosis

Process fault monitoring, detection and diagnosis and fire detection and isolation technologies have many common characteristics between them, and the amount of technological overlapping is being increased: Mitigation of sensor failures, context sensitivity, and minimization of Type I, II errors are important problems. This paper discussed how the abnormal situation management technologies, shown for the case of fault detection, monitoring and diagnosis system for CNG stations, would contribute in developing next-generation fire detection and management technologies and improve the safety of process plants and public safety for the realization of better sustainable society.

Abstract

We have developed a new method to evaluate plant operators' proficiency. In this method, an operating procedure is hierarchically analyzed so that the method can be applied to complicated operations. Furthermore, the method was evaluated with indices based on Levenshtein distance. The proposed method was applied to simulator training on the start-up operation of a distillation column. The results demonstrate the utility and effectiveness of the proposed method.

Keywords: Proficiency metric, Plant operation, Skill assessment, Skill transition, Simulator training

1. Introduction

Recently, plant operation has become highly complicated, and thus inexperienced operators must often learn new operational procedures in complex plants. Additionally, in Japan, many veteran operators have been retiring in recent years, forcing younger operators to assume more of a leadership role. Therefore, effective training systems are required to train inexperienced operators more efficiently and quickly. For this purpose, training simulators are often used. Training simulators have been significantly improved, and their level of realism has been greatly enhanced (Jeong et al., 2002; Barrero et al., 2003) . In particular, Mitsubishi Chemical Engineering Corporation has been developing a simulator training system called MECTRNR ®. This system is equipped with advanced functions that can evaluate an operator's proficiency and perform PKYK (Process-Kiken-Yochi-Kunren; "process risk assessment by operators" in Japanese) through simulator training. These functions are useful for developing ideal operating ability. In this paper, we present a newly developed proficiency evaluation method and apply it to the function of assessing operators' capabilities.

For effective simulator training, it is necessary to evaluate how far the operator's skill has progressed in order to check his or her present skill level and to design effective training programs. This proficiency assessment is usually done with a subjective measure such as trainers' observation records or trainees' self-evaluations such as NASA-TLX or SWAT (Hart and Staveland, 1988; Reid and Nygren, 1988; Nishitani et al., 1997). However, subjective evaluation results vary according to the judgement of the assessor. As objective measures, physiological signals, such as an electroencephalogram or heart rate, are often

*kurooka@eng.u-toyama.ac.jp

used (Kurooka et al., 1998, 2001, 2003). However, measuring physiological signals imposes a strain on subjects. Recently, a new proficiency evaluation method was proposed, which uses an operating procedure index and a process stability index, and it was shown that the method can evaluate a simple operation (Kurooka et al., 2008). However, it is still necessary to develop a proficiency evaluation method that can be applied to a complicated operation in a large-scale plant. For this purpose, we developed a hierarchical system that can analyze and evaluate an operator's proficiency in a large-scale plant.

2. Hierarchical proficiency evaluation

2.1. Operational data for evaluation

We used a message summary that consists of two types of information: "when and what kind of alarm occurs and stops" and "when and what kind of operation is executed." These data, i.e. a message summary, can be easily obtained through a distributed control system (DCS) included in the training simulator system.

2.2. Evaluation procedure

The proposed evaluation procedure is carried out as follows:

Step 1 Constructing the hierarchical structure of a standard operating procedure: :
Based on a standard operating procedure, a hierarchical structure is built as shown in Fig. 1. This is done by decomposing tasks into sub-tasks or by grouping small tasks that have the same sub-goal. For example, the activity of starting up a distillation column can be decomposed into tasks of starting feed, starting reboil-up, and so on. On the other hand, some elementary tasks, such as setting MV of FC101 and setting SV of PC103, could have the same goal, i.e. starting feed.

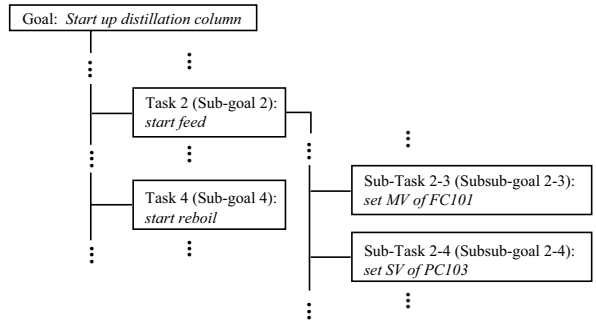

Figure 1. Example of an operation's hierarchical structure

Step 2 Building the hierarchical dictionary of a standard operating procedure: :
After constructing the hierarchical structure of a standard procedure, each task is symbolized and a layered task dictionary, i.e. a hierarchical dictionary, is built.

Step 3 Obtaining and symbolizing a trainee's operational data set:
Once the hierarchical dictionary is made, it is possible to hierarchically evaluate an operation. When a trainee is engaged in the target task on the training simulator, an alarm summary and an operating log are obtained through the distributed control system (DCS).

The obtained operating procedure is symbolized by referring to the symbols in the lowest sub-task level of the dictionary.

Step 4 Identifying higher-level tasks and calculating the task scores:
The obtained symbols of the trainee's operating procedure are divided into groups that are identified as higher-level tasks by referring to the dictionary. To identify the tasks, similarity indices are calculated. We adopted two types of similarity indices. When the sub-tasks of a task must be done in order, Levenshtein distance (*LD*) (Levenshtein, 1966) is calculated and similarity r is estimated by the following equation:

$$r = \frac{n - LD}{n} \times 100 \tag{1}$$

Here, n is the number of sub-tasks of the target task in the dictionary, and *LD* is the smallest number of insertions, deletions, and substitutions required to change one string into another, and it is applied in various areas such as spell checking, speech recognition, and DNA analysis. Through the process of calculating *LD*, we can not only analyze the extent of the difference between the trainee's operation and the standard operation but also identify the sub-tasks which produce the difference. When the sub-tasks of the task can be done in any order, r is estimated by the following equation:

$$r = \frac{n_d}{n} \times 100, \tag{2}$$

where n_d is the number of sub-tasks that are done by the operator as elements of the target task in the dictionary, and n is the total number of sub-tasks of the target task in the dictionary. The calculated r is recorded as the task score.

Step 5 Hierarchical identification:
Step 4 is done at the higher levels and repeated to the highest level of the hierarchy of the dictionary.

Step 6 Evaluating the operation:
We can evaluate and analyze the operation by observing the scores and the identification results from the highest level to the lower levels step by step.

3. Example

We applied the proposed proficiency evaluation system to actual simulator training. The target operation is starting up the distillation column shown in Fig. 2. Start-up is one of the plant's complicated operations and has many variations. The following four cases of this operation were performed by a trainee and then the results were evaluated:

Case 1) Operation according to standard operating procedure (changing the load in several steps)
Case 2) Operation while ignoring standard operating procedure
Case 3) Operation mostly according to standard operating procedure but drastically changing the load in one step
Case 4) Operation mostly according to standard operating procedure but changing the load in two steps

The evaluation results at the top of the hierarchy (Fig. 3) show that the ideal task sequence is listed in accordance with the dictionary made in Step 2. Here, r_{mean} and r_{max} are the mean and maximum values of the similarity indices of the identified sub-tasks.

More specifically, the evaluation results show that:

1) The overall scores r of operations in cases 1 and 4 indicate that those operations are similar to the standard (ideal) operation in outline.
2) The subtask scores r_{min} of case 4 are smaller than those of case 1 for task Nos. 8 and 9, which relate to loading up.
3) The overall score r of performing the operation in one's own way (case 2) is very poor.

These results are reasonable. As shown in result 2), the difference between cases 1 and 4 can be found by using a hierchical approach. If we want to analyze the difference in more detail, we can examine the lower-level evaluation results in sequence.

The r of case 1 does not show 100 due to the identified location of task No. 6. This is because the standard operation cannot describe the entire set of operations in full detail, and thus task No. 6 was difficult to identify in this example.

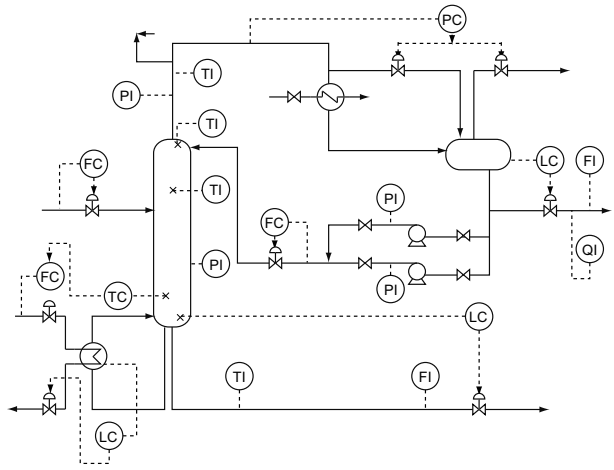

Figure 2. Example target plant

4. Conclusions

The proposed proficiency evaluation method can hierarchically evaluate and analyze an operation. This evaluation method was adopted in the simulator training system called MECTRNR, and the system was applied to a distillation column's start-up operation as an example. The results of trial evaluations show that the proposed method is useful in evaluating proficiency.

Simulation study of alternatives for the efficient start-up of dividing-wall distillation column sequences

Maria A. Vargas,[a] Georg Fieg[a]

[a]*University of Technology, Schwarzenbergstraße 95c,Hamburg 21071, Germany*

Abstract

The increasing interest in the use of dividing wall distillation columns demands procedures for its optimum operation. The start-up is a complicated process that requires the simultaneous and coordinated manipulation of multiple variables to take an empty column at ambient conditions to the required operation point. In the present research work is studied the start-up of a dividing-wall distillation column system (DWCSys) for the separation of a multicomponent mixture into five products using two different strategies. The implemented alternatives in the DWCSys are examined and evaluated according to the start-up time, energy consumption and accumulation of out of spec products. The results depict the influence of impurities and changes in the concentration of the feed stream on the start-up behavior of the column system. At the same time it was proven the robustness of the simulation model and the stability of the solution method to solve a very complex system of algebraic and differential equations with discontinuities that are commons in a start-up process.

Keywords: start-up, dividing-wall column, distillation sequence.

1. Introduction

The competiveness of today's market demands quality products at lower prices and thus it is required the implementation of more efficient processes. A clear example to diminish energy usage and at the same time reduce investment costs in a thermal separation process is the technology of dividing-wall distillation column (DWC). It consists of a column shell with a partition wall that separates the middle section of the column into two parts, the prefractionator and the side segment. This partition wall avoids the radial mixing of the internal vapor and liquid fluids in the prefractionator and main column, allowing the production of three pure components in a single column shell.

In recent years there have been a considerable growing interest in DWCs for industrial implementation. It demands clear procedures for the design and optimum but safe operation of the column, spanning the startup, production and shutdown periods. Numerous scientific publications have dealt with the design and control of DWCs but only few refers to the start-up process.

Start-up is a complex operation generally characterized by a long and unproductive duration. In this period, an empty column passes from ambient conditions to the required operation point. Non-specification products are produced and high amounts of energy are consumed. The economical and ecological interest to minimize the time of this non-productive period creates the necessity of developing time optimal start-up strategies which guarantee its feasibility, safety and easy implementation in columns of industrial scale. Additionally, the understanding of the process behaviour, avoids wrong

manipulations which could even retard more the start-up and create hazardous situations.
Rigorous simulation studies can be used to prepare adequate strategies and to plan a proper start-up procedure for operators.
In the simulation study of this work, start-up strategies are implemented in a dividing-wall column system (DWCSys). The system separates a mixture of linear alcohols in a direct sequence of two DWCs of industrial scale. The rigorous mathematical model used for this investigation was subject of an extensive experimental validation in a previous research in the Institute of Process and Plant Engineering (PAT) in the Hamburg University of Technology (*Niggemann et al.*). The implemented alternatives in the DWCSys are examined and evaluated according to the start-up time, energy consumption and accumulation of out of spec products.

2. Dividing-wall distillation column system

To separate a mixture into five products, three combinatorial possibilities of DWC arrangements (direct, side and indirect sequence) are feasible and the optimal column configuration is sought. The case study of this work consist of a mixture with equal mass concentration of the lineal alcohols, n-hexanol (C6), n-octanol (C8), n-decanol (C10), n-dodecanol (C12) and n-tetradecanol (C14). In a previous work from *Vargas et al.* was found that the direct connection results in the alternative with the lowest annualized total costs. A saturated liquid feed enters to the system with a mass flow rate of 5000 kg/h and is separated in products with a mass concentration > 0.99 wt.-/wt (Fig. 1). The two columns operate with a top pressure of 40 mbar which guaranteed a temperature in the condenser to cool with water and an enough low temperature in the bottom to avoid degradation.

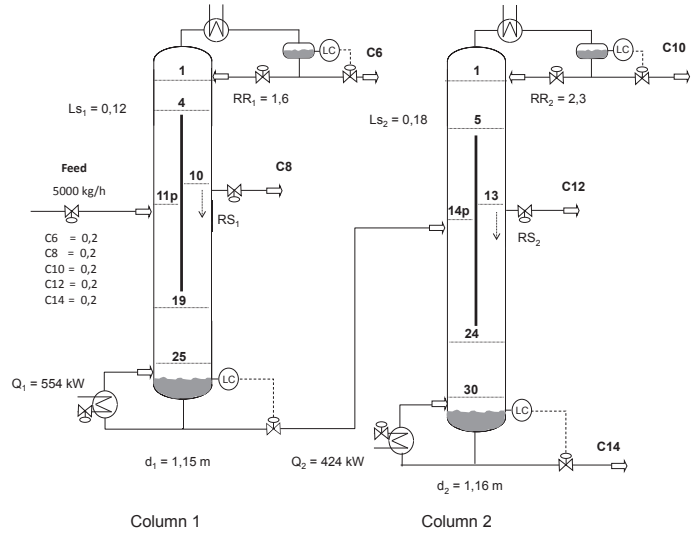

Figure 1. Dividing-wall distillation column system for five products separation.

The level in the reflux drum of both columns is controlled with the distillated stream, while the bottom level is controlled with the bottom stream respectively. The proportional controllers are set to have in the reflux drum 5 min retention time during normal operation and 5 min retention time in the bottom column. However, during the

start-up process the set point in the bottom column is doubled to avoid the dried up of the columns. Both columns are designed with Montz packing type B1-500. The column shell is of stainless steel with thickness of 0.012 m, determined according the standards AD 2000.

3. Simulation of the start-up process

A rigorous mathematical model built in the Institute of PAT capable of simulate the complete start-up process from an empty dividing-wall column at ambient temperature to steady state conditions is used. The model is composed of a system of differential and algebraic equations result of MESH balances in a column discretized in theoretical stages. Periphery equipments as reboiler, condenser and reflux drum are also integrated in the model. The simulation model also includes special features of DWCs as self adjustment of the vapour split by equalization of pressure drop in both sides of the dividing wall and heat transfer across the dividing wall.

The model is set according the column sequence design previously described, including all the design parameters, e.g., mass of packing, mass of column shell and liquids hold up which are required to simulate the heating up and filling of the column during the start-up process. Physical properties of the multicomponent mixture are determined with UNIQUAC activity coefficient model.

Typically the aim in a start-up process is to minimize the time required to achieve the steady state conditions and the production of off spec products. Several process variables can be manipulated in the attempt to speed up the process: feed flow rate, reboiler heat duty, reflux ratio, product flow rate and liquid split. These variables can vary during the start-up process within the constraints and set to the steady state value at the end of the process. In addition, during the start-up of a column system the time at which the columns are connected could have a major effect on the results.

In this work a conventional start-up strategy is implemented in the column system, in which the process variables are set to their steady state value as soon as feasible. Following the sequence of steps performed during the start-up operation:

- $t=t_0$: Begin feed input
- $t=t_1$: The liquid level set point in the bottom column is reached. Activation of reboiler (Q_i) and set to the steady state heat input.
- $t=t_2$: The boiling temperature is reached in the bottom column and the vapor starts to ascends until it reaches the condenser.
- $t=t_3$: The liquid level set point in the reflux drum is reached. The reflux ratio (RR_i), side split ratio (RS_i) and liquid split (Ls_i) are set to the steady state value.

The sequence of steps is equally performed in the two columns of the arrangements. However, during the start-up process the feed conditions to column 2 (e.g. flow rate, component concentration) may undergo changes until the stedy state conditions are reched in column 1. Two different start-up alternatives are evaluated. In the first alternative the feed to column 2 starts once the bottom product of column 1 is produced (simultaneous start-up strategy) and in the second alternative the feed to column 2 starts only after the steady state conditions in the connecting stream are reached (sequential start-up strategy).

3.1. Simultaneous start-up strategy

In the simultaneous start-up strategy the feed to column 2 starts as soon as feasible (t=0.34 h). At this moment the connecting stream (feed to column 2) still faces continues changes in composition, flow rate, temperature and pressure. Fig. 2(a) depicts

the concentration profile of the key components in the two columns of the sequence. In the first column the top and side products reach the steady state concentration relatively fast at t=1.34 h and t=1.37 h respectively (0.1 % of deviation from steady state value is accepted), but it is only at t=7.28 h when the steady state concentration is attained in the bottom stream. On the other hand in column 2, the steady state concentration of key components takes relatively longer to be reached. The low rate of increment of C10 in column 2 is mainly due to the presence of C8 impurities in the feed stream to column 2. The total start-up time of the column system is t=12.75 h limited by the bottom stream in column 2.

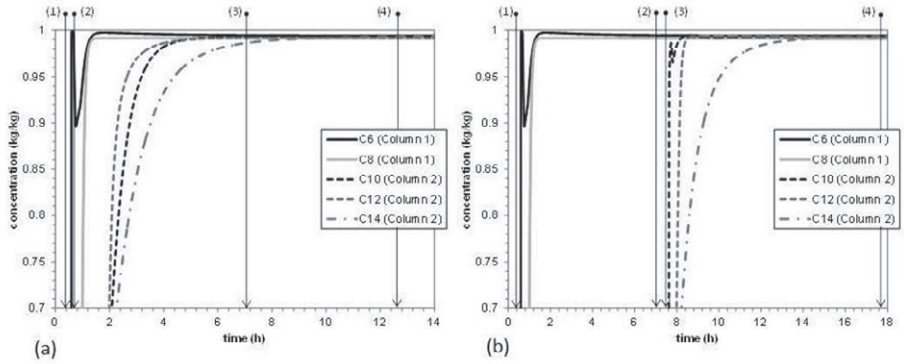

Figure 2. Concentration of key components during the (a) simultaneous and (b) sequential start-up of the dividing-wall column system, with (1) activation of reboiler (Q_1) in column 1, (2) activation of reboiler (Q_2) in column 2, (3) steady state in column 1 and (4) steady state in column 2.

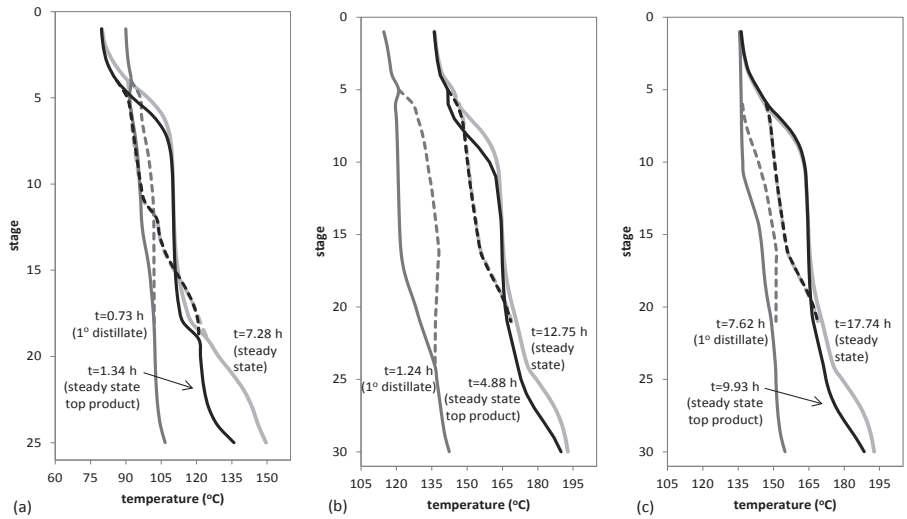

Figure 3. Temperature profile in (a) column 1 and column 2 during the (b) simultaneous and (c) sequential start-up of the dividing-wall column system. Prefractionator (- - - - -) and main column (——).

3.2. Sequential start-up strategy

In this strategy the connecting stream (feed to column 2) is deviated to a storage tank until it reaches the steady state conditions (t=7.28 h) . The concentration profile of key

components in column 2 (Fig. 2(b)) shows now a very similar behavior to the concentration profile of key components in column 1. The steady state concentrations in top and side products are reached relatively fast, once the reboiler is activated. The total start-up time of the system is t=17.74 h limited by the concentration of the bottom product in column 2.

The temperature profile during the start-up in the two columns of the sequences also reveals the consequence of impurities in the feed stream to column 2 (Fig. 3(b)). At the point the first drop of distillate is produced in column 2 with the simultaneous strategy, the temperature profile still very far from the steady state values. However, on the other hand, with both strategies is evident that after the steady state concentration in the distillate stream is reached, only in the lower segments of the column 1 and 2 there is a considerable difference with the steady state temperature profile (Fig. 3).

4. Comparison of start-up strategies

By only observing the start-up time, the simultaneous start-up strategy (t= 12.75 h) would results in the preferable alternative when compared to the sequential start-up strategy (t=17.74 h). However the total energy usage of the sequential strategy is around 13 % lower but with a higher amount of off spec product accumulation (Table 1). It evidence that in the development of start-up strategies the main objectives must be clearly define.

Table 1. Accumulated off spec products and waste energy during the start-up of the dividing wall column system.

			Strategy	
			Simultaneous	Sequential
Column 1	Accumulated off spec product, (kg)	Distillate	540	540
		Side	421	421
		Bottom	-	21253
		Q_1, (kW h)	404	404
Column 2	Accumulated off spec product, (kg)	Distillate	3475	2161
		Side	3409	574
		Bottom	13090	10882
		Q_2, (kW h)	5010	4341
	Total	Product, (kg)	20935	35831
		Q, (kW h)	5414	4745

5. Conclusion

Two different alternatives for the start-up of a direct sequence of two dividing-wall distillation columns have been presented. The results serve as the bases for the further development of optimum start-up strategies for DWCSys. In addition, it was evidenced the robustness of the model and the stability of the solution method to simulate the complex start-up process of two columns.

Abstract

In this work, a new approach to model identification and PI controller tuning based on model-based experimental design is presented. In the proposed strategy, system identification relies on a closed-loop set-point response. For this purpose, experiments are first exemplarily executed with a P-controller. Therefore, in this specific case only one design variable is considered that is represented by the controller gain. Additionally, we use the results achieved in the system identification step for the calculation of controller settings. In order to validate our approach and demonstrate the benefits of the proposed strategy, different scenarios are simulated.

Keywords: controller tuning, closed-loop, set-point response, PI controller, model-based design of experiments, model identification, parameter estimation

1. Introduction

In the chemical industry, PI controllers are widely used because of their simplicity and robust structure. However, it is still difficult to find good controller settings even though PI controllers only have a few adjustable parameters (Shamsuzzoha and Skogestad, 2010). There are basically two different methods for the calculation of controller settings. One of them is based on open-loop experiments whereas the other one uses closed-loop tests. Most tuning methods are based on information about process dynamics obtained from open-loop experiments. However, this strategy is usually time-consuming and expensive. Therefore, in this work, we focus on the determination of experimental conditions using closed-loop set-point response for the estimation of system model parameters with maximum statistical quality. For this purpose, we use a model-based optimal experimental design approach (Bauer et al., Franceschini and Macchietto, Barz et al.). The optimal experimental design strategy (OED) enables us to select experimental conditions for which the resulting data yields maximum information with respect to model parameters. The challenge of our approach is the need for model identification by closed-loop experiments. According to the concept of optimal experimental design, parameter estimation is applied in order to match the model to a real process. Therefore, our calculation of controller settings consists of two steps. First, we identify the system behavior using closed-loop set-point response and after that, we calculate the controller settings using an optimization strategy.

2. Problem Statement

We assume that a given process can be described by a set of differential-algebraic equations (DAEs) (Bauer et al., 2000)

$$\dot{y}(t) = f(t, y(t), p, u_{ED}(t)), \;\; y(t_0) = y_0(p), \tag{1}$$

where $\boldsymbol{t}$ represents the time, $\boldsymbol{y}$ denotes state variables, $\boldsymbol{p}$ is a set of parameters to be determined and $\boldsymbol{u_{ED}}$ represents the set of time-varying control variables, which are later used as design variables to plan experiments. Parameter estimation is done by fitting the results of the model simulation $\boldsymbol{y^{calc}}$ to the measured data $\boldsymbol{y^{meas}}$. We assume that measurement errors $\boldsymbol{\xi^{y}}$ are independent, normally distributed and can be characterized by a measurement-covariance matrix $\boldsymbol{MV}$. The parameter estimation is based on the minimization of a weighted least square functional

$$min_p \sum_{k=1}^{N_{exp}} \left(y_k^{meas} - y_k(u_{ED,k}, p)\right)^T \cdot MV^{-1} \cdot \left(y_k^{meas} - y_k(u_{ED,k}, p)\right). \tag{2}$$

The model-based experimental design strategy aims to maximize the accuracy of the parameter estimation that is mathematically represented by the variance-covariance matrix of the model parameters $\boldsymbol{C}$ and characterizes the statistical uncertainty of parameter estimation.

$$\min_{u_{ED}} \varphi(C)$$

$$s.t.\ \ f(\dot{y}(t), y(t), u_{ED}, p, t) = 0 \tag{3}$$

$$y(t_0) = y_0(p)$$

$$u_{ED}^{min} \leq u_{ED}(t) \leq u_{ED}^{max}$$

Statistical uncertainty is represented by the confidence region. Thus, decreasing the size of the confidence region for each model parameter leads to the minimization of the variance-covariance matrix C. The size of the confidence region (the amount of the matrix C) determines the expected information content that can be extracted from the measurement data. The form of the functional $\boldsymbol{\varphi}$ characterizes the chosen optimal criterion. Common design criteria are so-called A-, D- and E-optimal criteria whose definition can be found in (Franceschini and Macchietto, 2008). In the following we use the A-optimal criterion that represents the trace of the variance-covariance matrix and minimizes the mean parameter standard deviations.

$$\varphi(C) = \frac{trace(C)}{dim\,(C)} \tag{4}$$

The covariance-variance matrix is determined as inverse of the Fisher information matrix.

$$C = F^{-1} = \left(\sum_{k=1}^{N_{Exp}} F_k\right)^{-1} \tag{5}$$

We consider a sequential strategy, so, according to (Galvanin et al., 2007), the information matrix after N_{exp} experiments can be calculated as follows

$$F = \sum_{k=1}^{N_{exp}-1} F_k + F_{N_{exp}}\left(p, u_{ED,N_{exp}}\right) = F_C + F_{N_{exp}}\left(p, u_{ED,N_{exp}}\right) \tag{6}$$

where $\boldsymbol{F_c}$ represents a constant part of the Fisher information matrix calculated by the previous $N_{exp} - 1$ experiments. In eq. (6) only the vector $u_{ED,N_{exp}}$ can be varied during the optimization.

For one single experiment, the Fisher matrix is calculated based on the sensitivities coefficients for each estimated model output

$$F_k\left(p, u_{ED,k}, y\right) = Q_k^T MV_k^{-1}\, Q_k, \tag{7}$$

where $\boldsymbol{MV_k}$ represents the measurement-covariance matrix and $\boldsymbol{Q_k}$ characterizes the matrix of the sensitivities. Model parameters have often very different dimension. Therefore, it is convenient to use normalized sensitivity coefficients as defined in eq. (8) (Barz et al., 2010).

$$\overline{Q_k} = \left[\frac{\partial y_k(t_i)}{\partial p_j} p_j\right];\ \forall j \in N_p, \forall i \in N_{sp} \tag{8}$$

Based on these considerations, the normalized sensitivity coefficients are applied throughout this work.

3. New system identification strategy

Controller tuning requires a good process model. Therefore, our controller tuning strategy consists of two steps (s. Fig. 1). In the first step, we identify the process behavior experimentally by using closed-loop set-point response. After this, based on the results achieved in the first step, we numerically calculate the controller settings.

We assume that each process can be described by a first or second order with time delay model (Skogestad, 2003). That means that we have three or four model parameters that have to be determined. These are the process gain $\boldsymbol{K}$, the time constants $\boldsymbol{T_1}$, $\boldsymbol{T_2}$ and the time delay, $\boldsymbol{\tau}$.

Usually, an open-loop experiment is used to identify the process behavior. In the proposed strategy, we use a closed-loop set-point response (Fig. 1) for system identification. Here an experiment is executed with just a P-controller. By this method, we are able to reduce the experimental time and decrease the number of necessary experiments as well as the required amount of measured data.

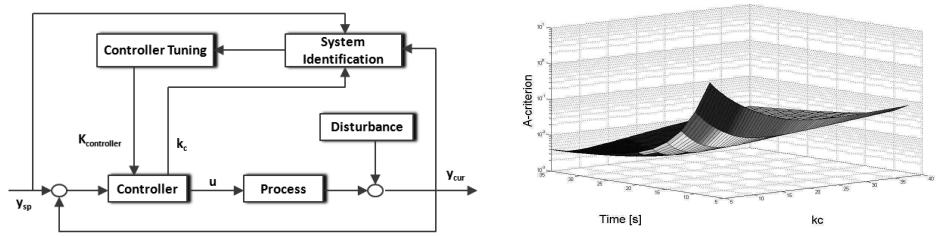

Figure 1. Controller tuning strategy (left), where $K_{controller} = [k_c, T_i]$; object function for OED over the design variable k_c for different measurement times (right)

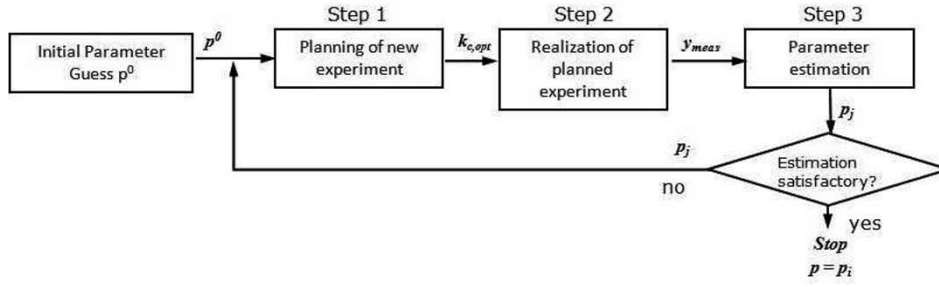

Figure 2. Model-based system identification strategy using closed-loop response

For a closed-loop system the experimental conditions are represented by controller gain $\boldsymbol{k_c}$. Here, by using the approach of OED we aim to determine the optimal value of the

controller gain $\boldsymbol{k_{c,opt}}$ for which the experimental data yields maximum information with respect to model parameters. According to the concept of OED, in the first step, the experiment is planned. Here, the optimal value of the control gain throughout the experiment is determined. Next, the planned experiment is executed and the measured data is analyzed. In the last step, the quality of the model is validated and a new set of model parameters is calculated (s. Fig. 2). These three iteration steps are executed sequentially without interruption until the required model accuracy is achieved. Important is here, that the design of a new experiment is based on the current information about model structure and parameter set obtained in the prior experiments.

4. Case Study

The strategy discussed in the previous section is applied to the first order plus time delay process (FOPTD). Based on the model reduction rule of Skogestad (Skogestad, 2003), we approximate FOPTD process with a second-order model. Here, we describe the second-order model by a model with a damping factor.

$$G_1(s) = \frac{K}{T^2 s^2 + 2dT\, s + 1} \tag{9}$$

Based on the assumed model, three model parameters have to be estimated during the model-based design. These are the process gain *K*, the time constant *T*, and the damping factor *d.* In this case study, we generate experimental data from the simulation and add a normally distributed measurement noise with the variance $\sigma^2 = 0.05$. Our goal during the parameter estimation was to get a model accuracy of 7% based on parameter standard deviations. In order to achieve the required accuracy, three experiments were executed. In the first experiment, the so called pre-experiment, the initial guess of the model parameters was identified. This experiment is unplanned and was executed with $k_c = 5$, whereas the next two experiments were designed. Table 1 shows that only two designed experiments are necessary in order to achieve the required accuracy of less than 7% for each model parameter. In addition, Fig. 3 shows the closed-loop set-point response for second designed experiment.

N_{exp}	Experimental conditions $k_{c,opt}$	Estimated parameters			Parameter standard deviations [%]		
		p_1	p_2	p_3	σ_{p1}	σ_{p2}	σ_{p3}
pre-exp	5	1.05	5.47	2.95	12.4	8.4	16.8
1st exp	15.3	0.96	5.19	2.75	7.5	4.5	7.9
2nd exp	**9.5**	**0.95**	**5.29**	**2.67**	**6.0**	**3.6**	**6.2**

Table 1. Parameter estimated during the model-based design of experiments

Once the model parameter estimation is finished, we numerically calculate the controller settings. The goal of the controller tuning is to achieve a good set-point response. Thus, our optimization problem is to minimize the overshoot while making sure that there is no undershoot. Here, the model dynamics is also represented by a second order process with a damping factor.

$$\min_{K_c,\, T_i} M$$
$$s.t.\ |\Delta y_s - \Delta y_u| \leq C, \tag{10}$$

where $\boldsymbol{M}$ represents the overshoot, $\boldsymbol{\Delta y_u}$ is the first minimum (undershoot), $\boldsymbol{\Delta y_s}$ denotes the set-point change and $\boldsymbol{C}$ is a constant. By solving of optimization problem (s. eq. (10)), we obtain the optimal controller settings that are represented by $k_c = 7.27$ and $T_i = 27.2$. Fig. 3 shows the closed-loop set-point response with the optimal controller parameters.

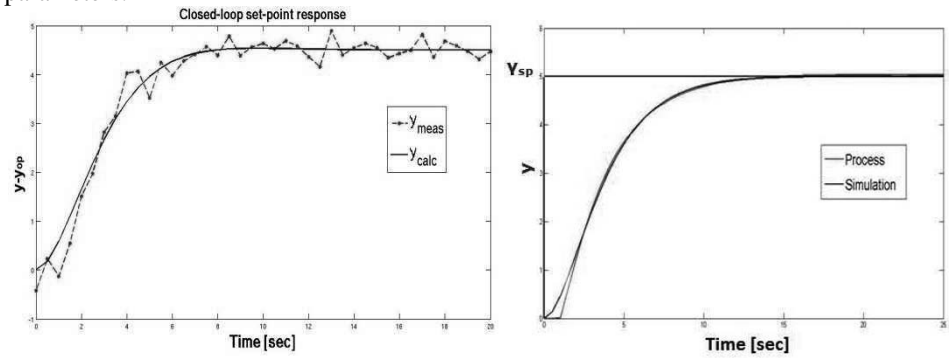

Figure 3. Closed-loop set-point response for the second designed experiment (left), where y_{op} is the operation point; closed-loop set-point response with the optimal controller settings (right).

5. Conclusions

The proposed strategy consists of two steps. In the first step, we identify the process behavior using a closed-loop set-point response. For this purpose, we first run experiments with just a P-controller. In the proposed procedure, the design variable for the optimal experimental design is represented by the controller gain k_c. After this, we calculate the controller settings by using an optimization strategy. Here, we use the model achieved in the first step for the calculation of optimal controller parameters. As the results of the case study show, one can use the second order model for calculation of the controller settings for a first order with time delay process.

Usually, a very time consuming part of the controller tuning procedure is the process identification. Here, using closed-loop set-point response leads to shorter experimental time compared to open-loop experiments. Furthermore, well designed experiments enable us to reduce the system identification effort even more. In summary, the sum of both benefits leads to reduced commissioning time in comparison to conventional methods.

Optimization and control of polystyrene batch reactor using hybrid based model

Mohammad Anwar Hosen* and Mohd Azlan Hussain

Chemical Engineering Department, University of Malaya, Malaysia

Abstract

The effects of operating conditions such as initiator and monomer concentration as well as reactor temperature of polymerization reactors have been studied in this work. A recently developed hybrid model for polystyrene batch reactor was utilized in simulation study. The simulation results revealed the sensitivity of polymer properties and conversion to variation of these operating conditions. Furthermore, the study deals with the optimization of batch polymerization reactors. The optimization problem involving minimum time optimal temperature policy has been formulated and solved. Different numerical techniques have been tested and compared. The online control works were performed to validate the optimal temperature profiles. The experimental studies reveal that the calculated optimal policies were able to reduce the batch time keeping the same polymer quality.

Keywords: Polymerization reactors; Optimization; Polystyrene; Batch reactor.

1. Introduction

Recently, the use of process optimization in the control of batch reactors has received much attention in the literature (Kiparissides, 1996). This provides a useful tool for operating batch reactors efficiently and optimally. In batch polymerization, the optimization problem is identified as the time dependent control actions which maximize product quality and minimize production time(Amrehn, 1977). Different techniques have been suggested (Kiparissides, 2006) and applied to calculate and control to the optimal trajectories. Method of Pontryagin's Minimum Principle PMP) was heavily used in work of styrene polymerization in a solution batch reactor. For past seven years, researchers used solely the PMP to solve their optimal control problem (Özkan et al., 2001, Özkan et al., 2006, AltInten et al., 2003, Altinten et al., 2006, AltInten et al., 2008a, Zeybek et al., 2004, Zeybek et al., 2006, Özkan et al., 2009). The objective of optimal problem in their solution problem was to produce 50% conversion and 500 number average chain length with minimum reaction process. The temperature optimal profiles were generated using Pontryagin's Maximum Principle without any initial guess of initial costate variable. Therefore, no iteration of costate variable was initialized to obtain the time optimal temperature.

In the present work, we have considered of interest to carry out the dynamic study for a batch styrene free radical polymerization reactor theoretically and find out which variables are more effective for polymerization reactor. Later, optimization problem of minimum time optimal temperature policy has been formulated and solved for batch reactor for the solution polymerization of styrene. Finally, The generated optimal temperature profiles was used to study closed-loop control using advanced control technique which can track the process variable along the developed open-loop optimal temperature trajectory.

2. Modeling of polystyrene batch reactors.

The success of optimization efforts depends very much upon the accuracy of the process models. It has been a trend to use the simplified process models for determining the optimal control profiles, as the complexity of the process models is restricted by the methods used to determine the optimal control profiles. In this work, a simple mechanistic modelling strategy (see the AltInten et al., 2008 for details model) were used to develop optimal temperature profile (AltInten et al., 2008). However, a hybrid model (first principle-Neural network model) was used to design the controller to implement the optimum temperature profile.

Psichogios and Ungar have introduced the idea of using first principles-neural network methodology for modeling chemical processes. Such a methodology attempts to utilize all accessible process knowledge possible by implementing black-box correlations for predicting process parameters. A similar methodology was considered in the recent work of Hosen et al. (2011) for modeling the polystyrene batch reactor. In this work, the six kinetic parameters were calculated from pre-trained ANNs with high prediction capabilities (see the Hosen et al., 2011 for details hybrid model). This hybrid model was used to study the dynamic behaviour as well as to develop the advanced controller to control the polystyrene reactor.

3. Results & Discussion

First of all the simulation study was performed to study the dynamic behavior by using previously developed hybrid model (Hosen et al, 2011) and conduct the response of reactor outputs with different initial operating conditions. Secondly, developed the optimum temperature profiles based on reliable simple mathematical model (Altinten et al., 2008). Finally, an advanced controller was developed to track the optimum temperature profile.

3.1. Dynamic Open Loop Behaviour

The following simulations are performed in order to verify the sensitivity of the control system and calculate the appropriate control and system parameters. Among the simulation are:

i. Different initial initiator concentration loading to reactor (0.013, 0.016 and 0.019 mol/ltr)
ii. Different heat input to reactor system with reaction
iii. Different cooling water flow rates in cooling jacket chamber (0.5, 0.7 & 0.9 g/s).

In order to simulate these studies, the values of physical and chemical parameters used are as given in Table 1

Table 1: Operating conditions and reactor specifications

Name of the parameters	*Value*	*Units*
Reactant specific heat (C_p)	1.96886	J/g.K
Coolant specific heat (C_{pc})	4.29	J/g.K
Heat of reaction, exothermic (H)	-57766.8	J/g.K
Coolant flowrate (m_c)	0.51	g/s
Gas constant (R)	8.314	J/mol.K
Coolant inlet temperature (T_{ji})	303.14	K
Overall heat transfer coefficient (U)	55.1	W/(m^2.K)
Reactor volume (V)	1.2	ltr
Reactor jacket volume (V_c)	1	ltr
Coolant density (ρ_c)	998.00	g/ltr
Reactant density (ρ_r)	983.73	g/ltr

3.1.1. Reactor Dynamics with Different Initiator Loading

One of the control objectives in controlling the batch polymerization reactor is to control the exothermic behaviour due to the extent of reaction as the initiator is introduced to the monomer and solvent mixture in the polymerization system. It is obvious that one needs to monitor the release of heat in order to control the target specification. Moreover, the heat release may break the glass reactor depending on the temperature it can withstand. Three conditions of polymerization were used with initial initiator concentration of 0.013, 0.016 and 0.019 mol/l for this study. Each starting condition has to be maintained at fixed steady state condition. Fig. 1 represents the time trend of temperature change in terms of different initial initiator load (mol/ltr). In this case, polymer quality (X_n) highly depends on the initial initiator concentration but the conversion (X) is little affected by it.

3.1.2. Reactor Dynamic with Different Heat Loading

In the second task, the initial initiator is fixed at a value of 0.013mol/l. Five different heat input simulated the reaction in the reactor with a fixed steady state temperature at 364K. Table 2 illustrates the conversion achieved when temperature reached the steady state after high release of heat upon initiation. In addition, Fig. 2 illustrates clearly the transient behaviour of reactor temperature. As can be seen from the figure, the reactor with highest amount of heat input attains the highest overshoot. The temperature ascends from 364K to a maximum temperature of 416K and starts descending to the steady state of 403.8K completely after 500min at a heat input 150watt. In addition, it can be seen in Fig. 2 that the final polymer quality highly depends on the heat input. At lower heat input the NACL and conversion is higher than at high heat input though it requires more reaction time.

Table 2: Results of different heat input simulation

Heat, Q	Final conversion (%)	T- highest	T_{ss}
150	34.17	416	403.8
120	40.61	411	386.2
100	48.46	401	376.4

3.1.3. Reactor Dynamic with Different Jacketed Flow Rate

In the third task, the jacketed flowrate were varied three times (0.5 g/s, 0.7g/s & 0.9g/s) with the other variables kept the same as Table 1 to observe the reactor dynamics. It can be seen in Fig. 3, that the final polymer quality (NACL) highly depends on the jacketed flow rate. At lower jacketed flow rate, the NACL and conversion are higher than at higher flow rate though it requires more reaction time.

For all three conditions it can be seen that the reactor temperature profile change significantly with changing initial operating conditions or inputs. Based on these results more attention will be taken for setting the values of these operating variables at the time of experimental work. Variation in this reactor may serve as disturbances to the reactor operation.

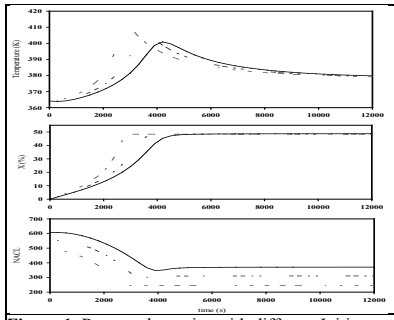

Figure 1: Reactor dynamics with different Initiator concentration. (——) at 0.013mol/ltr, (- - -) at 0.016mol/ltr and (·—·—·) at 0.019mol/ltr.

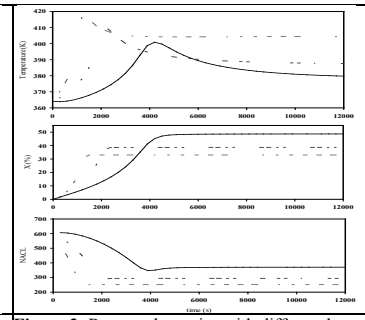

Figure 2: Reactor dynamics with different heat input. (——) at 100 watt, (- - -) at 120 watt and (·—·—·) at 150 watt.

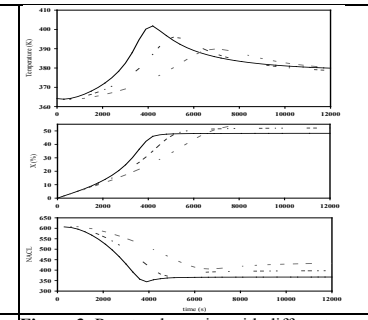

Figure 3: Reactor dynamics with different jacketed flow rate. (——) at 0.5g/s, (- - -) at 0.7g/s and (·—·—·) at 0.9g/s.

3.2. Minimum Time Optimal Temperature Profile

Recently, the offline or open loop minimum time optimal control policies were applied for the simulation of styrene polymerization in batch reactors (Altinten et al., 2008b, Zeybek et al., 2004, Zeybek et al., 2006). In this work, the optimization problem involving minimum time optimal temperature policy has been formulated and solved for a batch reactor for the solution polymerization of styrene based on previous work (Sata, 2007). This optimal temperature profile was used as set point for controller study.

The objective of optimization problem is to calculate the optimal temperature policy for a given initial initiator and monomer concentration that minimizes the reaction time, t_f, required to achieve a desired final monomer conversion, X_d. The performance target of a closed loop control minimum time optimal temperature tracking is to produce polystyrene with the specification of X_d =50% and **NACL,** $\boldsymbol{X_n}$ =500.

In order to obtain the operating conditions for minimum polymerization end-time, polymerization temperature and initiator concentration are employed as control variables. Since the temperature can be used to infer the end-quality of polymer, this work is devoted to produce specified polymer quality within the minimum time. The governing equation (Altinten et al., 2008b) for the optimal temperature profile is expressed as follows:

$$T = \frac{-(E_p + E_d/2 - E_t/2)/R}{\ln\left[E_d \Big/ \left(p_2 I^{0.5} M A_p \left(\frac{2fA_d}{A_t}\right)^{0.5} \left(E_p - \frac{E_d}{2} - \frac{E_t}{2}\right)\right)\right]} \quad (1)$$

The results of calculation for X= 50% and X_n =500 with optimal temperature T* is shown in Fig. 4. In this work, the value for initial initiator, I_0 has to be basically guessed. The procedure can determine any feasibility of the guessed value. In this study, it is found that the optimal initial initiator concentration for the initial monomer concentration of M_o=6.089 mol/l is I_o=0.016 mol/l. These optimal values are achieved within the reaction time of 138 minutes. It can be noted that the reaction time (t_f) increases with increasing I_0. Therefore, it is concluded that the optimal I_0 can be obtained by successively reducing the value of I_0 until a limiting value was reached below which the desired conversion can never be reached. Furthermore, as can be seen from the figure, as the I_0 is decreased, the gradient of the optimal temperature T* becomes more steep. The optimal temperature profile for I_0 = 0.016 will be used for tracking the set point in the control study.

3.3. Controller Design

In this work, an advanced neural network based model predictive controller (NN-MPC) was used to control the polystyrene reactor. The neural network is trained to represent the forward dynamics of the process. The experimental data of the

manipulated variable (heat load Q) and plant output (reactor temperature T) at t with two time delay units were used as inputs while the plant output reactor temperature at t+1 was used as outputs for training the neural network. The Levenberg–Marquardt method is used to train the NN based on a minimizing cost function. The mean square error (MSE) is used here as cost function. It is expressed mathematically as:

$$\mathrm{MSE} = \frac{1}{n}\sum_{k=1}^{n}\left(T_{\mathrm{tg}}(k) - T_{\mathrm{N}}(k)\right)^2 \tag{2}$$

where n is the number of training data, T_{tg} is the target/desired reactor temperature and T_{N} is the neural network output. Based on the minimizing of MSE error values, it was found that 10 hidden nodes achieve the minimum MSE value of $5.36\text{x}10^{-6}$. The design specifications for neural network model are given in Table 3.

Table 3: Design specifications of neural network model

No. of input nodes	6	
No. of hidden layer nodes	10	
No. of output nodes	1	
Total sample size	10000	
Training function	Levenberg-Marquardt Method	
	Sample size	Mean square error
Training data	5000	5.36×10^{-6}
Testing data	2500	4.13×10^{-6}
Validation	2500	4.69×10^{-6}

Before implementing the MPC controller in real time, its tuning parameters should be optimized to achieve best performance. For designing a good MPC controller it's important to specify the following controller parameters:

In this work, the developed hybrid model was utilized to determine the sampling interval and prediction and control horizon. Marlin (Marlin, 1995) general rule was used to determine the sampling interval of MPC. The prediction and control horizon were determined by trial and error method (see Dougherty and Cooper, 2003 for more details).

The performance of the controlled variable i.e. reactor temperature, was observed for a sufficient span of process dynamics time to determine the value of the prediction & control horizon. It was observed that the prediction horizon of 24 sample interval and the control horizon value of 4 sample interval provide satisfactory control performance. The other parameters of the NN-MPC controller are given in Table 4.

Table 4: Design specification of MPC

Prediction Horizon (N_2)	24
Control Horizon (N_u)	4
Control weight factor (M)	0.09
Move suppression factor(Λ)	0.003
Minimization routine	Backtracking Optimization

3.4. On-line optimal control of polystyrene reactor

In this study, the concentration of 0.016 mol/l and 6.089 mol/l for initiator and monomer loading were chosen to produce the desired target. It is noted that the benzoyl peroxide and styrene loading can produce the number average chain length (NACL) of 500 and monomer conversion of 50% at the end of 183 minutes polymerization period.

The experimental results of optimal setpoint tracking of polystyrene polymerization using NN-MPC are shown in Fig. 5. As we can see from the figure, when the initiator is introduced, the mixture temperature fell below the setpoint profile at nearly 2K. The response was realized by the controller and it acted back to increase the heat input (Q). As a result, the temperature overshot at maximum 2K and it later decayed away in decreasing oscillatory manner in 730 sec. An offset can be noted at less than .5K. This is attributed by the high exothermic load during the early course of polymerization. Nevertheless, the temperature controller performance performed well in tracking the temperature setpoint profile at the later stage of polymerization. Fig. 5 also shows the transient response of manipulated variable of heater. The regulation was smooth. It is worth mentioning that the heater regulation was initially at Q=150 Watt and it increased gradually until 200 Watt at the end of the batch-run. The final NACL and conversion can be found 496 and 52.8% respectively which is almost same as desired values.

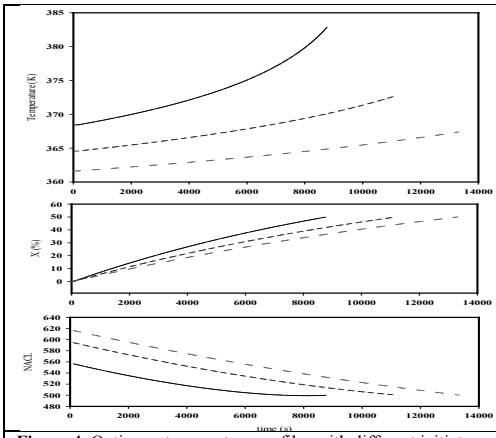

Figure 4: Optimum temperature profiles with different initiator concentration (I_o = 0.013 mol/l (—), I_o = 0.016 mol/l (- - -), I_o = 0.019 mol/l (·—·—·)

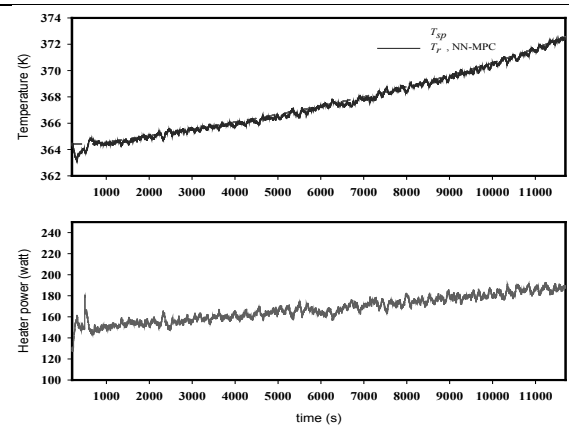

Figure 5: Optimal setpoint tracking using NN-MPC

4. Conclusion

In this work, the first principle-NN model is utilized in Matlab Simulink environment to study the dynamic behaviour of the polystyrene batch reactor. The effect of operating conditions on the properties of final product has been investigated. An optimization algorithm (Sata, 2007) was applied to optimize the reactor temperature profile based on minimal time operation. The conversion and number average chain length (NACL) was considered here as the target output for optimization. The optimized minimal time temperature profile was used as setpiont tracking for control study. An advanced controller named NN-MPC were designed and tuned for styrene polymerization batch reactor to track the optimum setpoint point experimentally. From the experimental results it can be concluded that the developed optimal temperature profile can give the desired polymer quality & quantity with the help of advanced controller.

Modeling and stochastic dynamic optimization for optimal energy resource allocation

Go Bong Choi. Seok Goo Lee. Jong Min Lee*

School of Chemical and Biological Engineering, Institute of Chemical Processes, Seoul National University, 1 Gwanak-ro, Gwanak-gu, Seoul, 151-744, Korea

Abstract

With ever-growing global demand for energy and severe environmental regulations, optimal management of energy distribution system and policy is becoming an important problem for many countries. We present a stochastic dynamic model that describes energy resource allocation under uncertainty and derive an optimal policy for long-term investments in novel energy technologies. Probabilistic model based on Markov chain that balances the demands and supplies are developed considering the city boundaries and electric power system in South Korea. We propose an algorithmic strategy based on the framework of approximate dynamic programming and demonstrate its efficacy using a prototypic example with the available data

Keywords: Energy planning, Markov decision chain, Approximate dynamic programming.

1. Introduction

Faced with the recent challenge of meeting soaring global energy demand without damaging the environment, there has been increasing interest in a strategic approach to determining which energy sources to use and how to supply energy to demand points at optimal cost under environmental and other federal regulations. However, obtaining an optimal policy for such problems is complicated by the inherent uncertainties in demand, fuel prices, stored amount of fuels, etc. Hence, a robust dynamic optimization problem needs to be formulated and solved for deriving a meaningful optimal policy in these applications. Dynamics of such systems are stochastic because the successor state is given by a probability distribution rather than a fixed deterministic point given a current state.

When only the bounds of uncertainties are known, worst-case optimization problem set-up is introduced. If the probabilistic behavior of uncertainties can be further assumed or found from intuition or historical data, stochastic dynamic optimization problem can then be formulated.

Markov decision process (MDP) is a useful framework for modeling the problem in that it is sufficient to consider the present state only, not the past history (Puterman, 1994) and is often used to formulate most scheduling problems under uncertainty. A universal solution approach to obtain the optimal solution for MDP is dynamic programming (DP), which involves calculation of the cost-to-go value for all possible states (Bellman, 1957; Bertsekas, 2000). The main bottleneck in application of DP for

*Corresponding author. Tel. +82-2-880-1878 Email. jongmin@snu.ac.kr

practical problems is the curse of dimensionality, which refers to the exponential increase of the number of states in the state dimension. Recently, a new body of theories called Reinforcement Learning (RL) (Sutton, 2000) or approximate dynamic programming (ADP) (Powell, 2007) has attracted much attention in field of operations research due to its ability to circumvent the curse of dimensionality. The main idea of these approaches is to use closed-loop simulation with initial policies, though they may not be an optimal one, and identify relevant regions in the state space. For these identified states, Bellman's optimality equation is iteratively solved in the form of policy iteration or value iteration (Bertsekas & Tsitsiklis, 1996). In this work, we propose a Markov chain model for energy management of capital region of South Korea and apply an ADP approach to derive a nearly optimal energy management policy starting from closed-loop simulations with simple heuristics.

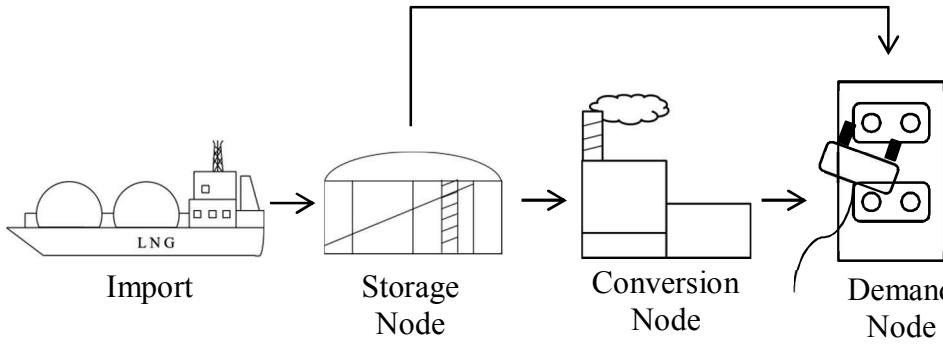
2. Problem description and model formulation

The objectives of this study are to develop an energy supply chain network model for the energy distribution system of capital region in South Korea and to derive an optimal policy for energy resource allocation, storage, and construction of new power plants and storage/processing facilities under demand uncertainty.

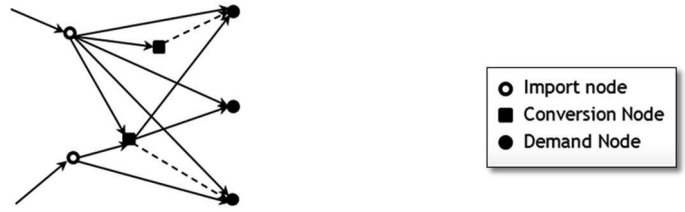
The system is composed of three types of nodes (storage, demand, and conversion nodes) and material flows. It manages energy resource flows from storage nodes (e.g., harbor, storage facility, etc.) to demand nodes such as households and corporations. It is necessary to make proper plans and minimize total cost incurred while respecting constraints. Various types of resources can be divided into primary resources and secondary resource. Resource can be carried from storage node too demand nodes directly or via conversion nodes. In this study, electricity is the only type of energy considered as the secondary energy resource and is assumed to be generated from coal, oil, natural gas, and renewable energy resources. To represent the capital region of South Korea properly, the system has two storage nodes, two conversion nodes, and three demand nodes. The data of the past 10 years on power plant constructions and consumption of energy resources in the region were obtained from KESIS (Korea Energy Statistics Information System). A prototypic energy supply chain network that represents the region is shown in Figures 1 and 2 and the details of the model are presented in the following section and summarized in Table 1.

2.1. State variable

The state vector consists of two types of variables. The first is a subset of controllable state variables that can be regulated by actions but not totally due to the existence of uncertainty. It includes the amounts of resources in the storage, the power production capacity, and the storage capacity. The second is a subset of disturbance state variables, meaning that even if it starts from the same state, its successor state cannot be always the same given the same action. The demand is only disturbance state variable in this study. Though we cannot control the demand, it is necessary to include this variable in the state vector because actions should be computed to meet the demand. The demand scenarios are constructed based on the historical data available from KESIS.



<Figure 1. Genral energy resource transit from import to demand node>



<Figure 2. Energy node network of the capital region in South Korea>

2.2. Decision variable

The decision variables are energy resource flows and capacity extension of resource facilities. The amounts of resources are divided into annual import volume and dispatch to power plants from the harbors. If the dispatch amounts are determined, the total amounts of electricity to be generated can be determined. With the assumption that all the demands should be met due to the national policy the resource flows to the households and businesses are the same with the predicted nominal demands. Capacity extension means that all the activities related to adding capacities to the current energy resource facilities. The energy resource facility has two types: power plant and storage/processing facility. Power plant capacity is defined as the maximum production of electricity from power plant for a year. Storage/processing facility capacity is the maximum volume of resources that can be stored and processed.

2.3. Objective function

The objective is to convert the available energy resources and supply the energy to meet the demand at a minimal cost. This can be cast as a stochastic dynamic optimization problem with a discounted infinite horizon cost as follows:

$$\min_{u_t} \mathrm{E}\left(\sum_{t=0}^{\infty} \alpha^t \emptyset(x_t, u_t)\right) \quad (1)$$

$$\emptyset(x_t, u_t) = \mathrm{C}(x_t, u_t) + \mathrm{X}(x_t, u_t) \quad (2)$$

, where E denotes the expectation operator and the stagewise cost $\emptyset(x_t, u_t)$ involves resource and construction expenses ($\mathrm{C}(x_t, u_t)$) and extra cost for each resource ($\mathrm{X}(x_t, u_t)$). For instance, the extra cost term can include costs for extra risk management in nuclear power plants.

2.4. State transition rule

State transition rule indicates how state evolves over one sample time given the current state and action. The state transition equation is given by simple balance equations as in

Table 1 for the controllable part. The disturbance part of the system is represented by the nominal demand scenario with additive noise based on the historical data for the capital region of South Korea from 2001 to 2010

2.5. Uncertainty

Demand is the only uncertain state variable. We represent the demand uncertainty as the fluctuation in the storage due to the constraints of meeting the demand as much as possible.

2.6. Constraints

Energy resource reservation plan is the only explicit constraint in this model. It is derived from the petroleum reservation program that a certain amount of petroleum should be secured in preparation for difficult situations to import. We assume that amount of stockpiles is bigger than a quarter of expected demand.

<Table 1.component of energy distribution model>

	Symbol	Description
State	$D_{r,t}$	Demand of resource
	$S_{r,t}$	Storage of resource
	$C_{r,t}$	Resource storage capacity of resource t
	$C_{r,t,e}$	Power plant capacity using resource
Action	$I_{r,t}$	Import of resource
	$E_{r,t}$	Extension of resource storage capacity
	$E_{r,t,e}$	Extension of power plant capacity
	$Di_{r,t}$	Dispatch to power plant of resource
State transition rule	$S_{r,t+1}$	$S_{r,t+1} = S_{r,t} + I_{r,t} - D_{r,t} - Di_{r,t}$
	$C_{r,t+1}$	$C_{r,t+1} = C_{r,t} + E_{r,t}$
	$C_{r,t+1,e}$	$C_{r,t+1,e} = C_{r,t,e} + E_{r,t,e}$
Uncertainty	$\widehat{D_{r,t}}$	
Constraint-Explicit	$S_{r,t+1} \geq \frac{1}{4} D_{r,t}$	reserves in preparation for energy crisis

2.7. Heuristics

In this study, we sample a subset of state points by performing closed-loop simulations with two simple heuristics. The first heuristic constructs a coal-fired power plant with the first priority and the nuclear and renewable energy plants are considered as a second choice. The second heuristic mainly constructs natural gas power plant. All these heuristics use a fixed value for the energy dispatch.

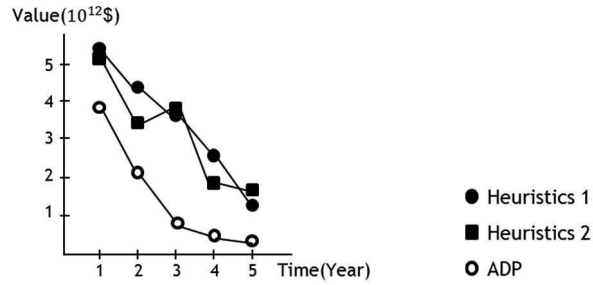
3. ADP-based approach for deriving an optimal policy

With the sampled state points and a function approximation scheme such as local averaging (Lee et al., 2006), the Bellman's optimality equation is solved iteratively as in Eq. (3)

$$J^{i+1}(x) = \min_{u \in U} E[\emptyset(x,u) + \alpha \tilde{J}^{i}(\mathrm{x})] \quad (3)$$

where *i* denotes the iteration index, J^{i+1} is the vector of calculated cost-to-go values for sampled state space, $\tilde{J}^{i}$ is the estimated value of cost-to-go for the successor state form the function approximator of the i^{th} iteration. The iteration is continued until (Use the infinite norm convergence criterion here. After how much iteration did you say it is converged with what criterion?) all the *J(x)* values are converged

The total number of possible state points is 1.53×10^{14} and the total number of action values is1.024×10^{7}. The number of visited state points in the proposed scheme is 1.95×10^{7}. Figure 3 shows the comparison between the converged ADP policy and two initial heuristics in terms of expected cost over five years in the future, and it shows significant performance improvement under uncertainty. The iteration scheme converged within an error tolerance $\left\| (J^{i+1} - J^{i})/J^{i} \right\|_{\infty} < 0.05$ after 2th iteration.



<Figure 3. Value on scenario of Heurstics and ADP>

4. Concluding Remarks

In this paper, we propose a Markov chain model for optimal energy management problem and solved it using ADP. In the revised manuscript, more comprehensive analyses and comparisons will be provided.

Seawater Desalination Processes: Optimal Design of Multi Effect Evaporation Systems.

Paula Druetta[a] , Sergio Mussati[a], Pio Aguirre[a]

[a]*lNGAR - Instituto de Desarrollo y Diseño, Avellaneda 3657, Santa Fe (3000),Argentina*

Abstract

This is the first paper of a series of articles that deals with the modeling and optimization of dual-purpose desalination plants which combine thermal desalination processes and combined heat and power systems, specifically solid oxide fuel cell SOFC electricity generators. This paper presents preliminary results obtained for the multi effect evaporation (MEE) process (stand alone process). The steady state performance of the MEE system is described by a simplified and no linear programming (NLP) model. Optimal operating conditions including profiles of temperature, flow-rate and heat transfer area along the evaporator are analyzed. In addition, the influence of the effect number on the evaporation efficiency is also investigated.

Keywords: Multi-effect desalination; Optimal design; Non-Linear Programming (NLP)

1. Introduction

In many countries the most pressing issue for water security is in meeting basic provision of fresh water supply and sanitation. Sea-water desalination plays and will play in the future an important role in contributing to the provision of fresh-water since the global requirements for fresh water are increasing rapidly as the global population.

The following are the main desalination processes: a) Thermal: multi stage flash (MSF) and multi effect (MEE) distillation, vapor compression (VC) and b) reverse osmosis (RO), electrodialysis (ED), membrane distillation (MD). The thermal desalination processes are energy intensive (which global requirement is also increasing) and the efficiency is greatly improved when they are integrated with heat-power plants (co-generation power desalting plants, CPDP). Thus, the waste heat of the power plant is used as thermal source to produce fresh-water. The main drawback of such plants, however, are the high consumption of fossil fuel and high CO_2 emissions which lead to global warming and inevitable climate changes. It is essential therefore to look for cost-effective and sustainable processes that combine alternative energy sources (wind, geothermal and solar energy, fuel cells and others) with desalination technologies.

The use of high temperature fuel cells [molten carbonate fuel cells (MCFC) and solid oxides fuel cells (SOFC)] has emerged as a suitable technology for cogeneration. Certainly, electricity can be generated in a cleaner and more efficient way than with conventional technologies. In addition, the temperature of the flue gases is high enough to produce high-temperature steam to be used as heating medium in energy intensive processes.

Fig. 1 shows a schematic and feasible flow-sheet which integrates fuel cell and desalination process. The mathematical model to be presented in this work is the first basic step of a more ambitious project aimed at determining the optimal synthesis and design of the integrated process including desalination processes and SOFCs.

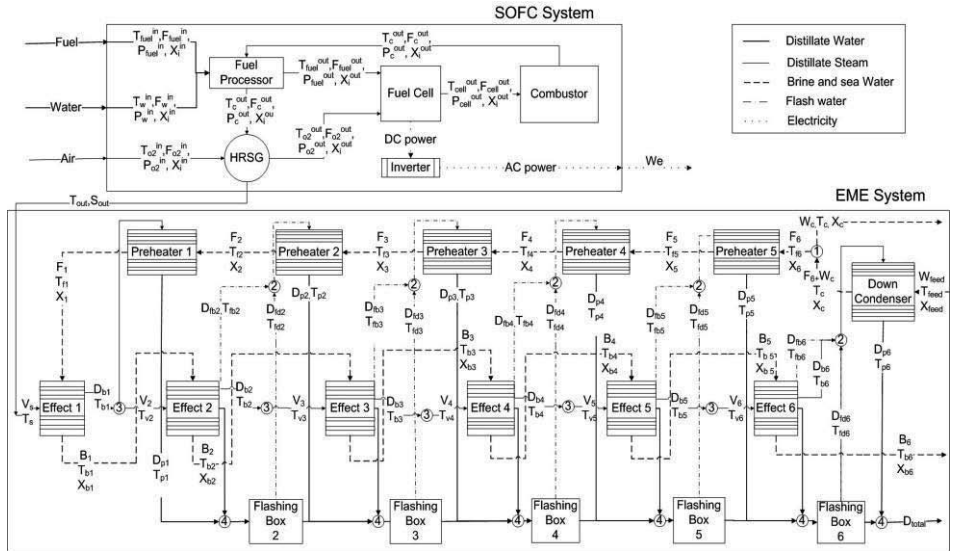

Fig. 1 Integration of SOFC and Multi-Effect Evaporation (MEE) process.

The MEE desalination system illustrated in Fig 1, which is the aim of this paper, is named "forward feed flow arrangement. As shown, each one of the effects involves a pre-heater, an evaporator and a distillate flash chamber. Feed seawater enters to the system and is preheated in the down condenser by the vapor formed in the last effect. A part of the seawater is then discharged to the sea. In the first effect, part of the vapor formed by evaporation of the brine is condensed outside the tubes of the pre-heater to heat the feed and the remaining the vapor is used in the second effect to evaporate part of the brine coming from the first effect. From the second to the last effect, the vapor formed by flashing of the brine and distillate is used to pre-heat the feed while the fresh vapor formed by evaporation is used to evaporate part of the brine in the next effect. This cycle of evaporation, condensing and heating is repeated at each effect until the last effect. The first and last stages need external heating and cooling respectively. The amount of heat removed from the last stage must nearly equal the amount of heat supplied to the first stage (Q). For sea water desalination purpose, the first stage is typically operated at a temperature below 70 °C in order to avoid scale formation.

2. Optimization Problem

The proposed optimization problem can be stated as follows. Given the sea-water conditions (composition, temperature and flow-rate), the goal is to determine the optimal operating conditions and the heat exchange values for the different heat exchangers in order to minimize the total heat transfer area in satisfying the fresh-water demand. The problem is solved for the following two cases: a) equal heat transfer areas (HTA) in all pre-heaters and evaporation effects and b) variation of HTA along the pre-heaters and evaporation effects. The output results are compared in detail. Finally, the influence of the number of effects and the steam temperature supplied in the first effect (heating utility) on the total heat transfer area is also analyzed. For this analysis, the optimization problem is systematically solved by varying both parameters.

3. Assumptions and mathematical model

The following are the main assumptions used to develop the mathematical model.

- Heat losses, non-equilibrium allowance (NEA) and Non-condensable gases effects are neglected.
- A mean value is adopted for the heat capacity coefficients (Cp), the latent heat of vaporization (λ), the overall heat transfer coefficients (U) and for the boiling point elevation of the brine (BPE), neglecting the effect of the chamber geometry, temperature, pressure and the fluid properties.
- The vapor form by flashing in the effects and the flashing boxes is used to heat the feed.
- The heat transfer equations model the HTA in each evaporator as the sum of the area for brine heating (A_b) and an area for evaporation (A_e).

3.1. Equations and computational aspects

The MEE system is represented as a No Linear Programming (NLP) model. This model consists in a set of mass and energy balances, and design equations used to compute heat transfer areas and physical-chemical properties of each one of the streams. There is mass and energy balances for each one of the pre-heaters, effects and flashing chambers. The logarithmic mean temperature difference (LMTD) is used to compute the HTA in pre-heaters. The model also includes non equality constraints which are used to avoid temperature crossover. In addition, lower and upper bounds have been imposed for each one of the variables in order to facilitate the model convergence.

The model involves non-linear constraints and bilinear terms which lead to local optimal solutions and therefore, global optimal solutions can not be guaranteed. In order to solve the optimizations, a feasible solution taken from Darwish's (2006) has been used to solve the first optimization problem. Then in order to solve the next optimization problem where some model parameters are varied, the previous solution is used as initialization. Thus, a sequence of several optimization problems is efficiently and systematically solved.

4. Results

The optimization problem described in section 3 is solved using the parameter values listed in Table 1. As mentioned earlier, the fresh-water demand (D), steam temperature (T_s), steam flow-rate (S) and seawater conditions [(X_{feed}), (T_{feed})] are given. In addition, an upper bound for the rejected brine salinity is imposed for environmental restrictions (XUp). The down condenser eject temperature (Tc) is also assumed as given.

Table 2 and Fig. 2, 3 and 4 compare the output results obtained by considering either uniform or non uniform distributions of heat transfer areas in pre-heaters and evaporation effects along the MEE system. In Table 2 are also compare same widely used variables to measure the system efficiency: the performance ratio (PR), the conversion ratio (CR), the specific total HTA (sHTA) and the specific cooling water ratio (sCWR).

Table 2 clearly shows that despite the cooling water flow-rate and the HTA in down condenser for non uniform area are greater than those required for uniform area, the total HTA required in pre-heaters and effects is considerably smaller than that required for uniform area. Fig. 2 compares the distribution of the HTA in pre-heater and evaporation effect along the MEE system (8 stages). It is possible to observe that the non uniform distribution of the HTA leads to the minimum total HTA of the process.

Fig. 3 compares the corresponding distribution of the driving force and the fresh water production in each one of the effects for both cases. It clearly shows that from the first to fifth effect the driving forces are similar in both cases and then in the last three effects the driving force for non uniform area is greater than the corresponding to

uniform distribution. In both cases, the total fresh-water production which is fixed is similarly distributed along the desaltor.

Fig. 4 compares the distribution of the temperatures in pre-heater and evaporation effect along the MEE system (8 stages) for both situations.

Table 1. Parameter values

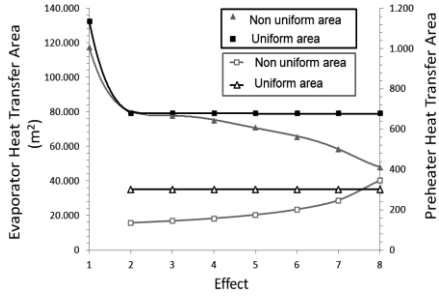

Fig. 2. Heat transfer areas vs. effect

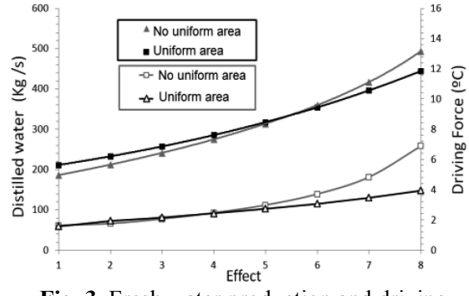

Fig. 3. Fresh water production and driving force vs. effect

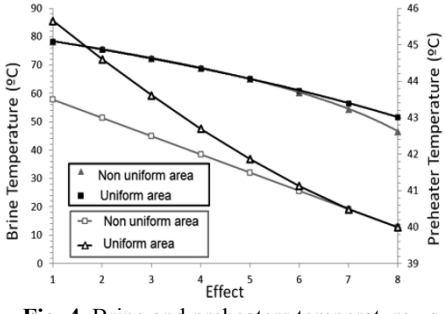

Fig. 4. Brine and preheaters temperature vs. effect

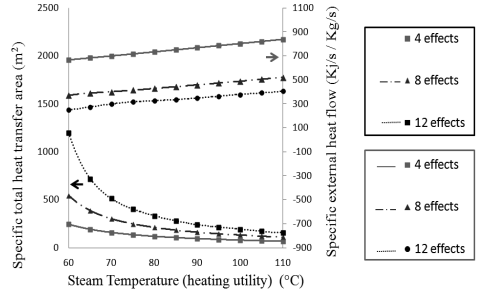

Fig. 5. Total HTA and heating utility vs. effect

The impact of the number of effects and the steam temperature used for heating utility on the total HTA and consumption of the heating utility is shown in Fig. 5. The illustrated results were obtained by minimizing the total HTA considering uniforms HTA in pre-heaters and effects and a given fresh water demand. In addition, in this case, the heating utility consumption was considered as a variable. Fig. 5 exhibits a similar behavior to those obtained via simulation by El-Dessouky (2002), instead of simultaneous optimization as is here used. As is shown, both the total HTA and heating

utility consumption are strongly influenced by the number of effects and steam temperature. The total HTA for N = 4 is not strongly influenced by the steam temperature. However, the total area is significantly increased as the number of effects increases and the steam temperature decreases. Certainly, for Ts = 65 ºC and N = 4, the total specific HTA is 192.17 m2/Kg/s, while for same steam temperature but N=12 the total specific HTA increases to 717.72 m^2/Kg/s, a 525 % higher.
By the other side, the heating utility consumption decreases as the number of effects increases and the steam temperature decreases. Certainly, for Ts = 65 ºC and N = 4, the total specific heating utility is 682.78kJ/s/Kg/s, while for same steam temperature but N=12 the total heating utility decreases to 273.57 kJ/s/Kg/s, a 59.93 % lower.

5. Conclusions and future work

A deterministic NLP mathematical model by effects for the MEE system was presented. Optimal temperature, salinity, areas dimensions and flow-rate evolutions through the equipment are obtained in order to satisfy a given fresh water demand. The proposed resulting model is a valuable tool not only to optimize the process but also to simulate the desalting process if the degree of freedom of the equation system is zero. After validation, several optimization problems using different criteria have been examined concluding that the total HTA require can be decreased a 11.4% by allowing HTA taking a non uniform distribution. It was verified that the minimization of the total HTA by fixing the fresh water demand and external heat, is equivalent to the minimization of the external heat by fixing the total HTA and fresh water demand. The effect of the number of effects and team temperature on the optimal solutions has been also investigated, obtaining similar results to those obtained by other authors. HTA and heating utility consumption are strongly influenced by the number of effects and steam temperature: the total HTA increased as the number of effects increases and the steam temperature decreases, while the heating utility consumption decreases as the number of effects increases and the steam temperature decreases.
At present, the proposed model is being expanded in order to consider the number of effects as an additional model variable (discrete decision), as well as the inclusion of the geometry, pressure drop, BPE, NEA and non-condensable gases. The coupling between the MEE system with SOFT cells and the minimization of the investment and operating costs of the entire process will be further investigated in detail. Finally, the application of a global optimum algorithm to solve the resulting model will be also addressed.

An Inverse Optimization Approach to Inducing Resource Conservation in Eco-Industrial Parks

Raymond R. Tan, Kathleen B. Aviso

Chemical Engineering Department/Center for Engineering and Sustainable Development Research, De La Salle University, 2401 Taft Avenue, 1004 Manila, Philippines

Abstract

The exchange of wastes among plants within an eco-industrial park (EIP) creates potential for significant gains in sustainability through efficient use of resources and reduction of environmental discharges. If the establishment of such resource conservation networks (RCNs) is not economically optimal, intervention of an EIP authority will be necessary in order to induce companies to act in an environmentally responsible manner. This conflict of interest between the EIP authority and the industrial plants results in a Stackelberg game, which may be represented as a bi-level optimization model. In this work, a bi-level linear integer programming model for optimizing waste exchange in an EIP is developed. Then, an inverse optimization approach is used to solve it. An auxiliary model is used to determine the best set of incentives and disincentives to induce the plants in the EIP to form an optimal RCN. The methodology is demonstrated using an illustrative case study.

Keywords: Resource conservation, industrial ecology (IE), eco-industrial park (EIP), Stackelberg game, bi-level programming, inverse optimization.

1. Introduction

The concept of industrial ecology (IE) was first proposed by Frosch and Gallopolous (1989) as a means of enhancing the sustainability of manufacturing by emulating the cyclic structures of natural ecosystems. In particular, eco-industrial parks (EIPs) have been shown to be effective in developing resource conservation schemes through waste exchange and reuse. There have been significant attempts to use process systems engineering tools to provide more rigorous decision support in the design of EIPs. For example, optimal design of inter-plant water networks using mathematical programming was first proposed in the late 1990s (Keckler and Allen, 1999; Nobel and Allen, 2000); in these early models, each plant in the EIP was modeled as a "black box." Subsequent models used more detailed models describing processes within the plants themselves (Lovelady and El-Halwagi, 2009; Chew et al., 2008; Chew et al., 2010a, b; Aviso et al., 2011). Further refinements of such models were later proposed to account for potential conflicts of interest among companies (Lou et al., 2004; Singh and Lou, 2006; Piluso and Huang, 2009; Chew et al., 2009; Aviso et al., 2010a; Aviso et al., 2011; Tan, 2011; Taskhiri et al., 2011b). While many of these works have focused on water reuse, it has also been shown that the basic modeling approach may be readily extended to other streams once relevant material and energy balance considerations have been identified (Lou et al., 2004; Piluso and Huang, 2009; Aviso et al., 2011). Game theory has been proposed for resolving conflicts of interest in EIPs (Lou et al., 2004; Chew et al., 2009). In particular, some approaches have explored the role of the EIP authority (e.g.,

government) in facilitating the emergence of sustainable resource conservation networks involving different plants through incentives or disincentives (Aviso et al. 2010b; Chew et al., 2011; Tan et al., 2011a). The interaction between the EIP authority (i.e., the leader, which seeks to maximize total public good) with industry (i.e., the follower, which in turn seeks to maximize profit) results in a Stackelberg game (Aviso et al., 2010b; Tan et al., 2011a). Such games can be modeled as bi-level mathematical programs (Bard, 1998). In practice, the problem for the leader is to induce environmentally responsible behavior in the follower, despite the fact that the latter is motivated predominantly by profit. Inducement can be achieved through incentives (e.g., subsidies) or disincentives (e.g., taxes). An optimal set of incentives can then be determined, for example via inverse optimization (Ahuja and Orlin, 2001). In this work, a bi-level linear integer programming model is developed for conservation of multiple resources in an EIP. An inverse optimization solution procedure is then proposed. The methodology is demonstrated using a simple case study. Finally, conclusions and prospects for future work are given at the end of the paper.

2. Problem Statement

The formal problem statement addressed in this work is as follows:

- The EIP is assumed to be comprised of m sources, n demand, and p streams. Any given plant within the EIP can act either as a source or a demand, or both.
- Each source i (i = 1, 2, …, m) is characterized by a non-negative flowrate S_{ik} of each stream k (k = 1, 2, …, p), while each demand j (j = 1, 2, …, n) is characterized by a non-negative flowrate D_{jk} of each stream k (k = 1, 2, …, p).
- The opportunity for reuse of an given stream k between any source-demand pair is given by a constant, R_{ijk}. The decision whether or not to activate a particular link is denoted by the binary variable x_{ijk}.
- The total cost borne by industry to implement resource conservation in the EIP is assumed to be a linear function of x_{ijk}. Note that the cost may be negative.
- The total cost to the EIP authority or government to implement resource conservation in the EIP is likewise assumed to be a linear function of x_{ijk}. In general, since this cost includes externalities (e.g., monetized cost of pollution), the authority's cost function will not be the same as that of industry. However, as in the latter's case, the cost may assume negative values as well.
- Both the EIP authority and industry seek to minimize their respective cost functions, resulting in a Stackelberg game. The leader then seeks to modify both cost functions, through incentives and disincentives, so that the optimal solutions of the two decision-makers coincide. The objective is to determine the optimal set of such interventions.

3. Model

The bi-level optimization model is:

$$\min \Sigma_i \Sigma_j \Sigma_k (A_{ijk} - \alpha_{ijk} + \beta_{ijk}) R_{ijk} x_{ijk} \quad (1)$$

subject to:

$$\min \Sigma_i \Sigma_j \Sigma_k (B_{ijk} + \alpha_{ijk} - \beta_{ijk}) R_{ijk} x_{ijk} \quad (2)$$

subject to:

$$\Sigma_j R_{ijk} x_{ijk} \leq S_{ik} \qquad \forall i, k \quad (3)$$

$$\Sigma_i R_{ijk} x_{ijk} \leq D_{jk} \qquad \forall j, k \quad (4)$$

$$x_{ijk} \in \{0, 1\} \qquad \forall i, j, k \quad (5)$$

where A_{ijk} and B_{ijk} are the unit costs incurred by the leader and follower, respectively, to implement reuse of resource k between source i and demand j; α_{ijk} and β_{ijk} are the specific incentive and disincentive for the reuse of resource k from source i to demand j; R_{ijk} is the maximum amount of resource k that can be reused from source i to demand j; x_{ijk} is the binary variable denoting the decision to implement reuse of resource k between source i and demand j; S_{ik} is the amount of resource k available from source i; and D_{jk} is the amount of resource k needed by demand j. The leader's objective function is to minimize the total cost (including external costs corresponding to monetized environmental damage) associated with implementing resource reuse in the EIP (Eq. 1); likewise, the follower seeks to minimize the total cost or resource reuse (Eq. 2). The costs given by Eq. 1 and 2 may assume negative values, indicating net benefit. Source and demand balances are given by Eq. 3 and 4, while Eq. 5 restricts x_{ijk} to binary values. It can be seen that $R_{ijk} = \min(S_{ik}, D_{jk})$. Furthermore, the leader and follower will clearly have identical solutions when the terms of Eq. 1 and 2 are proportionate. Thus, when the ratio A_{ijk}/B_{ijk} is a positive constant, the leader and follower will agree on a common solution even with $\alpha_{ijk} = \beta_{ijk} = 0$. However, such a condition will rarely arise in practice, and thus it is necessary to determine what the incentives should be.

Assume that the leader seeks a set of incentives which requires the least deviation from the original cost coefficients, as proposed by Ahuja and Orlin (2001). The following auxiliary model results:

$$\min \Sigma_i \Sigma_j \Sigma_k (\alpha_{ijk} + \beta_{ijk}) \tag{6}$$

subject to:

$$\lambda (A_{ijk} - \alpha_{ijk} + \beta_{ijk}) = (B_{ijk} + \alpha_{ijk} - \beta_{ijk}) \quad \forall i, j, k \tag{7}$$

$$\lambda \geq 0 \tag{8}$$

$$\alpha_{ijk} \geq 0 \quad \forall i, j, k \tag{9}$$

$$\beta_{ijk} \geq 0 \quad \forall i, j, k \tag{10}$$

where λ is the variable proportionality ratio. Note that there are bilinear terms in Eq. 7. The procedure is illustrated in the next section with a simple case study. The optimization software Lingo 12.0 with a branch-and-bound based global optimization toolbox for non-linear models (Gau and Schrage, 2004) is used to solve the example.

4. Case Study

Consider a hypothetical EIP with three plants (i.e., a power plant, a palm oil mill and a biorefinery) and two streams (i.e., waste heat and waste biomass). The power plant may export its waste heat to the palm oil mill or the biorefinery; on the other hand, the palm oil mill generates waste biomass, which can be co-fired in the power plant or used as feedstock for the production of value-added goods in the biorefinery. The relevant stream data are shown in Table 1.

Table 1. EIP Data for Case Study

	Waste heat output (MW)	Heat demand (MW)	Waste biomass output (t/h)	Waste biomass demand (t/h)
Power plant	100	0	0	12
Palm oil mill	0	25	10	0
Biorefinery	0	20	0	5

Cost coefficients for the reuse of streams from both EIP authority and industry standpoints are given in the second and third rows of Table 2. Note that these coefficients will cause the leader and follower to seek different optimal solutions, mainly because the leader's cost coefficients account for the externalities (i.e., effects of resource conservation or pollution reduction in monetary terms).

Table 2. Cost Coefficients for Case Study

	Waste heat reuse ($/MWh)	Waste biomass reuse ($/t)
EIP Authority	–10	–1.5
Industry	2	0.2
Incentive	2	0.2

Solving the auxiliary model (Eq. 6 – 10) gives the optimal set of incentives in the last row of Table 2. The incentives in this case are just sufficient to offset the costs of implementing resource reuse, so that the industrial coalition becomes willing to accept the solution preferred for implementation by the EIP authority. Substituting these values into the main model (Eq. 1 – 5) then gives the optimal resource reuse network as shown in Table 3. The power plant exports waste heat to the two other plants for a combined recovery of 45 MW, and receives all of the available biomass (10 t/h) from the palm oil mill for co-firing.

Table 3. Optimal EIP Resource Reuse Scheme for Case Study

Source/Demand	Power plant	Palm oil mill	Biorefinery
Power plant	0	25 MW	20 MW
Palm oil mill	10 t/h	0	0
Biorefinery	0	0	0

5. Conclusion

An inverse optimization approach to inducing resource conservation in eco-industrial parks has been developed. This approach involves formulating a bi-level integer programming problem, where the EIP authority or government assumes the role of the upper-level decision maker, while the coalition comprised of participating plants acts as the lower-level decision maker. An inverse optimization strategy can be used to determine the set of incentives/disincentives that the authority should impose in order to induce the companies within the EIP to participate in resource conservation. A simple case study involving has been used to demonstrate the methodology; the model may also be tested on more complex examples in the future.

Techno-economic analysis of ethanol production from marine biomass

Peyman Fasahati, Geongbum Yi, Jay Liu*

[a] *Department of Chemical Engineering, Pukyong National University, Busan 608-739, South Korea*

Abstract

The purpose of this study is techno-economic analysis of ethanol production from marine biomass (macroalgae), based on 10-year time frame for plant operation. This study is different from previous similar studies considering following facts: (1) Biomass considered in this study is macroalgae or seaweed, to which technologies available for conversion of biomass to fuels have been applied in limited ways. (2) This study does not provide production cost of ethanol, but target biomass cost for macroalgae production through large-scale cultivation that is a key factor for success of macroalgae as a biomass feedstock.

Currently high seaweeds price greatly limits the applicability of seaweeds as feedstocks for bioethanol production plant. To solve this issue a reduction of feedstock price seems the only option. This study develops a techno-economic model to analyze the economy of an ethanol production plant processing 100,000 MT/year (dry basis) brown algae. This study effectively defined maximum dry seaweed price (MDSP) that must be covered by large-scale seaweed production to reach a Return-On-Investment (ROI) break-even point after 10 years plant operation. The MDSP will act as target biomass cost for large-scale cultivation of macroalgae. Plant scale ups were also performed to examine the effects of plant capacity on MDSP.

Keywords: Techno-economics, Ethanol, Seaweed, Biomass, Macroalgae.

1. Introduction

Over the past 50 years, the world's population has more than doubled, coupled with an expectation of a higher standard of living and an ever-increasing economic output. This has resulted in a large increase in primary energy consumption, particularly the use of fossil fuel derived energy (BP Global, 2011).

Bio-fuels are environmentally friendly and carbon neutral, and can play a prominent role in an energy portfolio. However, if the bioenergy industry is to be successful, enough supply of biomass feedstock should be available at a low cost and on a very large scale (Antizar & Turrion, 2008).

The main obstacle of bio-energy development is stable supply of raw materials on a large scale. More than 60% of the cost for bioenergy is feedstock cost (Liu & Gu, 2008), which is a major constraint on the commercialization of algal biofuels (Johnson & Wen, 2010). It is the goal of this study to evaluate the economics of ethanol production from marine biomass, i.e., macroalgae or seaweeds (brown algae), and to calculate the maximum feed stock price based on 10-year time frame for plant operation so that industrialization of plant be economically possible. In addition, to identify most significant opportunities to decrease production costs.

* jayliu@pknu.ac.kr

An ethanol production plant from brown algae, based on a 100,000 MT/year dry feed, simulated using Aspen Plus® in order to obtain more accurate mass balance information than what typically assumed (Fasahati & Liu, 2011). Furthermore, the Aspen Plus model was used to estimate key parameters affecting the economy of the plant. Using the resulting flow rates, sizing and cost of each process unit estimated based on Aspen Process Economic Analyzer to determine the cost of bioethanol production plant. It is important to note at the outset that algal biofuel technology is still at the lab-scale or at the very early pilot stage of development; as such, the estimated cost of production may vary based on future developments on process condition and parameters change.

2. Process description

As shown in Figure 1, the simulated ethanol production process consists of three major units, feed pretreatment, simultaneous saccharification and fermentation (SSF), and finally purification. Feedstock for this plant is Saccharina Japonica, one type of brown algae, which is extensively cultivated in Korea, China, and Japan. Chemical composition for this seaweed derived from literature data (John et al., 1998; Horn S. G., 2000; Rioux et al., 2007; Jang et al., 2011). Total carbohydrates of this seaweed sum up to 66 percent of dry matter (Jang et al., 2011).

A pretreatment section carried out in two stages: The first stage is to heat up the feed stream by adding steam and H_2SO_4 for thermal acid hydrolysis. The second stage is to use enzymes for saccharification and SSF.

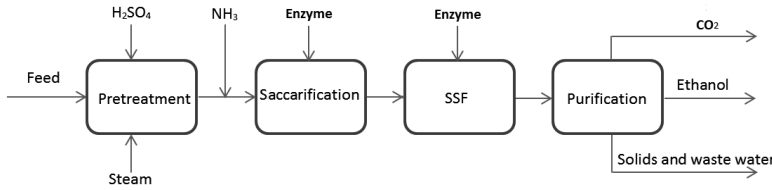

Figure 1. A simplified process flow diagram for bioethanol production plant

Slurry received from the pretreatment section first neutralized with Ammonia. Then it goes to saccharification vessels for further saccharification. Saccharified slurry, which has a reduced viscosity, goes to saccharification and fermentation vessels for SSF. Operating conditions are given in Table 1.

Table 1. Summary of plant operation conditions (Jang et al., 2011)

Unit	Condition
Thermal acid hydrolysis	10% (w/v) S. japonica, 40mM H_2SO_4, 121 °C, 60 min,
Biological saccharification	1 g dcw/L Bacillus sp. JS-1, 30 °C, 7.5 days
SSF	0.39 g dcw/L Bacillus sp. JS-1,0.45 g dcw/L P. angophorae, 30°C, 64 hr

A purification section separates the fermentation broth into water, anhydrous ethanol, and solids. Distillation and molecular sieve adsorption used to recover ethanol from the raw fermentation liquid and to produce 99.5% ethanol. Distillation accomplished in two columns. The first column, a water remover column, removes dissolved CO_2 and most of the water. The second column, an azeotropic column, concentrates ethanol from the first column to a near azeotropic composition. At the azeotropic condition ethanol products from this column goes to molecular sieves to reach 99.5 % purity. Overall process yield for ethanol production from dry seaweed is 0.25 (kg ethanol)/(kg dry seaweed).

3. Materials and methods

A list of assumptions common to all process scenarios includes the following:

- Plant base capacity is 100,000 MT/year of dry seaweed.
- Publicly available and experimentally validated literature data on reaction conversions and parameters are used.
- Equipment, chemical, and labor costs indexed to 2011 dollars.
- Contingency 18% of total project cost.
- Capital costs depreciated over 10 years of plant operation.
- Working capital 5% of total capital expense per year.
- Tax rate 24.75% per year.
- 15% internal rate of return (IRR).

The production costs include variable operating costs (such as process chemicals, bacteria, nutrients, etc.) and fixed operating costs (employee salaries, overhead, maintenance, and insurance). The chemical prices obtained from literature data and public available data such as ICIS chemical business (ICIS, 2011). Bacteria and yeast used in the process are not commercially available at a scale needed for the production plant, and this makes it difficult to obtain information needed for calculating operating costs. It is assumed that all the bacteria and enzyme will be delivered from outside to the plant and there is no onsite production. Table 2 shows material prices used in this study. CO_2 also selected as a selling material. Since this plant is capable of producing CO_2 at purity higher than 96%. We considered it as a product that can be sold.

Table 2. Raw material and product unit prices

Raw material	Cost (US$/kg)	Source
Ammonia	0.392	Humbird et al., 2011
Sulphuric acid	0.093	Humbird et al., 2011
Yeast and enzyme	0.340	Aden, 2008*
HP Steam @ 165 PSI	0.0179	Aspen utility specification
Nutrient	0.786	Aden, 2008*
Products	**Selling Price (US$/kg)**	**Source**
Ethanol 99.5%	0.891	ICIS, 2011
CO_2	0.040	Davis et al., 2011

* Nutrient and enzyme prices calculated for 2011 dollars using consumer price index, (CPI USA, 2011)

4. Results and discussions

4.1. Maximum dry seaweed price

The process model developed in Aspen Plus was sent to Aspen Process Economic Analyzer for economical evaluations. The total project capital cost is considered to depreciate, via a straight-line depreciation method, over the 10 years of economic Life of the facility. To reach a ROI break-even point after 10 years of operation, dry seaweed cost increased until net present value in 10^{th} year equals to zero. The maximum price for dry seaweed obtained was 160 $/Ton for the base case of 100,000 MT/year of dry seaweeds. Table 3 shows resulting production costs at this break-even point. Figure 2 shows a pie chart of the distribution of operating costs in 10^{th} year. From the chart, it can be seen that the raw materials constitute 68.5% of the total operating costs, and 18% of the operating cost is for utilities. This is in accordance with high raw material costs

associated for ethanol production plants using fermentation processes from biomass (Liu & Gu, 2008).

Table 3. Production costs (US$) at a ROI break-even point

Total Project Cost	12,901,300
Total operating labor and maintenance cost per year	1,466,000
Total raw material cost per year	16,302,200
Total product sales per year	26,783,400
Total utilities cost per year	4,449,870

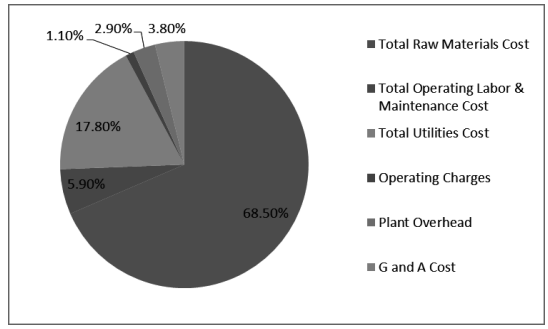

Figure 2. Operating costs break down at 10th year of plant operation

4.2. Effects of plant capacity

In order to examine the effect of plant capacity on production costs, a plant scale up from 50% to 700% of the base case (100,000 MT/Year of dry seaweeds) was performed using Aspen Process Economic Analyzer. It was found out from this study that plant economy can be improved at larger capacities. This allowed us to have increased MDSP at 10^{th} year. Figure 3 shows the trend of MDSP changes as a function of plant capacity.

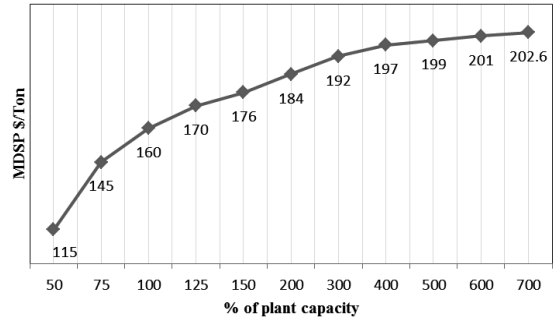

Figure 3. MDSP trend as a function of plant scale

As Figure 3 shows MDSP converge to 203 $/MT at the boundary and maximum quantity happened for plant scale up equal to 700%. Further scale ups did not affect MDSP very much and it remained constant at this value.

4.3. Conclusion

As the results of this study shows, this plant would be more economical if we can increase its capacity to five or six times of that of the base case. However, as the plant capacity increases, more biomass is needed for feed. Total production of Saccharina Japonica in South Korea in December 2011 was 43,651 MT in which 22,955 MT used

as food. This amount is much less than feedstock needed for the base case simulation. Currently, seaweeds mostly are used for food industry. Current market wholesale price of dry seaweed in South Korea is 5,622 US$/MT (December 2011) and wet seaweed price at cultivation sites is 393 US$/MT (AFL news.co.kr, 2011). Most of the seaweed available in market is wild and naturally cultivated. However, Large-scale artificial cultivation of seaweed will reduce this price. Results of this study show the necessity to perform a comprehensive study in the near future on seaweed mass cultivation procedures and efficiencies. Further technological advancements like increased conversions and process integration can further improve the plant economy and let the plant be economical even at higher seaweed prices.

Modeling and Simulation of Ship Transport of CO_2

Seok Goo Lee, Go Bong Choi, En Sup Yoon, Chonghun Han, Jong Min Lee*

School of Chemical and Biological Engineering, Institute of Chemical Processes, Seoul National University, 1 Gwanak-ro, Gwanak-gu, Seoul 151-744, Korea

Abstract

With growing concern about greenhouse gas emission, previous carbon capture and storage (CCS) research has mainly focused on efficient capture methods. However, there is a relative lack of studies on ship transport and offshore unloading. The available guidelines, if any, are simply suggested without a systematic analysis from the viewpoint of the optimal transport chain system. Thus, this study addresses the issue by modeling the ship-based transport network of CO_2. In particular, liquefaction, boil off gas (BOG) reliquefaction and offshore unloading processes are investigated to provide essential guidelines in terms of an optimal thermodynamic state (pressure-temperature: P-T). Optimal compression ratio and pressure-enthalpy flash are implemented on each compression-intercooling-separation stage, and a conceptual model for BOG reliquefaction process is also proposed.

Keywords: carbon capture and storage (CCS), CO_2, ship transport, optimal operating condition, modeling, simulation

1. Introduction

In recent years, there has been increasing demand for a significant reduction of CO_2 emissions from industrial sources to alleviate the global warming problem. Although several alternatives such as bio, wind, and solar energy are being studied to meet the huge energy demand, large amount of CO_2 emission seems to be inevitable in near future. Under the present conditions, carbon capture and storage (CCS) is considered to be the most practical approach for mitigation of CO_2 emission.

CCS technology consists of capture, transport and storage. Whereas a variety of researches have been conducted for CO_2 capture, research on systematic guidelines and technologies for transport and storage is still at its infancy.

Large amount of CO_2 can be transported via pipelines or ships. The technologies for CO_2 pipelines have been well established for many years, however this study is focused on ship transport of CO_2 due to its flexibility compared to the regional constraints of pipelines and wide range of applications. Despite the current limited knowledge and experience on ship-based CO_2 transport, there is much technical information available in the field of liquefied petroleum gas (LPG) and food grade CO_2 industries.

In order to ship CO_2, pressured-type or semi-refrigerated ship should be used for dense liquid phase conditions. Since CO_2 is in gas or solid phase at atmospheric pressure, depending on temperature, lowering the temperature at atmospheric pressure cannot liquefy CO_2 (IPCC, 2005). Hence, liquefaction of CO_2 requires a P-T condition between the triple point (T.P., 5.2 bar and -56.6 °C) and the critical point (C.P., 73 bar, 31 °C).

A key to the design for ship transport chain of CO_2 is to determine optimal P-T conditions of CO_2 because this significantly affects the system performance including liquefaction process, boil-off rate in the tank, hydrate and dry ice formation, etc. As

*Corresponding Author Tel.: +82-2-880-1878, E-mail: jongmin@snu.ac.kr

thermodynamic condition is close to the T.P., the amounts that can be transported are increased as the density rises. However, more compression energy is required for lowering the pressure for liquefaction and the amount of BOG can be increased with the temperature difference between inside and outside of the tank. If the pressure goes below the T.P., dry ice will not be necessarily formed immediately. In addition, the solubility of water in CO_2 gas decreases with higher pressure and lower temperature (Aspelund et al., 2006). For all these trade-offs, thermodynamic (P-T) conditions for liquefied CO_2 should be investigated systematically for each process.

Thus, this study systematically investigates the optimal operating condition by modeling and simulation of the major three processes, i.e., liquefaction, BOG reliquefaction, and offshore unloading.

2. Description of ship transport chain of CO_2

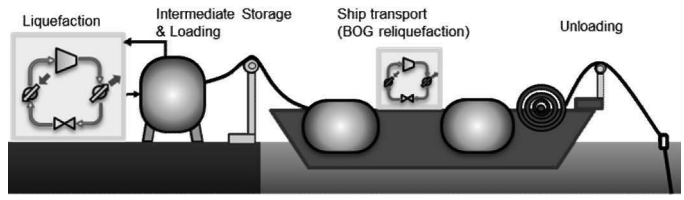

Figure 1. The ship transport chain of CO_2

As shown in Figure 1, the ship transport chain of CO_2 is divided into four parts: liquefaction, intermediate storage and loading, ship transport, and unloading. Liquefaction using Carnot cycle for volume reduction and intermediate storage tank are necessary at a terminal because CO_2 is continuously captured at the plant on shore. A loading arm or insulated flexible hose is placed between intermediate storage tank and ship. Furthermore, BOG reliquefaction process on the ship is considered in spite of much uncertainty in the amount of BOG. As the last stage, CO_2 is directly unloaded to aquifer via flexible riser (hose) which is mainly used in the field of oil/gas loading.

2.1. Liquefaction process

In the ship transport chain of CO_2, liquefaction process has the most significant influence on total cost and energy. Liquefaction of CO_2 can be classified into three categories according to the refrigeration system and refrigerant. The first is an absorption refrigeration system using NH_3. This method has the advantage of high specific heat capacity of NH_3, but is not suitable for this case due to environmental problems. The second is the method primarily used in the liquefied natural gas (LNG) industry, which lowers the temperature of CO_2 by compression-expansion loop using C_3 series refrigerant. This method has disadvantages in terms of efficiency and refrigerant cost. The last method, considered as the best, is an open cycle using the CO_2 feed as refrigerant by itself. Compared to conventional refrigerants, the most remarkable property of CO_2 is the low critical temperature of 31 °C. This means that the compression system operating at normal ambient temperatures thus works close to and even above the critical pressure of 73 bar. This leads to trans-critical cycle of CO_2 for liquefaction with favourable conditions for high compressor efficiency. In addition, most of the heat rejection at each stage takes place by air/seawater cooling instead of condenser. In other words, the refrigerant can be cooled to a few degrees above the entering coolant (air, seawater) temperature, and this contributes to the performance improvement (Neksa et al.).

As mentioned earlier, P-T condition has the most significant influence on performance for liquefaction process. This study investigates an alternative condition, which is 20 bar and -20 °C in the product stream, unlike the existing cases (7 bar, -50 °C) in the literature (Aspelund et al., 2006, 2007 & Decarre et al., 2010). Although the 20 bar and -20 °C condition may have disadvantages of high capital production cost of pressurized tank with a large volume due to the difference in density, liquefaction energy and BOG generation are smaller than the existing case (7 bar, -50 °C). This is an important problem of finding an economic optimal trade-off. However, 7 bar and -50 °C condition is unquestioningly applied to many previous studies (Aspelund et al., 2006, 2007 & Decarre et al., 2010). This study provides systematic guidelines for computing an optimal operating condition based on 20 bar and -20 °C condition.

2.2. BOG(Boil-Off Gas) reliquefaction process

With increasing fuel price, BOG reliquefaction technique has made much progress in the field of LNG transport. BOG reliquefaction for CO_2 transport is not yet reported, and there is much uncertainty about its necessity and technology. This is because there exists many difficulties in determining boil-off rate in CO_2 tank due to the uncertainties in its sensitivities with respect to insulation material and thickness, the number and size, structural shape, sloshing phenomena, impurities, etc. In addition, desirable simulation and/or experimental data for BOG reliquefaction of CO_2 has not been developed in the previous studies. Thus, to circumvent these difficulties, existing approaches in the LNG industry are applied in this study. Even though boil-off rate is determined by many variables, N_2 content is considered as a major factor in this modeling and simulation. This is because vapor-liquid equilibrium is largerly changed with N_2 content in BOG. The other variables such as insulation, surface area, and the number and size are assumed to be considered in the tank design as an economic trade-off. In addition, since N_2 is non-condensable in reliquefaction process, the amount of N_2 in BOG increases during the voyage. Thus, excessive amount of N_2 in BOG must be investigated and controlled by reliquefaction process and purge gas.

2.3. Offshore Unloading Process

There are two possible options for unloading process: indirect or direct unloading. Indirect unloading methods use a platform installed with buffer storage tank and injection facilities. Among them are submerged turret loading (STL) system and scaled-down platform (Aspelund et al., 2006). Although indirect methods can stand up to harsh condition on the sea, there are critical drawbacks that energy source for utilities on platform cannot be supplied by itself and relocation for scattered aquifers is relatively difficult.

The second method is to unload directly to aquifer without any buffer tank on ship instead of the platform. This method equips a pipeline at the bottom of ship (IPCC, 2005) or a flexible hose on the top of ship for injection. Compared with the indirect method, the direct method has many advantages such as flexibility for scattered aquifers, change of schedules and dynamic positioning. Though there are still uncertainties in choosing the best way between indirect and direct options according to given conditions, this study will focus on direct unloading methods with its economic advantages.

3. Simulation Results and Discussions

The suggested models are synthesized on process flow sheet simulator, Aspen HYSYS v7.2, and physical properties of the components were calculated by Soave-Redlich-Kwong (SRK) equation of state.

3.1. Liquefaction process

Table1. Specification of streams

	Component	Mole fraction	P-T condition	Mass flowrate
Feed gas stream	CO_2	0.95	1.1 bar, 35 °C	500 tonCO_2/hr
	H_2O	0.05		
Product stream (liquefied CO_2)	CO_2	0.9999	20 bar, -19.28 °C	475 tonCO_2/hr
	H_2O	0.0001		

Table1 shows feed flow of 500 tonCO_2/hr is used, which was determined by the thermal power plant of a unit grade 500 MW in South Korea, Boreyong city. The feed component mole fractions and P-T conditions were taken from (Aspelund et al., 2007)

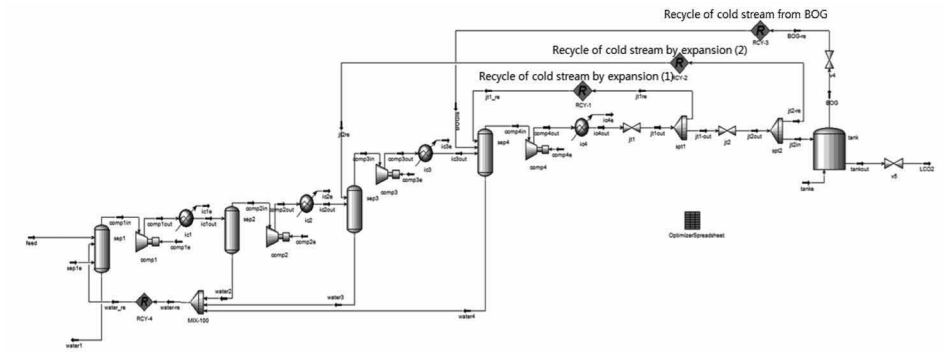

Figure 2. Process Flow Diagram of liquefaction process

For mechanical feasibility and thermodynamic efficiency, multistage compression-intercooling-separation processes are applied to increase the pressure for trans-critical cycle as shown in Figure 2, and then the liquid CO_2 is expanded over two stages to reach final specifications. The cold stream is generated by two-stage expansion and BOG from intermediate storage tank. This cold stream is recycled to pre-saturation for reducing compression power at 3 and 4 stages. Furthermore, compression pressure ratio is optimized via simulation tool satisfying mechanical constraints (i.e., in general compression ratio cannot exceed 5). As a results, the required compression power was computed as 103.42 KWh/tonCO_2. This is much more improved value compared to the previous studies (Aspelund et al., 2007 & Decarre et al., 2010). In addition, hydrate formation utility does not occur in simulation because water content is reduced to 100 ppm level in the product stream by the recycle. There are available results concerning the hydrate formation (Jakobsen et al., 2011). Hydrate will be formed at 20 bar, -20 °C when water content is contained more than 500 ppm. Thus this case does not have a problem for hydrate formation.

3.2. BOG reliquefaction process

N_2 content in the feed is contained to 500 ppm. N_2 content has a significant effect on vapor-liquid equilibrium in BOG. The boiling point of pure CO_2 at 20 bar is -19.27 °C. However the boiling point is changed to -24.35 °C when BOG contain 500 ppm N_2 content according to the SRK equation of state. The sphere tank volume and liquid volume flowrate are 10,000 m^3 and 10,000 m^3/hr, respectively. Overall heat transfer area is 2245 m^2. Heat ingress to storage tank is calculated as 64656 kJ/hr with the

overall heat transfer coefficient of 0.72 kJ/m^{2}·hr·°C. BOG massflow rate is 117.4 kg/hr containing 12 mole% N_2 content and 88 mole% CO_2 contained in BOG in the tank.

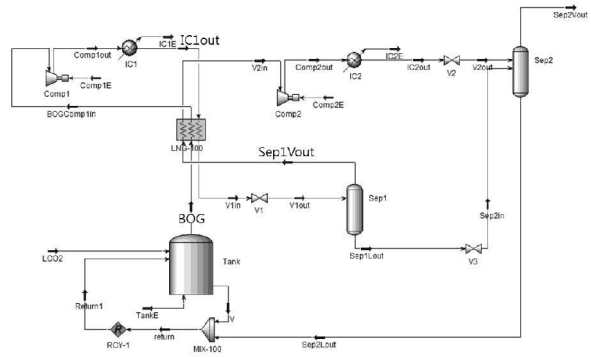

Figure 3. Process Flow Diagram of BOG reliquefaction process

Similarly, in the liquefaction process, design is proposed using CO_2 as a refrigerant by itself and two-stage compression-intercooling-expansion loop is shown in Figure 3. BOG and Sep1Vout as a cold stream pass through the multi-stream heat exchanger with hot IC1out stream after one-stage compression-intercooling. After that, the stream reliquefies via one more compression-intercooling-expansion in the last stage. Separated liquid stream containing 0.8 mole% N_2 content and 99.2 mole% CO_2 returns to the tank. It should be noted that, recovery rate is only 43%.

4. Concluding Remarks

By optimizing the compression ratio for each stage and integrating cold energy generated by expansion, the liquefaction process has been developed with 103.42 KWh/tonCO_2 of power for compression and the water content of 100 ppm level. BOG reliquefaction model for CO_2 storage tank is newly proposed to estimate the boil off rate.

Abstract

Korea Gas Corporation(KOGAS) has developed a process in which syngas is produced from natural gas and converted to dimethyl ether(DME) using a single-step reactor. We had conducted the study on the scale-up of the plant based on the operation experience of demo-scale plant and the numerical analysis result of the pilot-scale fixed-bed tubular reactor. Those studies didn't pay attention to the improvement of the process performance, but tended to center around the simulation of the plant with respect to development and validation of the model. In this study, we have conducted the simulation reflecting the result of a reactor modeling and the real operation data of demo-scale plant. And based on this simulation result, we make some modifications of the conceptual design of commercial-scale plant to improve its performance.

Keywords: Dimethyl-ether, One-step DME production, Conceptual Design

1. Introduction

Korea Gas Corporation(KOGAS) has developed a process in which syngas is produced from natural gas in proprietary auto-thermal reformer(Tri-Reformer) and then converted to DME in a single reactor. Based on the study of lab and pilot scale plant, KOGAS had constructed demo-scale plant since 2004 and has operated it. Scale-up study on DME plant has been carried out with the operation data of the demo plant.

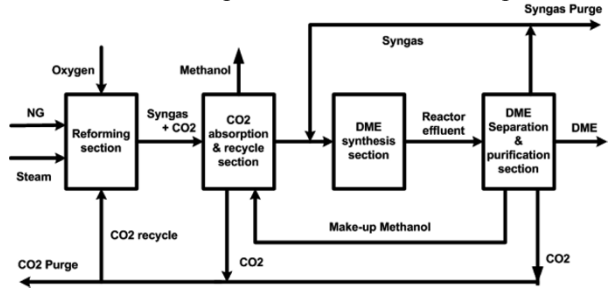

Fig.1 Simple process block diagram of one-step production of DME

The Tri-Reformer in the reforming section is an adiabatic auto-thermal reformer that is based on KOGAS' own technology. The pre-reformed natural gas (primarily methane), steam, oxygen, and carbon dioxide react to produce syngas containing the correct amount and ratio of carbon monoxide and hydrogen. The ratio of hydrogen to carbon monoxide in the Tri-Reformer outlet is set to be 1.2~1.3 to provide the correct H_2:CO ratio in the mixed feed into the DME reactor.

CO_2 absorption and recycle section uses chilled methanol as a solvent for absorbing CO_2 and serves two purposes; it removes CO_2 and water from the syngas stream going

to the DME synthesis reactor and it provides a CO_2 recycle stream being fed back to the Tri-Reformer.

The DME synthesis reactor is a tubular fixed-bed reactor with boiling water in jacket using KOGAS' catalyst. The inlet to the reactor is set to 230 C and 6.101 MPa. Given the specified feed composition and condition, the DME reactor is expected to achieve a 68% conversion of CO and provide the product profile specified by KOGAS.

DME separation and purification section is a single train that takes the combined output streams from the DME synthesis reactor, removes CO_2 to be sent back to the Tri-Reformer, recycle unreacted syngas (CO and H_2) to the DME reactor feeds, separates DME from the byproduct methanol and provides a DME product stream with the specified purity.

For the simulation of DME production plant, a commercial steady-state process simulator, Aspen Plus, has been used to model the KOGAS DME process. The previous simulation of process reflects only conceptual design of demo scale DME plants based on the pilot plant data. The revision of this simulation model should proceed for the purpose of more accurate analysis and studies.

In this paper, we have conducted simulations improved to reflect the data of experimental vapor-liquid equilibrium in the literature and the test operation data of the KOGAS' demo scale plant. And more reasonable and efficient alternatives are suggested by the modification of process.

2. Process Simulation Details

2.1. (Case1) Simulation changes by Demo plant operation data

Before this study, the simulation model had only reflected the pilot plant operation data. It should be revised to reflect the operation data of demo plant so that the simulation result of commercial plant could be correct in order for the simulation to be a useful tool for process design.

Major change from the demo plant operation is the feed and product composition changes of Tri-Reformer. This change is to increase CO_2 and O_2 composition in Tri-Reformer feed and to decrease steam demand.

This is for reasonable performance of Tri-Reformer, especially secure H_2/CO ratio in the effluent stream. As a result of this change, the demand of inlet natural gas and the flow rate of CO_2 purge stream increase since increasing demand of inlet natural gas also leads to increasing CO_2 effluent.

HP steam for supplying feed of Tri-Reformer is also serves as a preheating source of natural gas feed stream. So decreasing steam demand as a feed of Tri-Reformer causes the decreasing temperature of natural gas feed stream. As a result, the operation temperature of Sulfur Guard Bed which is required for absorbing sulfur contents in natural gas and protecting the downstream process is decreased by 10℃. Reactor performance and CO_2 absorber specification are also changed to reflect the operation data of demo plant.

2.2. (Case2) Improvement of Productivity

In the Case1, KOGAS DME plant produces DME and methanol simultaneously. KOGAS assumes that methanol produced in the DME reactor cannot be recycled due to the performance of reactor. So they allowed that the methanol needs to be purified to commercial grade and sold as a byproduct. But this means that the total capital cost and operation cost include the cost of production for not only DME but also methanol. This is not reasonable process with respect to productivity of DME.

The production of byproduct methanol also has implications for the Tri-Reformer. The amount of methanol byproduct produced impacts the H2:CO ratio required in the syngas produced by the Tri-Reformer. Methanol(CH_3OH) has an H:C ratio of 4 while DME(CH_3OCH_3) has an H:C ratio of 3. This means that as more methanols are produced, the H_2:CO ratio required in the makeup syngas will also have to increase.

To solve this problem, we added a separated methanol dehydration reactor(Fig.2). The underflow from DME separation column contains primarily methanol and water. This is sent to the primary methanol dehydration column. The reflux of methanol dehydration column is controlled so that the water content in the overhead methanol stream is maintained at 5wt%. This needs to be specified to match the feed specification for the methanol dehydration reactor. The methanol dehydration reactor is represented by a stoichiometric reactor model which converts 80% of the methanol to DME and H_2O. The reactor is assumed to be adiabatic.

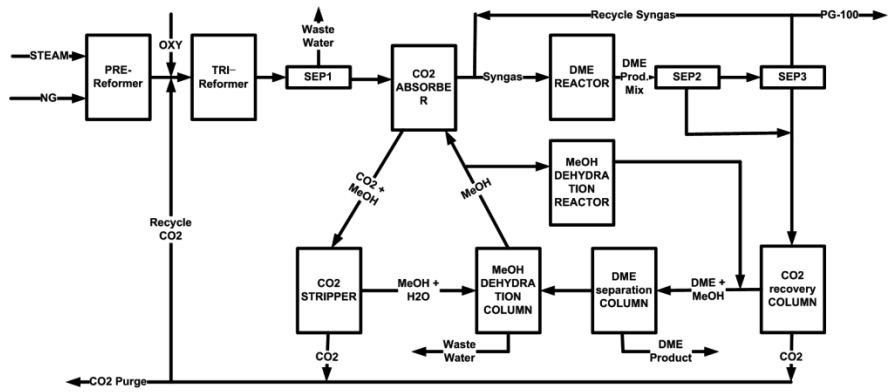

Fig. 2 Modified block diagram for Case2.

In addition, DME CO_2 absorber located between SEP3 and CO_2 recovery column in the previous cases is removed in this case. DME CO_2 absorber in DME separation and purification section is for absorbing CO_2 in the unreacted syngas recycle flow. But it seems to be unnecessary unit by the test operation of demo plant. So deleting DME CO_2 absorber from the separation process has no critical impact on the process-side streams but has an impact on the reduction of ISBL(Inside Battery Limits) and OSBL(Outside Battery Limits) fixed capital costs.

2.3. (Case3) Improvement of energy efficiency

Throughout the simulation model in the previous cases, Aspen Plus HEATER block are used to represent the process side heating and cooling. The utility side(e.g. refrigeration or steam) is not represented. In cases where process-process heat exchanger is taking place, this is represented by two HEATER blocks connected by a heat stream.

In the aspect of local energy integration, opportunities for minimizing heating and cooling utility requirements by matching hot and cold process streams were taken in all simulation cases. But the global (heat pinch type) energy integration is not conducted for 'first of a kind' plant.

In Case1 and 2, two heat exchanger blocks exist for calculating the steam generation rate in fired-heater. The fired-heater is for supplying heat duty to increase temperature of natural gas feed to 350℃. It is useful for start-up of plant, but could be substituted with an alternative reforming process scheme with respect to heat integration.

3. Result

3.1. Equipment Costs

Table 1. Equipment list in Case 1~3

	Case1	Case2	Case3
Fired-Heater	O	O	X
DME CO2 Absorber	O	X	X
Methanol Dehydration Reactor	X	O	O

The major difference of equipment costs is caused by fired heater as a reformer feed heater, DME CO_2 absorber as a CO_2 absorber in unreacted syngas recycle, and methanol dehydration reactor as an additional production of DME from byproduct methanol.

Fired-heater is the most expensive equipment but methanol dehydration reactor is the cheapest one. We can expect that Case3 can reduce about hundreds of thousands dollars of equipment cost against Case1.

3.2. Feedstock Costs

The difference of feedstock in each case is shown in Table2. Even if we only consider a natural gas feedstock, $948,000 per day can be reduced in Case3. The cost of natural gas assumed 2.0$/kg.

Table 2. Comparison of feedstock (Unit: metric ton per day)

	Case1	Case2	Case3
Natural Gas	3998	3524	3524
Oxygen	5665	4946	4946
Steam (High Pressure)	3510	3039	3162
Steam (Superheated)	1320	1193	-

3.3. Utility Costs

Table 3. Comparison of electric power requirement (Unit: kWh)

Section	Block	Case1	Case2	Case3
CO_2 Absorption and Recycle	C-2001	37087.9	34817.2	34817.2
	P-2001	3247.2	2803.0	2803.1
DME separation and purification	C-4001	1116.8	616.3	616.3
	P-4001	448.6	-	-
	P-4002	39.6	-	-
	P-4003	225.9	168.4	168.4
	P-4004	0.025	0.008	0.008
Total Costs ($/day)		50,599	46,086	46,086

Table 3 shows the electric power consumption of the whole process. Prefix ‘C’ means the compressor and ‘P’ means the pump. Case2 and Case3 consume the same electric

power which is decreased by 9% against Case 1. If the cost of electric power is 0.05 $/kWh, then the saving cost would be 4,513 $/day.

The steam requirement for reforming section is most remarkable change. This is caused by adopting methanol dehydration reactor(Case2) and deleting fired-heater from reforming section(Case3).

Table 4. Comparison of steam requirement in reforming section

Steam	Condition	Case1	Case2	Case3
SHP Steam	4.3 MPa @ 380℃	1320	1193	-
HP Steam	4.3 MPa @ Saturated vapor	3510	3039	-
HP Steam	4.3 MPa @ saturated liquid	-	-	3162

4. Conclusion

The process simulation of the commercial DME plant, which has the capacity of 3,000 metric ton per day, has been completed. The previous study on the design basis of demo plant only reflects the pilot scale plant data, but in this paper the improvement for scale-up of the commercial plant is achieved. Remarkable improvements are mainly reduction of capital costs and operating costs. This is due to adopting methanol dehydration reactor to convert the byproduct methanol to DME, removing the fired-heater as a reformer feed heater, and DME CO_2 absorber for recovery CO_2 in the syngas recycle flow. But this change of process could be influence the feasibility of operation or control. Therefore the verification of this suggestion should be performed by experiences of demo plant operation.

1. Abstract

Brazilian Pre-Salt oil reserves present associated natural gas (NG) exhibiting high concentrations of CO_2 which requires gas purification processes for compliance with specifications imposed by the local Regulatory Agency. Due to its recognized small footprint as compared to amine based absorption route, membrane equipment show considerable potential for offshore applications. Of particular interest is the use of contactors, which combines membrane permeation with facilitated transport via liquid absorption. Process design and optimization of such innovative alternative demand flexible models to predict equipment performance at a variety of process conditions. This work presents a mathematical tool for analyzing CO_2 separation with hollow-fiber membrane contactors, using aqueous solutions of ethanolamines. The model is applied to assess the technical feasibility of offshore CO_2 separation with membrane contactors.

The developed simulator is based on rigorous principles of thermodynamics, fluid mechanics, heat transfer and mass transport. Chemical absorption modeling is approached as a typical application of the well known Chemical Theory, which aims to model chemically and/or physically complex equilibrium systems via a set of chemical equilibrium processes involving real and fictitious species. Vapor-Liquid Equilibria of real species are superimposed on the multi-reaction chemical equilibria for formation of fictitious species – non-ionic and non-volatile complexes. A process flowsheet is simulated to assert technical feasibility of this technology to offshore installations.

Keywords: CO_2 Removal, Hollow-fiber Membrane, Ethanolamines, Natural Gas Conditioning

2. Introduction

Global warming effects associated to CO_2 emissions cause societal concerns and give rise to increasing demands for clean technologies to improve sustainability of the world economy through efficient and safe usage of raw materials, and decreased CO_2 emissions (Dovi *et al*, 2009). According to Rivera-Tinoco and Bouallou (2010), among the technologies proposed to reduce CO_2 emissions, the most relevant are

associated to CCS Technologies. Ebner and Ritter (2009) state that the CO_2 removal market is dominated by amine based absorption processes. However, the authors recognize that membrane technology offers competitive advantages such as not requiring separating agent nor involving phase changes (reduced regeneration costs), which is claimed to have positive cost impacts and small footprints compared to alternative processes. Nevertheless, they state that membranes for large-scale recovery of CO_2 from natural gas are a relatively recent development.

A more innovative alternative employs gas-liquid membrane contactors for CO_2 removal from natural gas, which offers the advantages of both membrane technology and absorption processes. This hybrid-type process combines membrane separation and chemical absorption (Keshavarz *et al.,* 2008a), where the solvent (CO_2 absorbing liquid) is responsible for the selectivity of the process (typical of absorption technology) while the membrane stands as a selective barrier between the gas and the liquid. Further advantages are listed by Zhang et al. (2006), such as independent liquid and gas flow rate manipulation, much larger gas-liquid interfaces and the flexibility to scale up or down.

Differently from traditional membrane separation processes, microporous membranes used in membrane contactors are not required to be selective. The liquid phase that flows in one side of the fiber absorbs gas components physically and chemically, enhancing mass transfer therefore reducing the demand for high process pressures (Keshvarz et al, 2008b). Keshavarz and co-workers (2008a) report that the advantages depend in gas-liquid systems, types of membranes employed and applied operating conditions. The design and optimization of this innovative process suffer from a relative unavailability of experimental data and reliable mathematical representation of the impact of operational variables on process performance.

To meet this need, the present work presents a model for CO_2 separation from natural gas in membrane contactors with aqueous blends of ethanolamines. Specifically, the model treats a hollow fiber contactor configuration, based on principles of thermodynamics, fluid mechanics, heat transfer and mass transport. The tool is further applied to a conceptual process to verify the feasibility to meet natural gas CO_2 specifications.

3. Model Description

The model treats the separation of CO_2 from a stream of natural gas employing aqueous solutions of ethanolamine. Figure 1a shows the transport of the diffusing component of interest (CO_2 rich natural gas) from the gas phase through the microporous membrane into the liquid phase (aqueous amine solution) in a gas-liquid membrane contactor. The liquid absorbent flows in the lumen of the membrane while the gas mixture flows countercurrently in the shell side, configured as a fluid envelope around the hollow fiber (Figure 1b). Interaction among fibers is neglected.

Considering that the CO_2 diffusivity in the gas phase is much higher than in the liquid phase, it is reasonable to assume the gas to exhibit plug flow regime, which implies that the gas velocity and concentration distributions in the radial direction can be ignored in the shell side (Zhang et al, 2006).

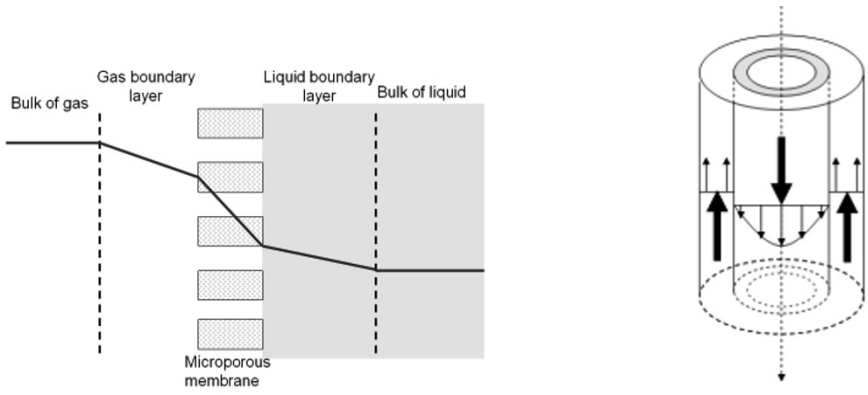

Figure 1 – Membrane Contactor. (a) mass transfer regions in membrane contactors for CO_2 absorption, (b) liquid and gas flows in a hollow fiber.

Peng-Robinson equation of state (PR EOS) has become the most popular EOS for natural gas systems (*e.g.,* Nagy and Shirkovskiy, 1982; Alfradique and Castier, 2007). The model applies rigorous thermodynamics with PR EOS to predict temperature changes associated with Joule-Thomson and dissolution effects, in a wide range of pressure, temperature and composition of multi-component gas feed stream. Chemical absorption of CO_2 in the liquid phase is represented by the *Chemical Theory* (*CT*, Prausnitz et al., 1986), which aims to model chemically and/or physically complex equilibrium systems via a set of equilibrium chemical reactions involving real and fictitious species (amine-CO_2 complexes). In the liquid compartment, multi-reactional chemical equilibria form complexes, as shown in Eqs. 1a through 1d, confined into the liquid phase, while vapor-liquid equilibria (VLE) of real species is applied.

$$CO_2 + H_2O + MEA \xleftrightarrow{K_1} CO_2 \cdot MEA \cdot H_2O \quad \text{(1-a)}$$

$$CO_2 + H_2O + MDEA \xleftrightarrow{K_2} CO_2 \cdot MDEA \cdot H_2O \quad \text{(1-b)}$$

$$H_2S + H_2O + MEA \xleftrightarrow{K_3} H_2S \cdot MEA \cdot H_2O \quad \text{(1-c)}$$

$$H_2S + H_2O + MDEA \xleftrightarrow{K_4} H_2S \cdot MDEA \cdot H_2O \quad \text{(1-d)}$$

Chemical equilibrium constants associated to the *CT* model (K_1 to K_4) were estimated via the Maximum Likelihood Criterion over VLE data of CO_2 with aqueous blends of ethanolamines (Barbosa *et al.,* 2011). The approach allows prediction of formation properties for the complexes, enthalpies and thermal effects. Barbosa *et al.* (2011) proposed an equilibrium approach for CO_2 absorption with aqueous solutions of ethanolamines using a large set of vapor-liquid CO_2/MEA/MDEA equilibrium data from the literature. The *CT* compartment was validated against the extensive databank (Barbosa *et al*, 2011) prior to application to the liquid phase of the contactor.

The *CT* model was added to the permeation model developed by Medeiros (2008), which describes the gas permeation process across a hollow-fiber membrane, with an outstanding performance when compared to the referred data bank. The combination of the two models – *CT* model and permeator model - allows investigating the performance of membrane contactors applied to CO_2 removal from natural gas. Figure 3 presents the scheme of the gas permeation module (Figure 3a) and contactors (Figure 3b). The developed contactor model is capable of describing CO_2 removal

processes using gas-liquid contactor with aqueous solutions of ethanolamines, at different process configurations.

4. Model Performance Evaluation

A process flowsheet - GN_CONTACT_1 - is used to illustrate the contactor simulator performance, shown in Figure 4, where MR1 and MR2 stand for Reacting Mixer and CGL is the gas-liquid contactor.

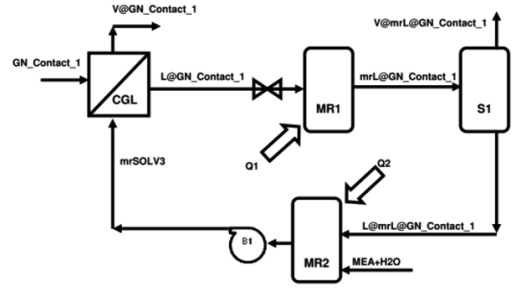

Figure 4 – CO_2 separation with Contactors

The feed stream GN_CONTACT_1 is Natural Gas with 10% of CO_2 to be purified with mrSOLV3, a stream containing an aqueous blend of MEA and MDEA. Table 1 shows a summary of stream inputs based in reported values by Formigli, 2008).

Table 1 - Summary of stream specifications and calculations for flowsheet GN_CONTACT_1

Stream V@ GN_CONTACT_1 shows that the natural gas (NG) leaving the contactor meets specification on CO_2 content. Simulation results illustrate additional outputs that could support process design and optimization. Furthermore, results of the model, within a solid phenomenological framework suggest feasibility of innovative membrane contactor processes in meeting specifications of CO_2 removal from NG.

5. Conclusions

This work presents a tool to simulate processes based on innovative membrane contactors for CO_2 removal from natural gas streams. A process flowsheet employing gas-liquid contactor fed with gas stream compatible with the scenario of the Pre-Salt Pole of the Santos Basin in Brazil is presented. Simulation results show technical feasibility of this technology to offshore installations. The computational tool can be used for experimental design of pilot units to provide data for model calibration, to allow subsequent process design and optimization.

A Comparative Economical Analysis of Technologies for CO_2 Removal from Offshore Natural Gas

Tatiana S. Gadelha[a], Aline R. S. Guimarães[a], Andressa Nakao[a], Ofélia de Q. F. Araújo[a], José Luiz de Medeiros[a]

[a]*Departament of Chemical Engineering, Escola de Química da Universidade Federal do Rio de Janeiro. Sala R-201, Bloco E, Centro de Tecnologia, Ilha doFundão, CEP: 21949-900, Rio de Janeiro, Brazil*

Abstract

In the scenario of the Brazilian Pre-Salt fields, where associated Natural Gas (NG) shows high concentration of CO_2, gas conditioning comes out as one of the main challenges. Among the possible capture technologies available, three alternatives stand out for CO_2 sequestration: (A) gas permeation through membranes, (B) absorption columns using aqueous blends of ethanolamines and (C) application of hybrid - membrane modules in series with amine absorption and regeneration columns.

The main objective of this work is to investigate the technical and economical feasibility of applying these three separation processes on offshore platforms, given the stringent constraints on footprint and equipment weight, and for minimizing NG production and transportation costs. The methodology involves: (i) development of cases based on the Brazilian Pre-Salt gas composition. NG streams with CO_2 molar concentrations ranging from 8 to 18% are applied; (ii) Simulations of three process flowsheets, corresponding to each one of chosen technologies - A, B and C; (iii) Equipment sizing; and (iv) Analysis of economic performance through calculation of capital (CAPEX) and operational (OPEX) costs.

Keywords: CO_2, Natural Gas, Absorption, Gas Permeation

1. Introduction

In the scenario of the Pole Pre-Salt of the Santos Basin (Brazil) it has been discovered a large reserve of Natural Gas (NG) containing an expressive content of CO_2 (range: 8 to 18% mol) (Formigli, 2008). This concentration must be reduced to minimize the emission of CO_2 and to meet the National Agency of Petroleum and Biofuel (ANP) standards of marketing of NG in Brazil.

Currently, the main technologies used in industry are membrane modules and absorption equipments employing aqueous solutions of ethanolamines. Absorption of CO_2 with weak alkaline solvents is a well established technology in the chemical industry. The basic principle is a reversible chemical reaction occurring in the liquid phase between a weak alkali and the solutes (CO_2). The reaction is first impelled to solute consumption (i.e. absorption) capturing it from the raw gas stream. In the second step, the reaction is reversed releasing the separated solutes (i.e. stripping) as a gas product stream. This process involves the continuous operation of two interlinked (packing or tray) columns. The first column – the absorber – contacts the gas stream with lean solvent at moderately high pressures and moderately low temperatures. The

rich solvent (in terms of CO_2) goes to a second column – the stripper – where at expenses of lower pressures, higher temperatures and contact with a stripping agent (e.g. steam), acid gases are liberated in the top vapor product, while the lean solvent is recovered as bottom product and returned to the absorber after some cooling and making-up (Barbosa, 2010).

For gas separation in offshore platforms, membranes offer comparative advantages over other technologies – e.g. absorption and adsorption - such as: (i) process is simple requiring no heating for change in either phase, (ii) units are compact, low weight; and (iii) the modularity of membrane makes the process a flexible technology (Baker et al, 2008). These characteristics make the technology in permeation membranes more appropriate to the capture of CO_2 in offshore pre-salt conditions. However, a main obstacle to the use of membranes is the outstanding scale of separation processes required in Pre-Salt oil and gas offshore platformes, where it is possible that membrane processes lose selectivity due to high flows transfer.

This work presents a comparative economical analysis applying three separation processes on offshore platforms: (A) gas permeation through membranes, (B) absorption columns using aqueous blends of ethanolamines and (C) application of hybrid - membrane modules in series with amine absorption and regeneration columns, shown in Figures I, II and III respectively.

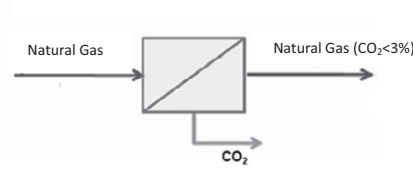

Figure I - Permeation system

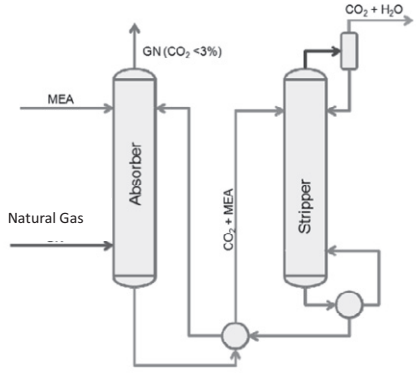

Figure II - Absorption Columns

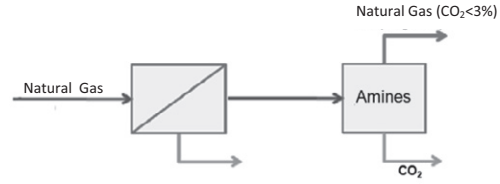

Figure III - Hybrid Process

2. Methodology

The methodology in this work deals with the following scenario:

- Development of three cases using NG streams with distinct CO_2 contents: Case 1: 8%; Case 2: 18%; and Case 3: 21%;
- Main goal of obtaining a NG stream with less than 3% of CO_2 (the standard of Brazilian Regulatory Agency);
- Operation flow is 50MMscfd;
- Three different technologies for CO_2 removal: Absorption using MEA; Membrane Permeation; and Hybrid process (Figure I, II and III);
- Processes simulations with a commercial simulator, employing a permeation module add-in developed by the Laboratory H2CIN, at Escola de Química, Universidade Federal do Rio de Janeiro, Brazil - The SPM2010 (Nakao, 2010);
- Equipment sizing.
- Calculation of Capital Expenditures (CAPEX) and Operational Expenditures (OPEX).

The economical analysis preformed is based on Turton *et al.* (2009), which was developed for chemical processes, therefore not including specifics features of the offshore environmental as modular equipments (skids), and restrictions of area and weight of these modules. However, it is emphasized that the goal of this work is the economical analysis and it is not the absolute quantification of the associated investments of each technology.

3. Results and Discussion

Compared to the absorption using amines, the hybrid process is a technology more flexible to different feeds conditions, as two different separation processes are employed.

For Cases 2 and 3, which have a process feed stream with higher CO_2 content, Baker and Lokhandwala (2008) recommend the hybrid process. In Case 1, with a feed stream with a lower concentration of CO_2, it is recommended the application of absorption column using amines. Because of this, hybrid process, in case 1, wasn't simulated.

These suggestions have been validated through the economical analysis of these three cases in this work, whose results are presented in Figure IV. The analysis shows that the flow rate and the CO_2 content have a direct influence in the technology selection for CO_2 removal.

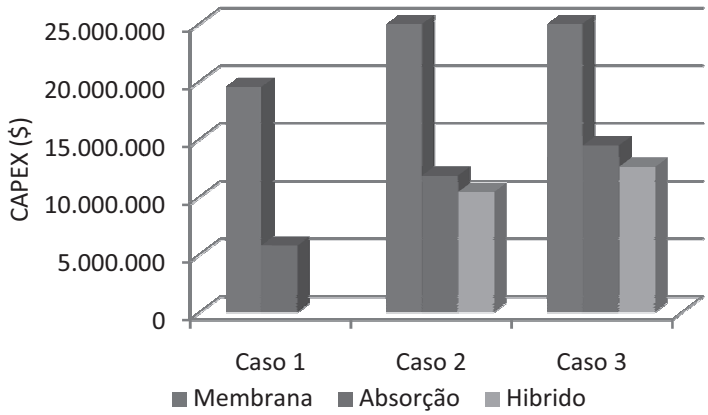

Figure IV - Capex results

Baker and Lokhandwala (2008) proposed a scheme, shown in Figure V, to guide the choice of CO_2 removal technology, based on the NG flow rate to be treated and the CO_2 content. In accordance to this scheme, this paper has conducted a preliminary economic analysis of these technologies for CO_2 removal.

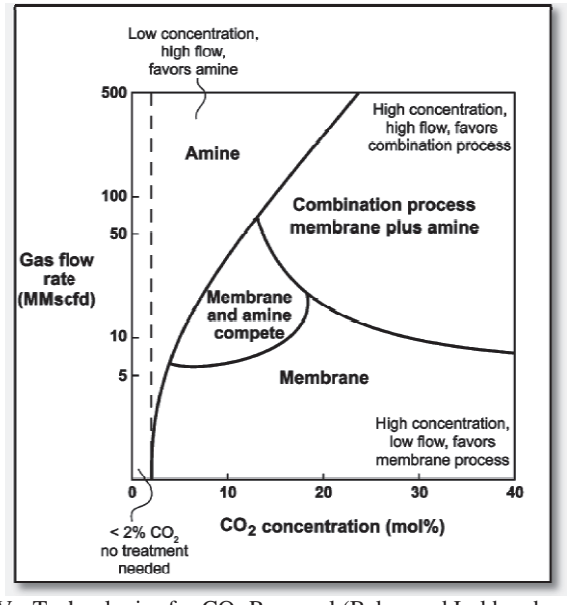

Figure V - Technologies for CO_2 Removal (Baker and Lokhandwala, 2008)

4. Conclusions

Absorption with amines showed the best results for streams with lower CO_2 content (Case 1), while hybrid process achieved better economical performance for NG streams with high concentrations (Case 2 and Case 3). These results arouse the interest in this process for the NG treatment, as proposed by Baker and Lokhandwala (2008).

Abstract

In order to efficiently convert microalgae into value added products, a sustainable integrated algal biorefinery is needed. Generally, conversion of microalgae into biofuel involves several processing steps: cultivation, harvesting, dewatering, drying, oil extraction, and biofuel production. One of the main challenges in designing and optimizing an integrated algal biorefinery is determining the configuration which meets the requirements for key outputs as well as environmental and resource limits. In this work, a systematic fuzzy linear programming (FLP) approach for design and optimization of an integrated algal biorefinery which considers water footprint, land footprint, and carbon footprint is presented. A hypothetical case study is presented to illustrate the proposed approach.

Keywords: Microalgae, biofuel, biorefinery, fuzzy optimization, and process design.

1. Introduction

One of the most promising systems to convert microalgae into value-add products is the integrated algal biorefinery (IAB). An IAB combines multiple conversion pathways of microalgae to generate a range of products, such as biofuels and biochemicals (Taylor, 2008; Subhadra, 2010; Subhadra and Edwards, 2011; Tay et al., 2011a;). Such multiple pathways provide opportunities for effective utilization of process residues, thus enhancing the overall efficiency and sustainability of the biorefinery (Tan et al., 2009). Given the growing global demand for biofuels, it is necessary to assess the design of an IAB through three main environmental performance metrics: water foot print, land foot print, and carbon footprint (De Benedetto and Klemeš, 2009; Tan et al., 2009; Čuček et al., 2012). This paper presents an optimization approach for synthesis of an IAB using a fuzzy linear programming (FLP) model which considers the three main environmental performance metrics simultaneously.

2. Fuzzy Linear Programming

Fuzzy mathematical programming is used in optimization problems wherein bands of partially acceptable ranges of different objective values are considered (Zimmermann, 1978). FLP models have been used to solve multi-objective optimization problems for bioenergy systems footprint (Tan et al., 2008, Tan et al., 2009, Tay et al., 2011b). Unlike the conventional approach of identifying the Pareto optimal curve, FLP has the advantage of giving a unique solution. In this particular study, FLP approach is adapted to optimize an IAB which solves conflict of multi-objectives.

The optimization objective is to maximize the level of satisfaction (λ) of the fuzzy footprint goals:

$$\text{maximize } \lambda \tag{1}$$

Subject to:

$$\mu_i = [(f_i(x) - f_i^u) / (f_i^l - f_i^u)] \geq \lambda,\ i = 1, 2, 3 \tag{2}$$

$$f_i(x) = \boldsymbol{c_i}^T \boldsymbol{y},\ i = 1, 2, 3 \tag{3}$$

$$\boldsymbol{Ax} = \boldsymbol{y} \tag{4}$$

$$\boldsymbol{y^l} \leq \boldsymbol{y} \leq \boldsymbol{y^u} \tag{5}$$

where μ_i = degree of satisfaction of footprint goal i, $f_i(x)$ = footprint functions, i = individual footprint (i.e., water footprint, $f_1(x)$; land footprint, $f_2(x)$; and carbon footprint, $f_3(x)$), Besides, f_i^u and f_i^l are the lower and upper limits of the individual footprint i. $\boldsymbol{c_1}^T$ = water footprint coefficient vector, $\boldsymbol{c_2}^T$ = land footprint coefficient vector, $\boldsymbol{c_3}^T$ = carbon footprint coefficient vector, $\boldsymbol{A}$ is the input-output matrix , $\boldsymbol{x}$ is the process scaling vector, $\boldsymbol{y}$ is the net output vector, $\boldsymbol{y^l}$ is the lower limit for fuzzy net output vector, $\boldsymbol{y^u}$ is the upper limit for fuzzy net output vector.

The variable λ provides control to the model objective constraints which are described by the water, land, and carbon footprint that corresponds to the max-min aggregation principle (Zimmermann, 1978). The max-min aggregation ensures the optimal value of λ is the least satisfied considering the objective constraint. A value of $\lambda = 0$ indicates a state of minimum satisfaction, while a value of $\lambda = 1$ signifies a state of complete satisfaction. Partially acceptable values of λ lie in the range $0 \leq \lambda \leq 1$ as defined by the linear membership functions (Eq. 2) (Zimmermann, 1978; Lai and Hwang, 1992). Often used in a life cycle assessment, a modeling framework is used in this study based on a linear input-output (Eq. 3) (Heijungs and Suh, 2002).

Note that, unlike in Tan et al. (2008) and Tan et al. (2009); all values of $\boldsymbol{y}$ within the given limits are considered equally satisfactory for an IAB as indicated by Eq. (5). The values of the net output vector $\boldsymbol{y}$, which represents the production level of each of the outputs of the IAB, are flexibly set given a lower and upper limit.

3. Case Study

An IAB which produces biodiesel as the main product and methanol, glycerol, electricity as well as steam as by-products is used as a case study. Due to space constraints, the case study has been simplified. As biodiesel is taken as the main product, the algal residues are then separated and reprocessed to produce the by-products.

Environmental Metrics

Table 1 shows the water, land, and carbon footprint coefficients for the case study.

Table 1. Environmental metrics for the case study.

Environmental Metrics	Values
Water Foortprint	78 kg per kWh eletricity; 12,775 kg per kg algal biomass
Land Footprint	1.98×10^{-5} ha-y/ kg algal biomass
Carbon Footprint	1 kg per kWh electricity; 0.17 kg per kg steam; 3.5 kg per kg natural gas

Integrated Algal Biorefinery

The IAB can be divided into the following sections: A – Oil Extraction (including the microalgae cultivation, harvesting, and dewatering processes); B – Transesterification; C – Combined Heat and Power (CHP); D – Steam Methane Reforming (SMR); E – Residue Separator (which separates the liquid residue from the solid residue); F – Anaerobic Digester; G – Gasifier; and H – Methanol Synthesis.

In this case study, integrated algal biorefinery system consists of cultivation, harvesting, dewatering, and oil extraction of microalgae in Process A. Processes A and B can be used to extract algal oil for transesterification process to produce biodiesel. Note that a by-product glycerol is also generated in Process B. To simplify the model, these two processes can be taken as a single process unit. Process E then separates the liquid and solid residue fraction from the total algal residue from Process A. The liquid residue fraction is then processed in anaerobic digester (Process E) to produce methane which is fed into the combined heat and power (Process C) to generate electricity and steam. On the other hand, the solid residue fraction is fed into the gasifier (Process G) to produce syngas. Process D which is steam methane reforming also recycles part of the methane produced from Process E to produce syngas. The syngas produced in both Process G and D is then fed to methanol synthesis (Process H). Meanwhile, Processes G, D, and H were also combined to represent as a single cluster in the input-output matrix producing methanol from solid residue fraction of the microalgae.

Table 2. Algal Biorefinery Input-Output Coefficient Matrix.

y's	Input-Output Matrix	A-B	E	F	C	G-D-H
y_1	Microalgae (kg)	-4	0	0	0	0
y_2	Electricity (MJ)	-171	-1	-2.37	15	0
y_3	Steam (kg)	-161	-0.5	0	12.5	-0.74
y_4	Total Residue (kg)	3	-3	0	0	0
y_5	Solid Residue Fraction (kg)	0	0.6	0	0	-1
y_6	Liquid Residue Fraction (kg)	0	2.4	-2.4	0	0
y_7	Biodiesel (kg)	1	0	0	0	0
y_8	Glycerol (kg)	0.1	0	0	0	0
y_9	Methane (kg)	0	0	1.08	-1	-0.76
y_{10}	Methanol (kg)	-0.1	0	0	0	1.25

Table 2 shows the input-output coefficients of matrix A as derived from various literature sources (Singh and Gu, 2010; Khoo et al., 2011; Razon and Tan, 2011; Subhadra and Edwards, 2011; Tay et al., 2011a). Each column represents material and energy balances for a given process or cluster as discussed previously.

In the column vector, the negative values indicate the process inputs while the positive values are process outputs. For example, Figure 1 shows Process F in column vector form. The numbers indicate that 2.4 kg of liquid residue and 2.37 MJ of electricity are needed to generate 1.08 kg of methane for Process F.

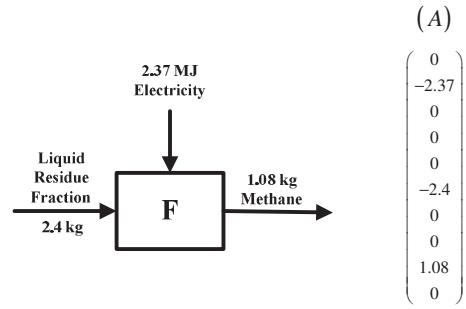

Figure 1. Example of column vector representation of a process.

4. Case Study Results and Discussion

Solving Eqn. (1) subject to Eqns. (2) – (5), the maximum λ is found as 0.95. Table 3 shows the optimized values for each desired outputs.

Table 3. Balanced process table for the optimal biorefinery configuration.

y's	Resulting Matrix	A-B	E	F	C	G-D-H	Net Outputs
y_1	Microalgae (kg/h)	-4,630	0	0	0	0	-4,630
y_2	Electricity (MJ/h)	-197,917	-1,157	-2,743	254,481	0	52,664
y_3	Steam (kg/h)	-186,343	-579	0	212,067	-514	24,632
y_4	Total Residue (kg/h)	3,472	-3,472	0	0	0	0
y_5	Solid Residue Fraction (kg/h)	0	694	0	0	-694	0
y_6	Liquid Residue Fraction (kg/h)	0	2,778	-2,778	0	0	0
y_7	Biodiesel (kg/h)	1,157	0	0	0	0	1,157
y_8	Glycerol (kg/h)	116	0	0	0	0	116
y_9	Methane (kg/h)	0	0	1,250	-16,965	-528	-16,243
y_{10}	Methanol (kg/h)	-116	0	0	0	868	752

As shown, it is noted that 4,630 kg/h of microalgae is used to produce 1,157 kg/h of biodiesel (via Processes A and B). On the other hand, the anaerobic digester (Process F) produces 1,250 kg/h of methane, which is then converted to electricity and steam in the combined heat and power system (Process C). Note that as the internally produced methane is insufficient to support the biorefinery, thus additional input of external methane (as natural gas) is needed. This external fossil-fuel supply adds to the IAB carbon footprint. Meanwhile, the resulting values of the water footprint, land footprint, and carbon footprint for the optimum case are 4.77×10^8 t/y, 792 ha-y, and 0 t/y; respectively. Note also that the resulting carbon footprint for the optimum case is 0 t/y since the negative carbon footprint from the export of electricity and steam offsets the carbon footprint required of the methane.

5. Conclusion

A fuzzy linear programming model has been developed to optimize the design of an integrated algal biorefinery. The model has been demonstrated for the case of an integrated algal biorefinery which produces biodiesel, glycerol, and methanol; as well as electricity and steam. Further work needs to be done in the future to include economic potential in the optimal design of IAB. Furthermore, fuzzy mixed integer linear programming approach with additional value-added products from microalgae such as bioethanol, biogas, and nutrient based-products are proposed for future studies.

Process Analysis Using *Umberto Carbon Footprint* Tool

Pedro Chainho[a], Henrique A. Matos[a]

[a]*CPQ, Department of Chemical Engineering, Instituto Superior Técnico, Av. Rovisco Pais, 1049-001, Lisboa, Portugal*

Abstract

The software Umberto Carbon Footprint calculates CO_2 footprint of products or activities. It is based on analysis of primary and secondary footprints during the product lifecycle. It uses the ecoinvent database to analyse individual contribution of the resources consumption required for the footprint of the final product.

Umberto Carbon Footprint was applied to two processes where the streams and resources were characterized using the process simulator Aspen Plus: A) production of cumene from benzene and B) production of acetone from IPA (Isopropyl alcohol). The analysis was carried out for each process at two different scenarios (with and without simplified energetic integration).The results show an improvement on the carbon footprint value for the scenarios with energetic integration and a good agreement with ecoinvent database values

Umberto Carbon Footprint was also applied at one Portuguese chemical company to a formaldehyde process (patent Perstorp Formox®). Real industrial data was used on the streams and resources characterization. The carbon footprint obtained for F-100 (maximum production system scenario) shows a relative deviation of 1.8% comparing to ecoinvent database value.

Keywords: Modeling, Carbon Footprint, Umberto software, Industrial Process.

1. Introduction

Carbon footprint is a relative measurement of the amount of CO_2 release on the environment during the life cycle of a product or activity. Normally it's calculated from the analyses of direct and indirect emissions of resources consumed on a certain process. All streams of the industrial process must be previously characterized by a process simulation or using the industrial data. This tool could help in the discussion of different operating conditions scenarios, such as raw material diversity, process integration degree, utilities type, among others.

Nowadays this issues is has become increasingly important, and big supermarkets chains in UK and USA were wondering about putting the CO_2 footprint on the products descriptions labels, granting to the consumer the option of a more responsible choice in terms of ecologic matter.

The methodologies for carbon footprint calculations are still growing and it is emerging as an important tool for sustainability analysis. The concept of carbon footprinting has permeated and is being commercialized in all the areas of life and economy, but there is little coherence in definitions and calculations of carbon footprints among the studies. Carbon footprint is intended to be a tool to guide the relevant emission cuts and verifications, its standardization at international level are therefore necessary. Pandey et al. (2011) made a review where they describe the prevailing carbon footprinting

methods and raise the related issues. Some studies are being made as calculation of the corporate carbon footprint of the cement industry by MC3 methodology by Cagiao, et al. (2011). Yuttitham, et al., (2011) determined the carbon footprint of sugar produced from sugarcane in eastern Thailand. Graphical representation of carbon footprint reduction for chemical processes was applied by Tjan et al. (2010).
In this paper the carbon footprint calculation and analysis of chemical products with the application of software Umberto for Carbon Footprint using simulation and real industrial data.

2. Process simulator approach

2.1. Cumene process
Cumene is produced from a reaction in gas phase between benzene and polypropylene, with a main reaction (1) and parasite one (2):

$$\text{Propylene} + \text{Benzene} \longrightarrow \text{Cumene} \quad (1)$$

$$\text{Propylene} + \text{Cumene} \rightarrow \text{P} - \text{diisopropil benzene} \quad (2)$$

It was considered a minimum annual production of 120 kton of cumene with a specification of 99% in molar purity without any kind of heat integration (Scenario 1).

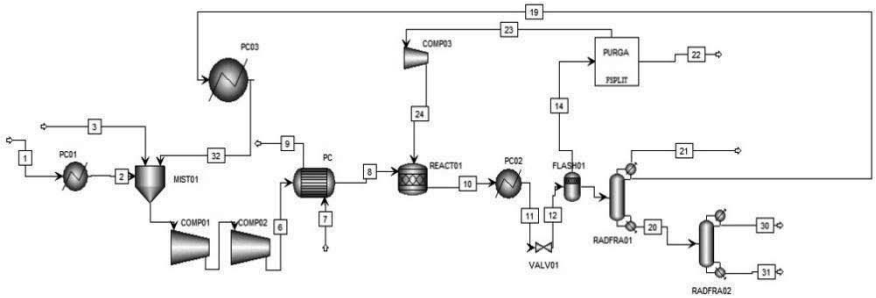

Figure 1: Cumene Process diagram in AspenPlus®. (Scenario 1)

An alternative diagram was tested with a simple energy integration of reactor effluent as hot fluid on exchanger named PC (Scenario 2).The hot utility used in Figure through stream 7 was removed.

Table 1: CO_2 Footprint and main contributions for the cumene process

Carbon Footprint (kg CO2 eq.)	
Scenario 1	Scenario 2
3.74	3.48

Contributions for the footprint			
Scenario 1		Scenario 2	
Benzene	65%	Benzene	70%
Propylene/ Propane	21%	Propylene/ Propane	22%
Others	14%	Others	8%

As expected it was noted an improvement of the CO_2 footprint of the process with simple energy integration that corresponds to a decreasing of 7% of the CO_2 footprint. The contribution of field "Others" (table 2) was smaller in the integrated process because this field includes the consumption of energetic resources that were reduced with the energetic integration.

2.2. Acetone process

The process of production of acetone from IPA contains a main reaction (3) and 2 other parasite ones (4) and (5).

$$\text{Isopropanol} \rightarrow \text{Acetone} + \text{Hydrogen} \quad (3)$$

$$\text{Isopropanol} \rightarrow \text{Propylene} + \text{water} \quad (4)$$

$$\text{Propylene} + \text{Hydrogen} \rightarrow \text{Propane} \quad (5)$$

It was considered a minimum annual production of 120 kton of acetone with a specification of 99% in molar purity (Scenario 1).

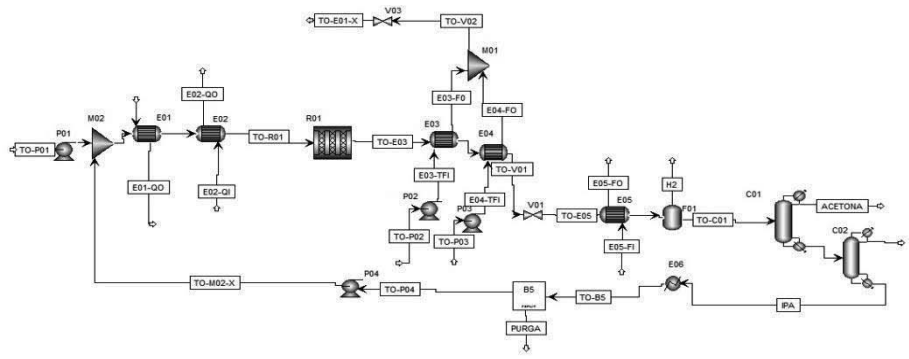

Figure 2: Acetone process diagram in AspenPlus®. (Scenario 1)

Also an alternative scenario was tested with simple energy integration. It was produced steam on the exchangers E03 and E04 and was recirculated to E01 (Scenario 2).

Table 2: CO_2 Footprint and main contributions for the acetone process

Carbon Footprint (kg CO_2 eq.)	
Scenario 1	Scenario 2
3.11	2.95

Contributions for the Footprint			
Scenario 1		Scenario 2	
IPA	77%	IPA	81%
Net steam	14%	Net steam	15%
Others	9%	Others	4%

The result is analogous of the previous process. It was verified a footprint decreasing of 5%.

3. Chemical Plant Data aproach

The carbon footprint calculation using the software Umberto for Carbon footprint is also applied to a real chemical plant data, instead of the previous approach where data was obtained by simulation with a process simulator.

This approach was applied to a process of production of formaldehyde type Perstorp Formox® of a Portuguese chemical industry. The formaldehyde production occurs on a fixed bed reactor through the partial oxidation of methanol.

The main reaction is strongly exothermic, and the heat of reaction is used to produce steam in exchanger E-2/1. The units E-18, E-22 and E-15/1 constitute the emission control system (ECS) which control the gas emissions to the atmosphere.

The equipment and streams before T-1 and T-2 are double and work in parallel, system-1 (S-1) and system-2 (S-2). The main product (F-50) is collected in T-2 and the Product F-30 on T-1.

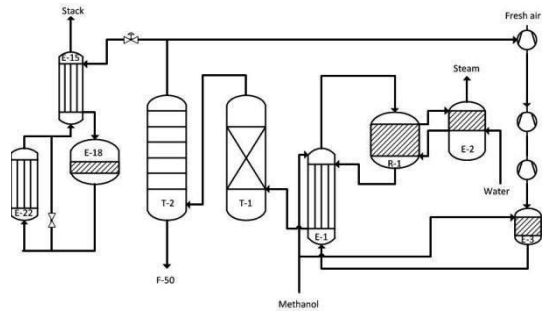

Figure 3: Simplified formaldehyde process diagram based on the Industrial site analysed.

Several production scenarios were tested:

- Scenario **3500-0**: Minimum production status, S-1 with a fresh methanol consumption of 3500 kg/h and S-2 stopped with only F-100.
- Scenario **0-4900** : S-2 with a fresh methanol consumption of 4900 kg/h and S-1 stopped;
- Scenario **3500-3500 :** S-1 with a fresh methanol consumption of 3500 kg/h and S-2 with a fresh methanol consumption of 3500 kg/h;
- Scenario **4900-4600:** S-1 with a fresh methanol consumption of 4900 kg/h and S-2 with a fresh methanol consumption of 4600 kg/h.

The scenarios with higher productions rates are the ones with smaller footprint. The carbon footprint is analysed by kg of product produced and is strongly dependent of the raw-materials utilization, and consequently in terms of process efficiency, so is expectable smaller footprints for those scenarios because they are the most efficient ones (also in observed in economical terms).

Table 3: CO_2 footprint of formaldehyde process – F100 and F-30

Methanol Consumption				
Scenario	S-1 (kg/h)	S-2 (kg/h)	CO_2 footprint (kg CO_2 eq.) F-100	CO_2 footprint (kg CO_2 eq.) F-30
3500-0	3500	0	1.11	-
0-4900	0	4900	1.22	9.91
3500-3500	3500	3500	1.07	13.45
4900-4600	4900	4600	1.09	16.49

It is predicted by ecoinvent 2.2 a carbon footprint for a formaldehyde process type Perstorp Formox® of 1.11 kg CO2 eq., for a maximum production system. Comparing this one with the value for scenario 4900-4600 is observed a relative deviation of 1.8%. The cause of deviation is explained by some differences in the calculation by ecoinvent and this one:

- Input values in ecoivent are from literature and project predicted values of several European production units.

- The ecoinvent footprint considers the contribution of final product transportation and in this project the formaldehyde was for own consumption.
- Ecoivent value uses input values from another process patent (silver catalysis) in addition to the patent Perstorp Formox®.
- Contribution of catalyst for the footprint is higher in ecoinvent because of a more regular replacement is used on the units analyzed.

Table 4: Individual contributions of Carbon footprint : F-100 and F-30

Contributions for the footprint								
Scenario	**3500-0**		**0-4900**		**3500-3500**		**4900-4600**	
	F-100	F-30	F-100	F-30	F-100	F-30	F-100	F-30
Methanol	73.3%	-	78.8%	78.9%	82.7%	83.2%	84.7%	84.5%
Electricity	3.5%	-	5.0%	4.3%	5.2%	4.2%	5.6%	6.0%
Chemical plant infrastructure	8.3%	-	6.1%	6.9%	5.2%	5.1%	3.4%	3.9%
Stack emissions	13.3%	-	9.1%	9.6%	6.9%	7.2%	5.1%	5.4%
Others	1.5%	-	1.1%	0.3%	0.1%	0.3%	1.2%	0.3%

Other causes of deviation lies on some approximations used in the footprint calculations as the assumption of CO_2 stack emissions similar for all scenarios tested and on the estimation of cooling water flows. In the future a deeper analysis will be done to overcome some practical difficulties encountered.

4. Conclusions

The Umberto for Carbon Footprint allows two different approaches for calculation of chemical processes footprints. With auxiliary data obtained for instance in a process simulator or plant data, the software becomes very easy and quick to use. The results obtained in this work show a good agreement with the ones from ecoinvent data base. In the future this contribution could be integrated with SustainPro® tool (Carvalho et al., 2008) to provide a more reliable sustainability analysis. It seems to be also an important tool to compare different process design scenarios.

Abstract

In this study, we analyze two design configurations for post-combustion carbon capture (PCC) namely inter-stage cooling and split flow. The results show that inter-stage cooling configuration has notable impact on improving PCC performance. It is found that, for a flue gas with 13.0 mol% of CO_2, and with objective of capturing 90% of CO_2 at purity of 98%, base case configuration imposes a 4.7GJ/ton-CO_2 reboiler duty. This energy burden decreases (about 34.8%) to 3.1 GJ/ton-CO_2 with single-stage cooling configuration. Two-stage-cooling configuration further improves the efficiency but only incrementally. Similarly, split flow design configuration shows considerable improvement in efficiency (3.8GJ/ton-CO_2 vs. 4.7GJ/ton-CO_2 for base case).

Keywords: Post-combustion carbon capture (PCC), inter-stage cooling, split flow.

1. Introduction

Solvent based PCC was evaluated by Metz et al. (2005) and described as the most mature technology for commercial scale industrial carbon capture from power plants' flue gas. The standard carbon capture process is illustrated in *Fig.1*. A stream of amine solution is continuously recycled between absorption and desorption units where the lean stream removes the CO_2 from the bulk flue gas in an absorber column and the rich stream is regenerated in the stripper column.

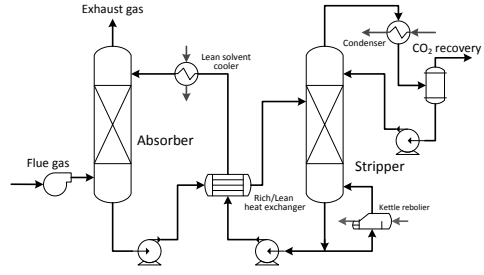

Fig.1: Schematic of standard post-combustion carbon capture process.

Despite recent progress in solvent-based PCC, the implementation of this technology still burdens a notable energy penalty mainly due to solvent regeneration. The energy penalty though varies by the type of power plant and by different techno-economic studies, is estimated to be above 20% (Khalilpour and Abbas 2011). This inevitably leads to a significant reduction in the power plant's load. The critical parameters influencing the efficiency are solvent type, solvent concentration, operating conditions

of absorption/desorption columns, percentage of CO_2 avoided, captured CO_2 purity and amount of regeneration. There are extensive research to study the impact of these parameters and their potential process improvements.

Configuration of absorption-desorption processes is also an important factor. In a conventional PCC scenario, gas enters at the bottom of the column and exists from the top. This traditional design does not exploit potential heat integration possibilities of the exothermic/endothermic absorption/desorption operation. Therefore, application of conventional simple column coupling configurations results in inefficient performances of both absorber and desorber. This leads to higher capital and operating costs. Recent studies see great potential for energy savings by introducing flow sheet innovations. Cousins et al. made an overview of several proposed configurations for PCC (Cousins et al. 2011). The purpose of this paper is to assess two improved flow schemes: Inter-stage cooling and split flow, validating their potential in relieving the energy penalty on a basis of 30wt% MonoEthanolAmine (MEA) being employed as the absorbent. Process flow diagrams of inter-stage cooling and split flow are presented in *Fig.2*. Aspen HYSYS V7.1 is used in this study.

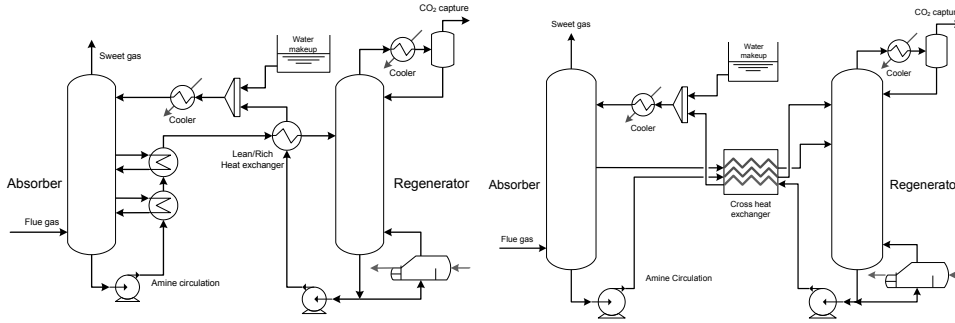

Fig. 2: Process flow diagram for (left) inter-stage cooling scheme, and (right) split flow scheme.

2. Process simulation

2.1. Fluid package

A reliable fluid package is the basis of simulation and its competency can be verified by comparing the predicted solubility of CO_2 with experimental data. Jou et al. (1995) experimentally measured the solubility of CO_2 in 30 wt% MEA solution by relating the CO_2 loading to its partial pressure. Case studies of CO_2 solubility were carried out using Amine pkg, Electrolyte NRTL respectively.

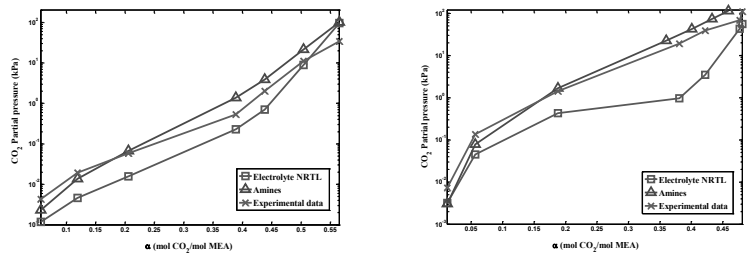

Fig.3: Validation of simulation fluid packages in terms of CO_2 solubility in 30 wt% MEA solution at (left) 60°C, and (right) 100°C.

2.2. Base case specification

The base case model was designated to achieve 90% of CO_2 removal and 98% purity of CO_2 captured. The critical operating conditions and equipment parameters are listed in *Table 1*. The composition of flue gas was set to be 12.99 mol%, after Khalilpour and Abbas (2011).

Table 1: Absorption/desorption column specifications.

Absorber		
Item	**Value**	**Reference**
Tray No.	10	
Tray Efficiency (%)	25	(Øi 2007)
Temperature (°C)	50	(Cousins, Wardhaugh et al. 2011)
Pressure (kPa)	101.3	
Stripper		
Item	**Value**	**Reference**
Tray No.	6	
Tray Efficiency (%)	50	(Øi 2007)
Reboiler pressure (kPa)	200	(Abu-Zahra, Schneiders et al. 2007)
Feed position	2	
Feed condition	Saturate liquid	

2.3. Inter-stage temperature control

The optimal temperature range for CO_2 absorption is 40-60°C since the reaction rate is highest within this range for 30 wt% MEA (Cousins et al. 2011). However the exothermic effect can raise this temperature beyond 70°C and away from the theoretical equilibrium limits, thus lowering the absorption capacity of MEA. Maintaining the temperature along the column within its optimal range could enhance the absorption performance. This idea can be realized by withdrawing a hot stream out of the column's top section (say at the third plate) and cooling it with the bottom product which is around 54°C. The cooled stream is then returned to a position below the withdrawal location (say at the fourth plate). This brings the bottom lean stream closer to the feed condition of the stripper. A temperature control strategy can further enhance the process by implementing multi-stages of cooling. In this simulation work, the side draw streams are extracted from the third and sixth trays separately and sent back to the fourth and seventh trays, respectively, after being cooled down.

2.4. Split flow

A split flow configuration provides a reduced flow to the lower section of the stripper where it can be recycled to a lower CO_2 content with the same energy input. The semi-lean solution extracted from the mid-section of the stripper removes the bulk CO_2 passing through the lower section of the absorber where partial pressure of CO_2 is sufficiently high to provide a large driving force. A side draw stream, the semi-rich amine, is extracted from the fifth plate of the absorber and sent to a cross heat exchanger where it is heated up by stripper bottom product as well as the lean amine stream from the bottom of the absorber. Then, the semi-rich amine is fed to the stripper at the fourth plate. The flow rate and the tray position where side stream is drawn from the absorber were determined by trial and error. The properties of concerned amine streams are tabulated below.

Table 2: Properties of the main process streams.

Stream properties in standard flow sheet				
	Flow rate	Temp. before HX	Temp. after HX	Loading
	tonne/hr	°C	°C	mole CO_2/mole MEA
Rich	5209	52.3	108	0.448
Lean	4980	121.3	165.5	0.241
Stream properties in split flow configuration				
	Flow rate	Temp. before HX	Temp. after HX	Loading
	tonne/hr	°C	°C	mole CO_2/mole MEA
Rich	3875	37.1	95	0.508
Semi-rich	1197	67.4	100	0.310
Lean	4843	120.7	73.6	0.252

3. Simulation Results

3.1. Temperature profile along the absorber

From *Fig.*4, it is observed that the inter-stage cooling configuration significantly levels the parabola-shaped temperature profile of the base case. It extends almost horizontally throughout the first four plates since the hot solution to be cooled down is withdrawn from the third plate. The process target is to achieve 90% of carbon capture and the ratio of amine solution to flue gas (L/G) in wt./wt. was set to be around 20. Similarly, but not as significant as inter-stage cooling, implementation of split flow also relieves the high temperature within the column (*Fig.*4).

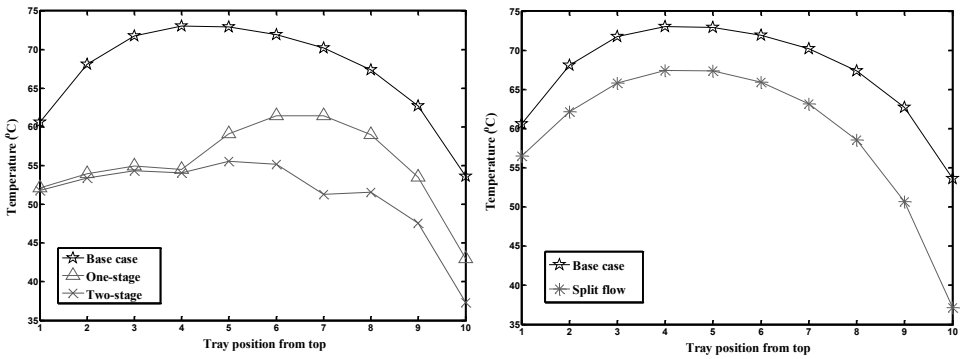

Fig.4: Temperature profile for (left) inter-stage cooling, and (right) split flow.

3.2. Improved performance in energy savings

Intensive reboiler energy consumptions in terms of GJ per tonne-CO_2-captured for base case and the new configurations were compared on a consistent basis. From Table 3, one-stage temperature control has effectively reduced the energy penalty for amine regeneration by 34.8% and split flow 18.5%.

Table 3: Reboiler duties for base case, inter-stage cooling and split flow configurations.

	L/G (tonne/tonne)	Carbon capture (%)	**Reboiler duty(GJ/tonne)**
Base Case	20.25	90.09	**4.696**
One-stage inter-cooling	20.27	90.04	**3.062**
Split Flow	20.27	90.07	**3.828**

*Fig.*4(left) shows that two-stage cooling allows a better temperature control where it has been kept below 55°C. The performances of one-stage and two-stage in terms of carbon capture with equivalent reboiler duty are compared in Table 4. With the implementation of multi-stage cooling, it yielded around 1% higher carbon capture rate with the same reboiler duty than that of single stage. These results agree well with the predicted temperature profile of *Fig.*4.

Table 4: Carbon capture rates of one-stage and two-stage inter-cooling.

	L/G (tonne/tonne)	Reboiler duty (GJ/tonne)	**Carbon capture (%)**
One-stage inter-cooling	20.25	3.008	**91.06**
Two-stage inter-cooling	20.24	3.015	**92.32**

4. Conclusion

Alternative process flowsheet models were simulated and analyzed for PCC operations. The performances with and without design changes were evaluated and analyzed on a consistent basis (90% of CO_2 removal and 98% purity of CO_2 captured). From the simulation results, we found great potential for reducing the energy consumption in PCC via the process design configurations of inter-stage cooling and split flow. Compared to the base case, both inter-stage cooling and split flow schemes successfully relieve the exothermic effect during the reaction process within the column and therefore enhance the absorption. One-stage cooling reduces the reboiler energy consumption by 34.8% while split flow reduces 18.5%. A two-stage cooling configuration was also simulated to study the performance of multistage cooling and showed 1% rise in carbon capture rate under equivalent energy consumption.

Effect of the microfiltration phase on pervaporation of ethanol produced from banana residues

Roger H. Bello, Ozair Souza, Noeli Sellin, Sandra H. W. Medeiros, Cintia Marangoni

University of Joinville Region (UNIVILLE) - Chemical Engineering Department, Rua Paulo Malschitzki 10 Zona Industrial, Joinville-SC 89219-710, Brazil;

Abstract

The objective of this paper is to investigate the use of microfiltration as a process of suspended solids separation in the pervaporation of bioethanol produced by banana culture residues. The composition of the fermentative broth influences on the separation, and the use of different substrates lead to a revaluation of the process, even if this is well established. Therefore, the ethanol pervaporation was studied by using polydimethylsiloxane membranes with binary mixtures (ethanol and water) as well as with fermentative broth. The fermentative broth pretreatment through microfiltration was compared to its centrifugation. It was possible to observe the reduction of the permeate flow rate, however the increasing in parameters such as the enrichment factor and the ethanol concentration in the permeate was also seen when the microfiltration was employed, comparing to the centrifugation as well as to the binary mixture.

Keywords: bioethanol, microfiltration, pervaporation, lignocellulosic residues.

1. Introduction

The need to amplify the offer of raw material for the production of ethanol without causing damage the planted areas for food, is the main factor of the development of researches using different residues for the ethanol production [1,2]. Several studies approach the use of agricultural or forest waste for the ethanol production [3]. Known as residual biomass, sugarcane bagasse and straw, or corn stover and fiber, wheat and rice straws, eucalyptus wood and residues of culture of fruits like bananas, grapes and apples are good examples. In the case of banana, although they are few, the applications are through the use of the fruits, leaves and other residues such as the stem [4].

Although the researches using banana residues show the viability of the fermentation process and consequent production of alcohol, it is important to emphasize that they are focused on the study of the hydrolysis [5] and a few of the others phases are evaluated, such as the ethanol recuperation. The use of distillation is a challenge due to its cost and the high energetic expenses [4,6]. In this context, the process of separation through pervaporation presents many advantages, because of the simplicity of its operation, use of low amounts of energy, low operational cost besides reducing the inhibition of ethanol on the fermentation [7].

Continuous fermentation processes with distillation through membranes have stood out due to the fact that they are, energetically speaking, more advantageous processes when compared to the traditional ones [8]. In this area, in the past few years pervaporation has became an alternative because of the possibility of being used coupled to the

fermentation [9,10]. However, the integrated process of fermentation and separation of the ethanol through pervaporation demands a phase of cell separation which is commonly carried out through microfiltration. There are many difficulties associated to this coupled design, related to low flows and selectivity because of the pore obstruction of the microfiltration membranes and to the swelling of the pervaporation membranes due to the presence of solids of the broth [11].
In addition, the composition of the fermentative broth influences on the separation and, the use of different substrates leads to the need of reevaluation of the process, even if it is already well established [12]. Therefore, a study of the separation of the bioethanol obtained from the residues of banana culture, employing pervaporation with commercial membranes of polydimethylsiloxane (PDMS) is proposed, aiming to evaluate the effect of the microfiltration phase as a process of separation of the solid material.

2. Materials and methods

In order to evaluate the proposal of this paper, preliminary experiments were conducted with an ethanol-water model binary mixture. This mixture was used as a pattern to analyze the results. Then, tests with the fermentative broth produced from the residues of banana pulp as a substrate were carried out. The amount of ethanol obtained in the broth was approximately 3% in mass. Two processes were compared for the cell and particulate material separation prior to the pervaporation: centrifugation and microfiltration.
The pervaporation process performance was expressed in terms of selectivity of the membrane (α) and mass flow of the permeate (J), according equations 1 and 2, where, W is the mass (g) of the permeate, A is the membrane´s effective area (m²) and, τ is the time interval (h) of the pervaporation process; y_i and y_j are the mass fractions of ethanol and water on the side of the permeate and x_i and x_j are the mass fractions of ethanol and water on the feed respectively.

$$\propto_{EtOH} = \frac{{}^{y_i}/_{y_j}}{{}^{x_i}/_{x_j}} \qquad \textit{Eq.}\ (1)$$

$$J = \frac{W}{A.\tau} \qquad \textit{Eq.}\ (2)$$

Another parameter used consisted of the enrichment factor - β_{EtOH} (Equation 3) which investigates the influence of other components on the ethanol enrichment in the permeate comparing to the feed. Yet, the index of separation through pervaporation – PSI (Equation 4) is determined by the properties of the membranes permeation and selectivity. $W_{EtOH,p}$ is the ethanol mass fraction in the permeate and $W_{EtOH,f}$ in the feed; J is the mass total flow (g/m².h) and, α the membrane´s selectivity.

$$\beta_{EtOH} = \frac{W_{EtOH,p}}{W_{EtOH,f}} \qquad \textit{Eq.}\ (3)$$

$$PSI = J.\alpha \qquad \textit{Eq.}\ (4)$$

2.1. Pervaporation

The pervaporation unit consists of a permeation removable module in PVC, with hollow membranes made of poly(dimethylsiloxane) - PDMS (PAM-PV S 0.01/PAM-Membranes), containing 50 capillaries with area of 0.04 m². The fermented broth or the model solution at approximately 22 ºC was fed with flow rates of 20 $L.h^{-1}$ from a 1 L reservoir, positioned upward the membrane, through a gear pump FE 611 (B. Braun). The vacuum pump DV 142N 250 (J/B Industries), on the permeate side, provided the pressure drop for the bioethanol vaporization (permeate pressure was lower than 5 mmHg). The vapor of permeate was collected into a reservoir refrigerated by cryogenic bath at -196 ºC, containing liquid nitrogen, for condensation. The simplified scheme of the pervaporation unity is shown in Figure 1.

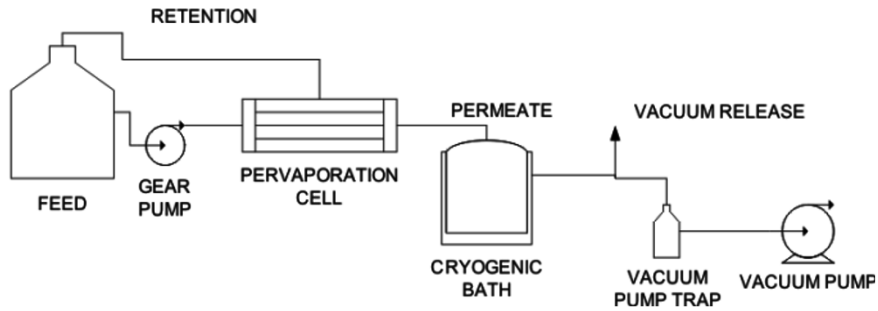

Figure 1 – Pervaporation process scheme.

The tests were carried out in duplicate, and the results presented consist on their averages. From each test, feed samples at the beginning and at the end of each experiment were taken, as well as the permeate in order to quantify the ethanol concentrations in gaseous chromatograph (GC).

2.2. Microfiltration

In natura fermented broth at environment temperature was fed from a 1 L reservoir, positioned before the membrane, by a gear pump FE 611 (B. Braun) at 90 $L.h^{-1}$. The concentrated returned to the feed in the whole microfiltration process. The microfiltration module is also made of PVC (membranes PAM) and has poly(imide) hollow membranes, with a 0.08 m^2 membrane area.

3. Results and discussion

The results obtained for the pervaporation of the ethanol and water binary model mixture are shown in Table 1. In Figure 2 the results of the flow parameters, enrichment factor and ethanol mass concentration in the permeate when centrifugation and microfiltration were used as a pretreatment are presented.

When analyzing the permeate flow, it is possible to observe that the experiments carried out with the centrifuged broth produced better results, even when they were compared to the model mixture. Those superior values can be attributed to the influence in the presence of fermentation subproducts and/or the presence of cells. In microfiltration, suspended particles may settle on the membrane surface, thus blocking feed channels and increasing friction losses (pressure drop) across the system. The result is a lower flux.

Table 1. Results of the efficiency of the separation of the ethanol and water mixture in pervaporation module with PDMS membrane

Parameter	Value
Mass Flow ($g.m^{-2}.h^{-1}$)	3.57
Selectivity (α)	8.31
Enrichment Factor (β)	7.56
PSI	29.71
Permeate Ethanol Mass Fraction % (wt/wt)	10.24

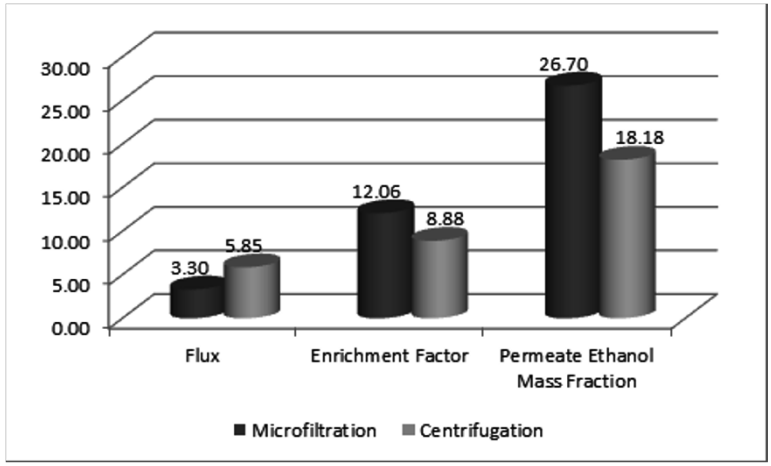

Figure 2. Comparison of the pervaporation results when the microfiltration and centrifugation processes were used as pretreatment.

On the other hand, it is possible to observe that better results for the enrichment and concentration factor of permeate were obtained when the microfiltration as pretreatments in the fermented broth cell separation was used. It was also possible to observe a 26.4% increase for the enrichment factor and 32% for the permeate ethanol mass concentration, which shows a higher potentiality in this treatment related to centrifugation. In fact, some authors [11] observed that the most used separation method for the cell segregation to be used as feed in the pervaporation process is the microfiltration, because centrifugation is widely used in liquid-solid separations at industries that produce ethanol and use distillation to recover this component.

4. Conclusions

The use of the microfiltration process coupled to the pervaporation in order to recover bioethanol from the fermentative broth produced from the lignocellulosic residues used in the banana cultivation showed itself as a very attractive alternative. The pretreatment of the fermentative broth through microfiltration presented a higher potentiality related to the centrifugation in the remaining solids separation step as well as for retaining some subproducts originated from the alcohol fermentation that influence on the pervaporation process.

Virtual and Augmented Reality as Viable Tools to Train Industrial Operators

Davide Manca, Roberto Totaro, Salman Nazir, Sara Brambilla, Simone Colombo

Dipartimento di Chimica, Materiali e Ingegneria Chimica "Giulio Natta", Politecnico di Milano, Piazza Leonardo da Vinci 32, 20133 Milano, Italy

Abstract

The sensitivity and significance of operator training increased profoundly with the increase in automation of industrial plants. The paper proposes and discusses the use of Virtual Reality and Augmented Virtual Reality to train industrial operators. A detailed and immersive 3D model of the plant allows the operators understanding the details of equipment and operating conditions. Both the dynamic behavior and the control strategies of the process can be reproduced with a 3D immersive virtual environment by implementing and coupling a dynamic process simulator and a dynamic real-time accident simulator. The AVR feature enhances the VR by adding further information and analysis that result in better understanding of operators that work either in control room or in the field. The proposed training methodology allows achieving significant improvements in reliability, cost effectiveness, environmental friendliness, and process safety.

Keywords: Virtual Reality; Augmented Virtual Reality; Operator training; Dynamic process simulation; Accident simulation.

1. Introduction

The increase in complexity, technological improvement, automation, and environmental and safety constrains in the process industry, are tightly interconnected to the following demanding features:

- Retrofitting and revamping of chemical processes;
- Operators retiring and lack of viable tools to preserve their expertise, skill, experience, and knowledge without dispersing the know-how;
- Training of new operators that do not have any experience of the process since they come from different jobs and therefore are practically unaware of the specific plant features;
- Meeting quality, safety, and environmental requirements, which are difficult to achieve and preserve dynamically;
- Optimization of plant productivity, with respect to both law and process constraints.

Operator Training Simulators (OTSs) can play a major role in addressing these challenges and allowing companies to remain competitive and updated in terms of workforce. OTSs comprise both hardware devices and software tools that allow simulating the dynamic evolution of the plant and therefore allow training the operators before going on-line in the real plant. Conventional OTSs are mainly focused on replicating the control room environment by means of a mock-up of the Distributed Control System (DCS). Consequently, such OTSs (see also Figure 1) allow training

control-room operators (CROPs) whilst field operators (FOPs) are rather neglected and not looked after satisfactorily.

Figure 1: A conventional session of Operators Training.

According to the Authors, current OTSs can be expanded into three main directions:

1. Extend and improve the participation of FOPs. This allows increasing the knowledge of the field and allows facing unexpected process conditions in the shortest time while preserving the operators' safety.
2. Simulate accident events and their consequence and interaction with the plant equipment. This feature allows increasing the operator responsiveness and effectiveness (of both FOPs and CROPs) when facing real accidents.
3. Use OTSs for both business decisions and plant management to improve process performance and enhance overall safety.

These open issues are quite challenging not only in terms of single pieces of software but also in terms of effective tools to improve the skill and understanding degree of both FOPs and CROPs. Actually, one of the main objectives of modern OTSs is improving the situation awareness of operators and assessing quantitatively the training level (Endsley and Garland, 2000).

2. OTS extension to FOPs through virtual reality

The field operator section in conventional OTS is either absent or relegated to an approximated and simplified adaptation respect to the core module of the control room. Consequently, the training of FOPs, in most cases, is done on the job, *i.e.* in the real plant where the novice FOP is trained by a more experienced colleague. However, this procedure appears to be limiting, since the novice is trained to operate usually under normal operating conditions. Most of the transients (*e.g.*, startups, shutdowns, and grade changes), abnormal conditions, alarms, failures, and accidents are not easily replicable in a real plant. Actually, these scenarios are quite rare and it may happen that working in real conditions a field operator does not attend or take part to any of previous events for years.

The training of FOPs by means of a specifically designed and properly developed OTS represents a promising, and challenging solution to the aforementioned problems. However, such a feature requires the development of dedicated tools, whose function consists in building and improving the knowledge, concerning not only the process principles, but also the plant and equipment characteristics, as well as their position in the field and the interaction with the sub-assemblies, devices, valves, switches that complete the physical structure of the plant. As far as the FOP's training is concerned,

learning the plant structure means knowing not only the signs and symbols, but also the location of the equipment and devices, together with the operating procedures to run the plant under normal conditions as well as startups, shutdown, transients.
FOPs work in a complex reality where the main senses, especially sight and hearing, are called to capture every single operating detail. FOPs are able to decide and set the appropriate actions by projecting the expected results based on their choices.
In order to achieve this goal, it is recommended creating an environment based on a virtual plant, which is virtually identical to the real one. In this environment, the operator can be trained adequately without any risks for his/her safety and that of his/her colleagues. This allows avoiding any risks of economic losses and any impacts on buildings, population, and environment in case of errors done during the training session.
In order to build such a virtual environment, VE, the following features are recommended if not mandatory:

- Each process unit and device must be reproduced in the VE by using appropriate 3D editors to reconstruct its exact geometry and location. The required 3D data can be retrieved from either plant CAD drawings or laser scans of the real plant.
- A detailed photographic recognition on the plant is necessary, to achieve an accurate reconstruction of the details of the equipment in terms of external skin and usage degree. By accomplishing this step, the operator can recognize the plant as perfectly realistic. Through this measure, the gap between physical reality and the virtual one can be reduced and even dissolved.
- The operator should recognize the plant not only through the sense of sight but also of hearing. Therefore, it is advisable to implement a spatialized audio system that reproduces the surround sounds of the real plant. Using appropriate audio systems allows the operator identifying the proper source distance and the noise power.
- To increase the participation of the FOP to the VE it is possible to surround the FOP with the plant by exploiting the concept of stereoscopy, thereby, creating an immersive environment. Appropriate 3D glasses for stereoscopic vision allow the trainee to live the perception of being immersed in what s/he is observing. Using large screens allows increasing the immersivity and the sense of participation of the FOP to the training session.
- In order to increase the usability and the realism of the solution, some simple and intuitive interaction devices must be used to recognize the movements and actions done by the FOP within the chemical plant (*e.g.*, walking, looking around, climbing a vertical ladder, opening a valve, selecting and pressing a button). These devices (also known as natural interfaces) are connected to the 3D graphics engine, and present the advantage of not altering significantly the interaction between the FOP and the plant.

These recommended features of a VE represent a necessary but not sufficient condition for the training of industrial operators. Actually, the ultimate goal of a training tool is to transfer the operator a deep knowledge and understanding of the chemical process, not just to drive him/her inside an environment that is similar to the real one. To bring the OTS to a higher level of realism, the VR solution must be connected to a simulation tool capable of reproducing the dynamics of the plant. Both process and accident features should complement the simulation tool so to be able to reproduce either normal or abnormal/accident conditions. By coupling a dynamic accident simulator to a dynamic process simulator, it is possible to simulate the causes, evolution, and consequences of an accident on the equipment, the FOPs, and the environment (see also Figure 2).

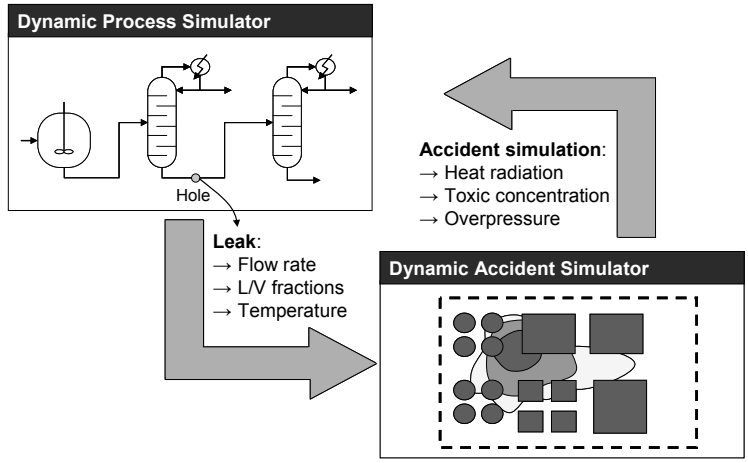

Figure 2: Two-way interaction between dynamic process and dynamic accident simulators.

3. Accident events simulation in OTS

To increase the situation awareness of operators respect to possible accident events, it is advisable to couple a dynamic process simulator to a real-time dynamic accident simulator (Brambilla and Manca, 2009). This two-way interaction was effectively implemented in an OTS for training of both CROPs and FOPs (Brambilla and Manca, 2011). The accident simulator can assess, as a function of the process variables evaluated by the process simulator, the event dynamics, which has some feedback effects on both the plant response and the FOPs' actions. The accident simulator can manage a wide range of accident scenarios, using literature models whose computation time is lower than the wall-clock time. The two-way dynamic interaction between the process and the accident simulators is carried out by considering the output variables of the process simulator (*e.g.*, flowrate) as input variables for the accident simulator, and *viceversa* (*e.g.*, the heat flux emitted by a pool fire that radiates to the surrounding equipment). In order to increase the situation awareness of FOPs about accidents, it is useful to provide the trainee(s) with some pieces of information that otherwise could not be easily visualized and understood. These details and variables fall under the realm of Augmented Virtual Reality (AVR).

4. Augmented Virtual Reality

In order to increase the operators' understanding of the process and also the effects and consequences of possible industrial accidents it can be of real help to show some additional bits of information during the training session. These bits of information are usually unavailable in real conditions but can augment the virtual reality scene by showing precious values that otherwise could not be quantified. This concept can be summarized by the AVR acronym that stands for Augmented Virtual Reality.

All the process and accident data evaluated by the corresponding dynamic simulators can be shown (according to the trainer decision) to the trainee so to increase the depth of understanding and supply statistics and records that otherwise would remain unknown. For instance, the AVR feature allows displaying the process variables that characterize the plant equipment (*e.g.*, temperatures, pressures, compositions, flowrates). The AVR feature allows also presenting the data related to the simulated accident (*e.g.*, pool diameter, jet length, cloud concentration, radiative flux, fire length, flame tilt, thermal

load, inhaled dose). These data can be shown by means of dynamically changing values, diagrams, schematics of the equipment (as shown in Figure 3). The combination of VR and AVR within the 3D VE is appealing and promising. For the sake of example, the proposed enhanced OTS (also named Plant Simulator, PS) can reproduce a process malfunction that may lead to a severe accident. Such accident event may imply the release of a liquid jet that forms a pool that spreads on the ground and that may either evaporate or be ignited with a subsequent pool fire. The PS allows displaying not only the physical features such as the liquid jet, the pool, and the fire (that are shown in the VR environment) but also the additional variables of AVR such as the radiative heat flux, the thermal load, and the consequences on the exposed FOP(s) in terms of time to reach the I, II, and III degree burns and eventually the death (Figure 3).

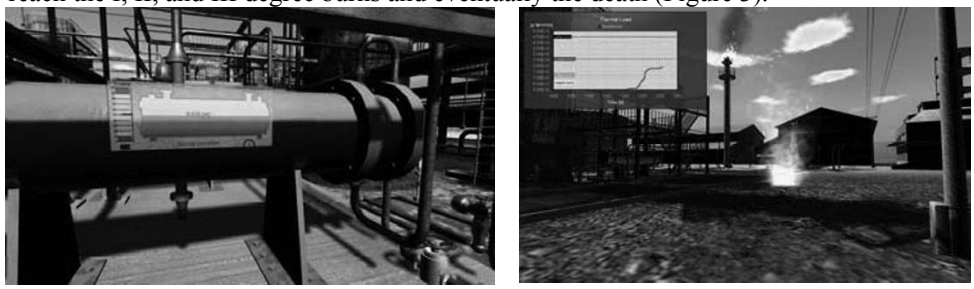

Figure 3: Two examples of AVR showing variables from the process simulator (left, reboiler level and corresponding alarms) and from the accident simulator (right, thermal load with I, II, and III degree burns).

While VR replaces the real plant, AVR is added to VR and represents a valid tool for training and increasing the conscience of operators which also refers to situation awareness. It is worth underlining that during assessment procedure, in order to make the training session consistent with what is available in the reality, the AVR tool is removed.

6. Conclusions

The challenging task of modern industrial OTSs was presented and discussed. Both VR and AVR were proposed as practical tools to improve the training level of operators and increase their situation awareness. The positive effects of an enhanced OTS and specifically of a PS consist in experimenting rather rare events such as startups, shutdowns, process transients, alarms, abnormal situations, and possible accidents. These features allow reducing the impact of human errors and human factors when running a plant by increasing the process understanding and conscience of both CROPs and FOPs.

Abstract

The use of incident information in GMP-regulated manufacturing environments has been impeded by the lack of an effective approach to extract information. Case-based reasoning provides opportunities to extract incident information by considering an incident and its resolution as a case. Case-based reasoning relies on good similarity measures which have largely been proposed for numerical similarities. However, little has been reported for semantic similarities that can be used in case-based reasoning systems that represent part of its information using ontologies. This paper investigates semantic similarity measures based on the comparison of classes in a taxonomy by using attribute information obtained with formal concept analysis.

Keywords: semantic similarity, case-based reasoning, GMP, ontologies

1. Introduction

Good Manufacturing Practice (GMP) regulations apply to pharmaceutical, medical device, and food manufacturers to ensure that their products are processed reliably, repeatedly, consistently, safely and to a high quality. Current GMP regulations (CGMPs) require manufacturers to investigate near-misses, and other incidents that have an impact on the product quality and safety. GMP requires the result of an incident-investigation to be reported with data about the incident, including the materials and equipment involved in the incident (e.g. process lines, products, batches and raw materials), possible or actual consequences, possible causes, products made prior to and during the event and corrective or preventive actions. However, as incident reports are stored in text-form, it becomes difficult to extract information that can be used to avoid similar incidents while improving product quality and productivity.

One approach to extract information is to use case-based reasoning (CBR) in which problems are solved "by using or adapting solutions to old problems". In CBR, a case is both a representation of the problem and a solution to that problem. In this paper, a case is made up with information contained in an incident report. Incident reports are stored in a case base where incident information follows a predefined structure based on domain ontologies. When a new problem arises (for example when new incident occurs), the information that is available about this target incident is entered to retrieve similar cases from which the best matching case is selected.

Case-based reasoning uses similarity measures to identify cases which are more relevant to the problem to be solved. Approaches such as the Euclidian distance are used to evaluate the similarity of numerical attributes. Traditionally, syntax-based approaches such as the Levenshtein distance are used to calculate the similarity between

character strings. However, syntax-based similarity measures often fail to produce good matches when confronted with the meaning associated to the words they compare. For example, although pump and compressor are objects that are semantically close, a low degree of similarity is obtained.

Class hierarchies can be used in similarity measures that are based on semantics as a way to overcome the limitations of syntactic similarity measures. Thus, the similarity between two objects is based on the comparison between the classes to which the object belongs.

Unfortunately, lacking systematic approaches for their design, class hierarchies are often developed in an ad-hoc manner. Consequently, the resulting taxonomies lack the justification of the decisions that led to their creation.

To remediate this problem, we employ Formal Concept Analysis (FCA) during the taxonomy development. FCA is an analysis technique for knowledge processing based on applied lattice and order theory. FCA works by processing a collection of objects and their properties to identify hidden relationships.

2. Semantic similarity

Semantic similarity is the similarity between two classes of objects in a taxonomy (Lin, 1998). A class C_1 in the taxonomy is considered to be a subclass of C_2 if all the members of C_1 are also members of C_2. Therefore, the similarity between two classes is based on how closely they are related in the taxonomy. Wu and Palmer (1994) proposed the following similarity measure based on use of subclass links between classes:

$$\mathrm{sim}(C_1, C_2) = \frac{2N_3}{N_1 + N_2 + 2N_3} \tag{1}$$

where N_1 and N_2 are the number of subclass edges from C_1 and C_2 to their closest common superclass; N_3 is the number of subclass edges from the closest common superclass of C_1 and C_2 to the root class in the taxonomy. Note that the measure of Wu and Palmer fails when the closest common ancestor of both classes happens to be the root class.

3. Proposed approach

Based on the concept of ontology (Sowa, 2000), a class is considered to be equivalent to another class if both classes have exactly the same attributes. Similarly, for a given class *C*, all attributes of *C* are also attributes of any subclass of *C*. Therefore, similarity measures can be developed based on the number of common attributes that are shared between two classes.

However, for any taxonomy-based similarity, the correctness of a given similarity between two classes depends on the structural correctness of the taxonomy. This statement equally applies to ontologies, in which the taxonomy is a fundamental part. Here we propose the use of Formal Concept Analysis (FCA) as a way of designing the ontology as it is based on attribute information.

Equations (2)-(6) represent some attribute-based similarity measures. These equations were obtained by combining the equations given by van der Weken *et al.* (2004) but replacing fuzzy sets with attribute sets.

$$\mathrm{sim}_{Union}(C_1, C_2) = \frac{|A_1 \cap A_2|}{|A_1| + |A_2|} \tag{2}$$

$$\mathrm{sim}_{Max}(C_1, C_2) = w_1 \frac{|A_1 \cap A_2|}{|A_1| + |A_2|} + w_2 \frac{|A_1 \cap A_2|}{\max(|A_1|, |A_2|)} \quad (3)$$

$$\mathrm{sim}_{CMax}(C_1, C_2) = w_1 \frac{|A_1 \cap A_2|}{|A_1| + |A_2|} + w_2 \frac{|A_1' \cap A_2'|}{\max(|A_1'|, |A_2'|)} \quad (4)$$

$$\mathrm{sim}_{Min}(C_1, C_2) = w_1 \frac{|A_1 \cap A_2|}{|A_1| + |A_2|} + w_2 \frac{|A_1 \cap A_2|}{\min(|A_1|, |A_2|)} \quad (5)$$

$$\mathrm{sim}_{CMin}(C_1, C_2) = w_1 \frac{|A_1 \cap A_2|}{|A_1| + |A_2|} + w_2 \frac{|A_1' \cap A_2'|}{\min(|A_1'|, |A_2'|)} \quad (6)$$

where A_1 and A_2 are the sets of attributes of classes C_1 and C_2, $|A_1 \cap A_2|$ is the total number of attributes shared by C_1 and C_2, $|A_1|$ and $|A_2|$ represent the number of attributes of C_1 and C_2, A_1' and A_2' are the complements of sets A_1 and A_2 respectively. w_1, and w_2 are weights.

4. Case Study

The case study focuses on comparing the similarity measures presented in the previous section for equipment used in therapeutic protein processes.

4.1. Taxonomy construction

The equipment-class taxonomy was developed using FCA. The attributes in the context table were selected based on: (1) the behavioral characteristics of each device, (2) type of components in the device, (3) materials used or transformed by the device. ConExp (2009) was used to generate the concept lattice which is shown in Fig. 1. After analyzing and correcting the lattice, the resulting lattice and attribute information were converted to OWL format and then used in the similarity calculations. The nodes labeled with *A*, *B*, *C* and *D* represent classes obtained by the FCA analysis, which are identified by their attributes. For example, *B* represents a class of devices that contain semi-permeable membranes.

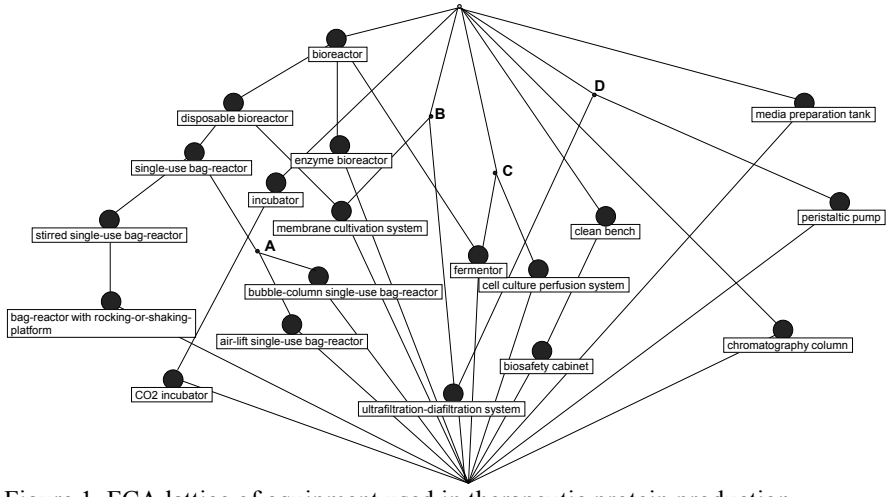

Figure 1. FCA lattice of equipment used in therapeutic protein production

4.2. Similarity calculation

A program was developed in Java to calculate similarities using the proposed approach. The program reads the OWL file and calculates the similarity between classes using equations (4) to (8). Calculations were carried out for several values of w_1, and w_2. Specifically, we focused on the similarity between *enzyme bioreactor* with the rest of the equipment classes.

Table 1. Semantic similarity measures and their correlation against human judgment

membrane cultivation system	0.50	0.57	0.50	0.40	0.93	0.67	0.97
peristaltic pump	0.06	0.33	0.22	0.17	0.88	0.33	0.95
single use bag reactor	0.83	0.33	0.80	0.67	0.98	1.00	1.00
stirred single use bag reactor	0.78	0.29	0.57	0.50	0.95	0.67	0.98
ultrafiltration diafiltration system	0.33	0.22	0.17	0.88	0.33	0.95	0.22
Correlation with human judgment	1.000	0.57	0.79	0.76	0.59	0.81	0.77

In the analysis of the results, we utilized the method proposed by Lin (1998) who compares semantic similarity measures by correlating their similarity scores with assessments made by human subjects. For this purpose, we relied on the evaluation that was carried out by a plant engineer who is knowledgeable about the use and characteristics of all the devices considered in this case study.

The results are shown in Table 1. The calculated similarities are also compared against the similarity of Wu and Palmer. Equation (5) yielded the highest correlation with a correlation coefficient of $r = 0.81$ ($w_1 = 0$, $w_2 = 1$). Using traditional statistics, it was found that the similarities against *cell culture perfusion system*, *CO_2 incubator*, *fermentor*, and *stirred single use bag reactor* performed poorly in all similarity measures, possibly due to missing attributes in the FCA analysis. This observation was also corroborated with hierarchical clustering which was carried out on both the results obtained with equation (5) and the reference data (Figure 2). The comparison of the results of the clustering analysis shows that the same four similarities are clustered differently. For example, with the propose similarity measure the similarity between *enzyme bioreactor* and *fermentor* is put closer with the similarity of the pair *enzyme bioreactor – air lift single use bag reactor* while the human expert perceives it as being closer to the similarity of the pair *enzyme bioreactor – disposable bioreactor*. After omitting these points a much higher correlation coefficient $r = 0.95$ ($w_1 = 0$, $w_2 = 1$) is obtained.

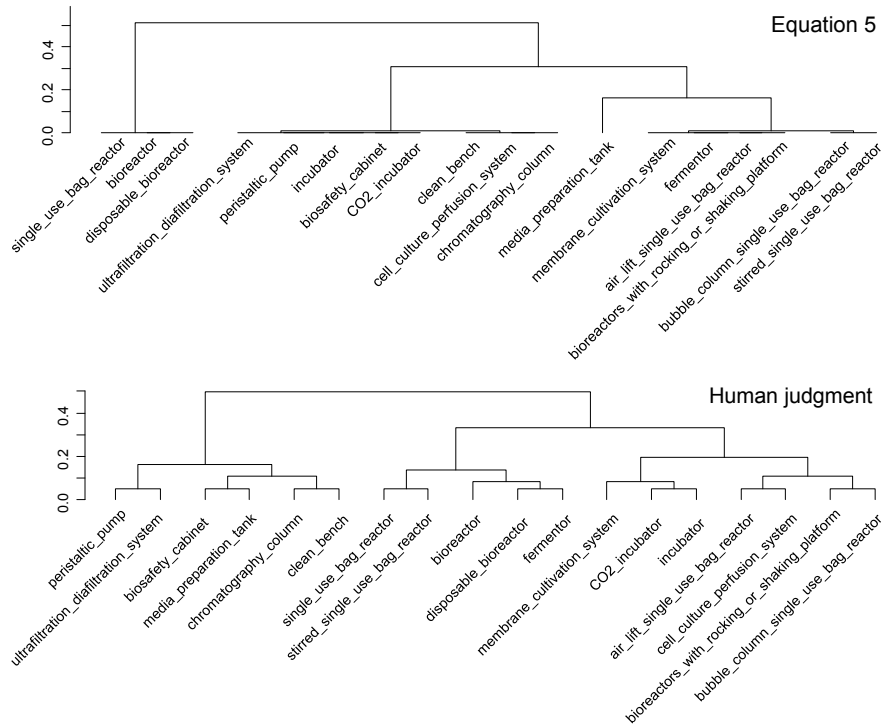

Figure 2. Comparison of the clustering of the two similarity results

5. Conclusions

This paper presented semantic similarity measures based on ontology to determine the degree of similarity of two classes. The results of the experiment show that the cardinality of the intersection between the sets of attributes of the two classes divided over the minimum cardinality performs better when compared against other semantic similarity measures. Furthermore, while Wu-Palmer's similarity is only defined for trees, our approach can be applied to taxonomies containing a class with multiple direct-superclasses (multiple-inheritance). This is because the proposed similarity measures are not only based on the taxonomy but also on the properties that characterize each class in the ontology.

Abstract

Computational Fluid Dynamics (CFD) is presented as a powerful tool to support design and optimization of microfluidic reactors. This is demonstrated by means of three case studies. First a three-dimensional scaffold for tissue engineering purposes is investigated using a combination of CFD and a simple biological model. The result is a suggestion of an improved geometry design. In the second case study a microfluidic cartridge of a novel automated in vitro fertilization device is presented, where the CFD model has supported the fluidic design of the microfluidic network in which the stem cells are grown. In the last case study a biocatalytic microfluidic reactor design is presented in which the material characteristics of substrates and products of the catalytic reaction can be investigated. As model system the transaminase catalyzed formation of methylbenzylamine (MBA) from acetophenone is investigated and it is demonstrated how the experimental investigation along with the CFD model can be used for the characterisation of the performance of the reactor system.

Keywords: computational fluid dynamics (CFD), microfluidics, biocatalytic reaction, in vitro fertilisation, optimisation

1. Introduction

Computer aided process engineering has many potential applications. One of the most eloquent ways of applying computational tools is to predict the performance of systems and to use the predictions for optimization of future designs. This can for instance be the configuration of single unit operations or complex process plant designs. Computational fluid dynamics (CFD) has throughout the last decades undergone a breathtaking development and is used increasingly in industrial applications. The prediction quality has indeed reached such a level of maturity that many scientific and industrial users increasingly apply the method for a broad range of applications. Often the companies are performing virtual investigations rather than experiments, or at least they are trying to reduce the number of experiments as much as possible. Typical application areas are for instance the automotive industry [1], the ship building industry [2 and 3] or turbine optimization [4]; where often the improvement of a fraction of a percent of the efficiency is guaranteeing a multimillion Euros return on investment.

A well suited field of application for CFD supported design or analysis is in the area of fluid dynamic conditions with low Reynolds numbers. Typical applications can be found where the flow channel geometries are in the range of micrometers, giving the field the name microfluidics. From a mathematical point of view the equation system is reduced to the Navier Stokes equation and hence no turbulent terms have to be implemented. Therefore the prediction quality of the CFD models is expected to supply excellent qualitative and quantitative results for such systems. In this article three different case studies of the use of CFD in designing microfluidic systems are presented.

2. Materials and Methods

2.1. Software and Modelling

In all presented cases the CFD simulations have been performed by using the ANSYS CFX software. For meshing of the geometry ICEM CFD has been used for the generation of structured hexahedral meshes. In the first case a simple biological model has been implemented with help of the CFX Command Language (CCL). This model is described in [5]. The model considers the growth of biomass with help of a Michaelis Menten kinetic and involves the growth of biomass based on the consumption of substrates and oxygen respiration. Furthermore an additional weight factor is considered in which the existence of a specific shear strain rate (SSR) will have a positive influence on the growth rate of the biomass.

2.2. Scaffold 3D Geometry Design and Optimization

The main hypothesis in this case study is that a biological model is known, which can describe the growth of autologous bone stem cells in an artificial support scaffold in which cells are cultivated in a perfusion type reactor. Besides the material transport of the substrates, the oxygen and the biomass it is assumed that a certain physiological stress level due to the laminar flow around the cells will be beneficial and is known. This assumption is made in order to consider the ongoing discussion in the medical community working in this field [6] and giving therewith the opportunity to design an optimal scaffold from a theoretical point of view.

With help of this model an automatic procedure is started in which a geometry is simulated and a cost function is calculated which is basically the squared sum of the deviation of the actual SSR from the optimal SSR. Then a change of the geometry is proposed and the new value of the cost function is calculated. If the new result is more optimal this geometry will be stored and will serve as the basis for proposing a new change to the geometry again. Otherwise the new solution will be discarded and the old version will still serve as the starting point for the search. This procedure is placed in a loop, programmed with help of a *Practical Extraction and Report Language* (PERL) routine and is automatically actuated over a specified number of runs (ca. 500). A similar evolutionary strategy has been used and is described in [7].

2.3. CFD as software sensor

In the second example a new microfluidic in vitro fertilisation chip [8] is investigated with help of a CFD model. In this chip a series of cultivation chambers are connected by means of a microfluidic channel. An automated flow is generated in this channel due to a hydrodynamic height difference between a medium reservoir and the outlet chamber, where a piston pump is removing the surplus cultivation medium with help of a capillary. A second medium reservoir can be actuated by opening and closing of an equilibration inlet. This system has been modelled by the introduction of an additional

component to the fluid which has a diffusion coefficient of $0.67 \cdot 10^{-9} m^2 s^{-1}$, corresponding to glucose in water.

2.4. The design of a microfluidic biocatalytic reactor

In this last example a biocatalytic reaction has been chosen for a microfluidic reactor system. As model system the transaminase catalyzed formation of methylbenzylamine (MBA) from acetophenone is investigated. This reaction is in detail described in [9] and is expected to be inhibited by the formed MBA or by material transport limitations of the substrate acetophenone. A reactor design in which the produced MBA can be removed simultaneously along with its formation will be desirable, and hence a simulation study of an interdigitated channel system was performed, where short diffusion distances will contribute to the fast product removal. In most cases the material characteristics such as diffusion velocities, solubilities or reaction rates are not documented. It is therefore desirable to have a mathematical tool to design experiments for verification of such key information. Similar to *2.3,* different reaction components have been modelled as additional components with different diffusion coefficients. The performance of a first experimental setup was investigated with the help of dyes, which are mixed with the different flows.

3. Results and Discussion

3.1. The optimal 3D scaffold geometry

As a starting point of the simulation it was expected that the resulting optimal geometry would be a tubular system with the corresponding diameter, which will induce the appropriate SSR at all points of the tubular wall system. In Figure 1a the starting geometry is presented with a gradient surface plot of the SSR. Figure 1b shows an intermediate result of the simulations, where it can be observed that the SSR has already considerably changed. In Figure 1c the final geometry is illustrated as a 3D surface and it can be seen that the optimal geometry is not a tubular system, as anticipated. It is rather a tube, which is squeezed in the middle and then again squeezed twice in the start and the end in a direction that is perpendicular to the first diameter reduction. In this way a larger surface is obtained along with the appropriate SSR at this increased surface area.

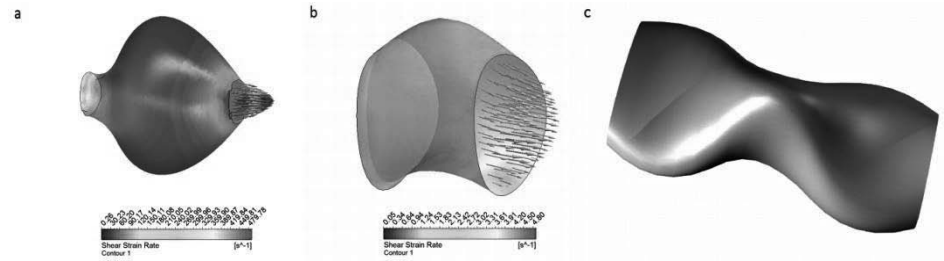

Figure 1.a. Starting geometry with SSR plot; b. intermediate result; and, c. the final 3D geometry in the optimized form.

3.2. CFD as software sensor

In this case study the IVF Chip [8] has been modelled and a transient simulation has been performed. In Figure 2a the qualitative concentration is shown in the middle plane of the flow channels and cultivation chambers. It can be seen that the upper part of the fluid domain is filled rather quickly, while the lower part, where the cells are located will not be filled as fast as the compartments above. A visual experiment with help of image analysis, shown in Figure 2b, cannot be used for the determination of the

concentration level at different depths of the system. In Figure 2c the streamlines of the flow through a cultivation compartment are presented and the worst case scenario for the placement of the embryo cell is indicated as a red cross. Finally the transient concentration profile of the averaged outlet concentration is presented in Figure 2d along with the concentration profile corresponding to the location indicated by the red cross on Figure 2c in the most downstream well. It can be seen that the transient build up of new medium at the bottom of the last well behaves much more sluggish than the outlet average concentration. But after approximately 12 minutes also the worst case placement of the cell has reached a concentration level corresponding to 95% of the desired concentration.

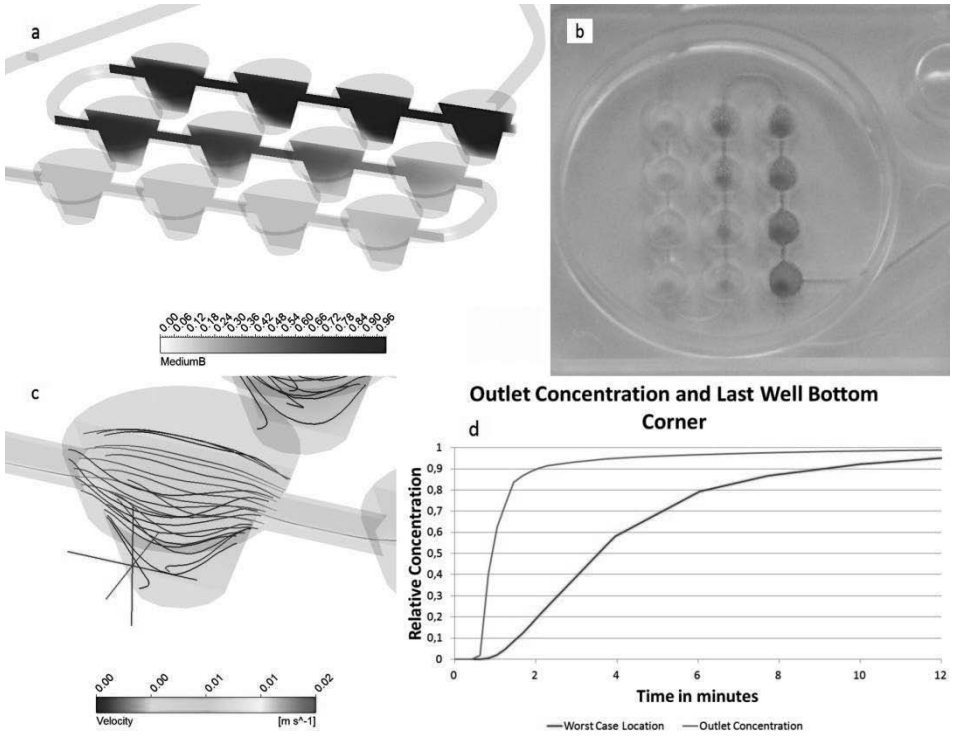

Figure 2.a. intermediate concentration profile; b. photograph of a medium change experiment with a blue dye; c. streamlines in the last cultivation chamber with the worst case placement of the cells (red cross); and, d. the transient dimensionless concentration at the outlet (averaged) and worst case placement (red cross)

3.2.1. Design of a biocatalytic reactor

In the presented simulation results in Figure 3.a the diffusion pattern of two substrate streams are shown which result from introducing alternating flows into a flow reactor (on the right hand side of figure 3a). It can be seen that the mixing due to fast diffusion coefficients ($2 \cdot 10^{-9} m^2 s^{-1}$) leads to a relatively equilibrated concentration profile already after a short distance. When performing the experimental investigation in an experimental setup with red and blue dyes with a much slower diffusion coefficient no mixing can be observed (Figure 3b). This information can be used consequently for a detailed investigation of the material properties which are predicted and observed, yielding new reactor designs, mathematical tools and simulation experiments for

optimisation of the biocatalytic reaction. Even though this result is only for demonstration purposes, the subsequent extraction of side streams at different positions of this reactor system combined with subsequent HPLC analysis will yield the exact concentration levels of the respective components. The latter will then result in a more detailed understanding of material characteristics, reaction kinetics or other information that is relevant for the specific biocatalytic reaction.

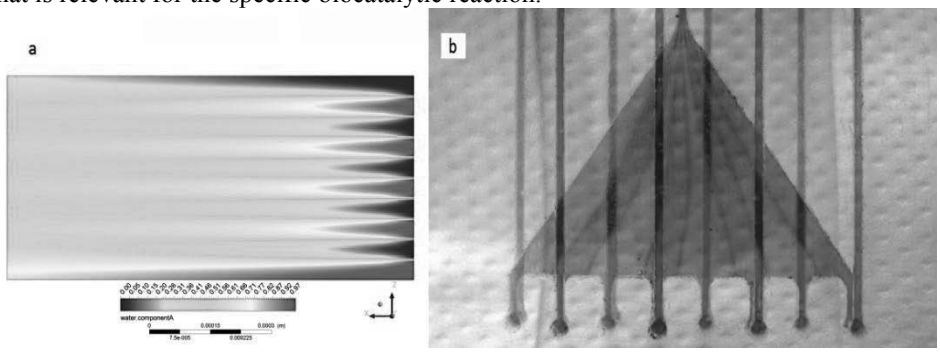

Figure 3.a. Simulation of the interdigitated fluidic array (fast diffusion coefficients for both media); b. Experimental setup with dyed liquid streams.

4. Conclusions

CFD has been demonstrated as a powerful tool for development of new theoretical qualitative insight or quantitative understanding of difficult measurable key components in microfluidic applications. Due to the lack of turbulent flow conditions in miniaturized systems the CFD results have a high predictive quality and can be obtained with relatively small effort.

Abstract

In-vitro fertilization (IVF) is the most common technique in assisted reproductive technology and in most cases the last resort for infertility treatment. It has four basic stages: superovulation, egg retrieval, insemination/fertilization and embryo transfer. Superovulation is a drug induced method to enable multiple ovulation per menstrual cycle. The success of IVF majorly depends upon successful superovulation, defined by the number and similar quality of eggs retrieved in a cycle. Hence, modeling of this stage in terms of distribution of eggs (oocytes) obtained per cycle involving the chemical interactions of drugs used and the conditions imposed on the patient during the process would provide a basis for predicting the possible outcome. This is the focus of current endeavor. The model will be made more robust by considering uncertainties; like the response of a patient depending upon previous medical history, suitability of medicine and type of protocol used. This model will then be used to decide optimal drug delivery so as to maximize good quality egg formation. Thus, a phenomenon currently based on trial and error will get a strong base. It will help the patient to decide whether to undergo superovulation or start the IVF from donor eggs, which in turn would save the patient from financial loss as well as emotional distress.

The aim of crystallization is to get maximum crystals of similar size and purity, while superovulation aims at eggs of similar quality which include the properties of size and number of chromosomes to enlist a few. The rate of crystallization and superovulation are both dependent on the process conditions and varies with time. Thus, model formulation for multiple ovulation will be on parallel lines to crystal formation in a batch process and will be modeled such.
Keywords: superovulation, batch crystallization, protocol, infertility treatment

1. Introduction

Around 80 million people in the world are suffering from infertility issues. The rate of fertility is constantly declining in the developed nations due to late marriages, postponed childbearing and primary infertility. On the contrary, in the developing world the reasons for infertility involve prevalence of sexually transmitted diseases, infections increasing the rate of secondary infertility. Childlessness is often stigmatized and leads to profound social suffering for women in the developing nations. In 1995, United Nations included rights of men and women to choose the number, timing and spacing of their children by calling reproductive health programs to include prevention and treatment of infertility (de Melo Martin, 1998).

In most countries cost is a major hurdle for access of infertility services. Most centers offering treatment for infertility operate outside of government financed health facilities. The treatment is only accessible to elites who can afford to pay for such high tech therapies. Even in a country like United States, the cost for an IVF cycle amounts

to 20% of the total annual income of a median American family. In developing nations, the cost of an IVF cycle is about 50% of the total annual income (Pennings, 2008).

2. In-vitro fertilization:

It is a process by which oocytes or egg cells are fertilized by a sperm outside the body in a laboratory simulating similar conditions in the body and then the fertilized eggs are implanted back in the uterus for full term completion of pregnancy.

2.1. Four stages in IVF:

1. Superovulation: It is method to retrieve multiple eggs using drug induced stimulation. In normal female body only one egg is ovulated per menstrual cycle, but with the use of fertility drugs and hormones, more number of eggs can be ovulated per cycle.
2. Egg collection (retrieval): On the maturation of the multiple eggs produced in the previous stage, the eggs are retrieved through special techniques like ultrasonically guided transvaginal oocyte retrieval.
3. In vitro fertilization (inseminaton/fertilization): This stage is accomplished in the IVF laboratory. Fertilization is done in the incubator using the retrieved oocytes and sperms. The conditions are maintained so as to mimic the invivo environment.
4. Embryo transfer: It takes place after several days of oocyte retrieval and after the fertilization stage is successful. The fertilized embryos are implanted into the uterus via a non-surgical technique using ultrasound guidance.

IVF treatment is an expensive treatment. There are a lot of complications associated with each stage and hence the success is highly unpredictable. The major cost of IVF is associated with the superovulation stage where expensive drugs are used and almost daily monitoring is required. Success of this stage in terms of number and quality of eggs affects the outcome of IVF and hence is a very important stage. In this work, we concentrated on modeling this stage and the approach is presented in the next section.

3. Superovulation:

In this work, we follow the analogy between batch crystallization and superovulation.

3.1. Analogy between Superovulation and Batch crystallization:

The moment model for follicle number and size is adapted from the concept of batch crystallization (Q. Hu. et. al., 2005) based on the analogy between batch crystallization and superovulation presented in Table 1.

Table 1: Analogy between batch crystallization and IVF superovulation stage

Batch Crystallization	Superovulation (IVF stage I)
Production of multiple crystals	Production of multiple oocytes or eggs
Crystal quality is determined in terms of size distribution and purity	Oocyte quality is determined in terms of no abnormalities, similar size.
The rate of crystallization or crystal growth varies with time and process conditions	The rate of ovulation or oocyte growth varies with time and drug interactions
Process is affected by external variables like agitation, and process operating variables like temperature, pressure, etc.	Process is affected by externally administered drugs and body conditions of the patient undergoing the process

The superovulation follicle growth model in general resembles greatly to the growth of seeded batch crystals. The aim of seeded batch crystallization is to allow the

seeds added to the solution to grow to desired shape and size and truncate the process of nucleation by maintaining certain process conditions. The numbers of seed added to the solution are constant and hence the zeroth moment of seeded batch crystals which corresponds to its number is constant. Similarly, when we look at superovulation, the number of follicles activated during an IVF cycle is constant. Thus, the moment model for both the processes remain the same the growth term which is a function of process variables like temperature and supersaturation in batch seeded crystallization will become a function of medicinal dosage in case of superovulation process.

4. Model details

Due to ovarian stimulation using externally injected hormones the number of follicles activated to enter into the ovulation stage are more in number as compared to a single follicle in a normal menstrual cycle. From the current data on successful superovulation for patient 1, organized in Table 2; it can be observed that during FSH dosage regime, as the time progresses the size of the eggs increase.

Table 2: Variation of Follicle size (diameter) with time and FSH dose

Sr. No	Size range (mm) / Days →	Day 1	Day 2	Day 5	Day 7	Day 9
1.	0-4	15	8	6	0	0
2.	4-8	3	6	4	2	0
3.	8-12	0	4	10	14	4
4.	12-16	0	0	0	2	11
5.	16-20	0	0	0	0	3
	FSH dose	0	300	300	300	225

4.1. Model Assumptions:

The rate expression for follicle growth is dependent on FSH administered. Thus, we can write the growth term as;

$$G=kC_{fsh}{}^{\alpha} \quad (1)$$

Assuming moment model, we consider the first six moments; zeroth moment corresponding to follicle number, the first moment corresponding to follicle size and the other 4 moments. Since, we have assumed follicle number to be a constant, hence the zeroth moment will have a constant value. Also, 1st to 5th moments are being used since they help in recovering the size distributions more precisely as against lower number of moments.

4.2. Model equations (Q. Hu. et. al., 2005):

$$\mu_0=\text{constant} \quad (2)$$

$$\frac{d\mu_1}{dt}=G(t)\mu_0(t) \quad (3)$$

$$\frac{d\mu_2}{dt}=2G(t)\mu_1(t) \quad (4)$$

$$\frac{d\mu_3}{dt}=3G(t)\mu_2(t) \quad (5)$$

$$\frac{d\mu_4}{dt}=4G(t)\mu_3(t) \quad (6)$$

$$\frac{d\mu_5}{dt} = 5G(t)\mu_4(t) \qquad (7)$$

Conversion of the data available on follicle number and size to moment using the expression given in literature by Flood, 2002:

$$\mu_i = \sum n_i(r,t) r_i^n \Delta r_i \qquad (8)$$

Here, $\mu_i = i^{th}$ moment

$n_i(r,t)$ = number of follicles in bin of mean radius 'r' at time 't'.

r_i = mean radius of i^{th} bin

Δr = range of radii variation in each bin

4.3. Moment evaluation:

Table 3: Experimental moments evaluated using equation 8

Sr. No	Time (day)	μ_0	μ_1	μ_2	μ_3	μ_4	μ_5	FSH	Cumulative FSH
1.	2	36	92	324	1340	5988	27932	300	300
2.	5	36	146	584	2728	13160	64456	300	1200
3.	7	36	180	932	4980	27428	155700	300	1800
4.	9	36	248	1764	12920	97188	749048	225	2025

5. Results:

We integrate the equations 2-7 for predicting the kinetic constants in the follicle growth expression. Later we use non-linear optimization algorithm to predict the values of these kinetic constants along with the integration constants obtained after integrating the set of moment equations. The moment values obtained from the model equations and the experimentally evaluated moments are compared and it is observed that the lower moments show some deviations, while the fit is much better for higher moments. In real practice, the model will be calibrated with the first two days of data and then used for prediction of the complete cycle.

5.1. Model Validation:

The current moment model predicts the moment values, however our final output desired is the follicle size distribution, thus in model validation the approach to obtain follicle size distribution from moment values are shown. For predicting the size distribution it is essential to have atleast 5 orders of moments to be known. The method is adapted from the literature by Flood 2002; where he shows the method to recover particle size distribution from moments in batch crystallization. Using the model predicted moment values we evaluate *n(r,t)* and compare with the actual data to check the model accuracy. We plot the follicle size distribution for four patients for various days. The experimental size distribution is shown by symbols while the continuous curve shows the model predicted values after using the inversion method. It can be seen that the predicted values are close to experimental size distribution.

6. Conclusion

The moment model developed for IVF superovulation predicts the follicle size distribution which is in well agreement with the actual size distribution seen in the IVF cycle data. The model can be used to predict the outcome. This will reduce the almost daily requirement of testing. The model can also provide a basis for predicting the optimum dosage for the desired outcome from the superovulation stage. The model used

here is a very basic model and the complexities present in the patient are not considered. Later, we aim to include these complexities and model the system uncertainties, using more data for analysis, modeling and validation.

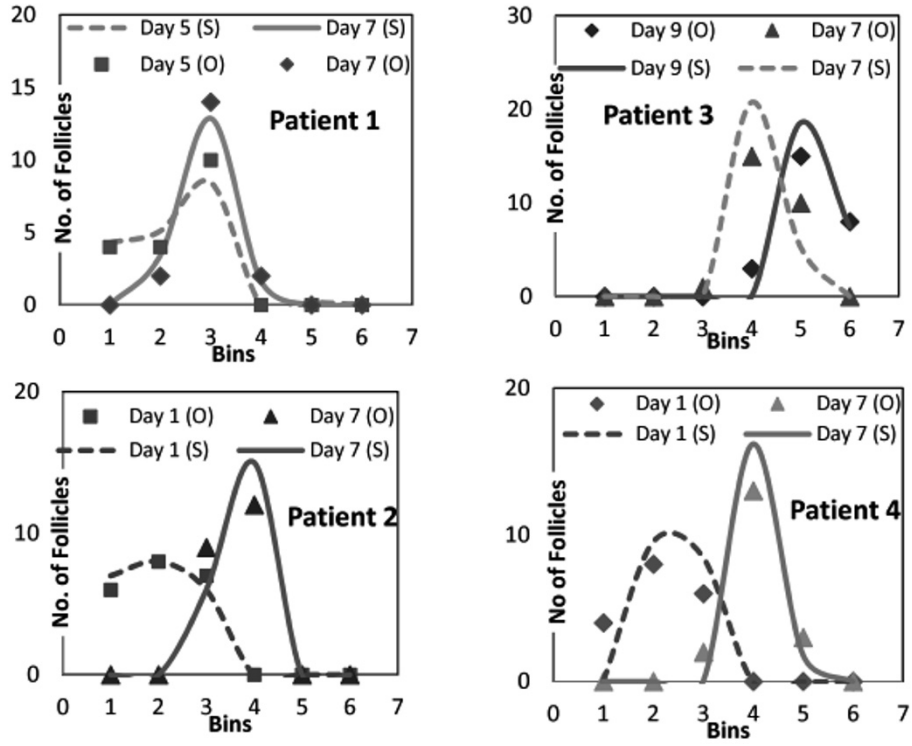

Fig 1. Follicle size distribution for four patients for various days

Abstract

This paper addresses the analysis of a distillation process by descending liquid film, more specifically the feed distribution system. This system offers simple construction, low resistance to liquid flow high capacity and. In this new equipment configuration the feed distribution system directly influences the efficiency of the separation. The objective of this study is to determine the best configuration of the feed distribution system through Computational Fluid Dynamics (CFD) simulations. The results obtained for this system indicate the formation of a thin liquid film on the walls of the distillation tube. The observed flow pattern oscillates between intermittent and gush, with a predominance of intermittent. Results were also obtained for the same geometry but with rotational movement.

Keywords: falling film, CFD, feed distribution system.

1. Introduction

Distillation by falling liquid film is a process with a low residence time and simple structure when compared to conventional distillation. It basically consists of a vertical unit, through which the liquid flows downwards, creating a film. Also, when the construction details are optimized, it is possible to obtain high heat and mass transfer rates [1]. However, this is an inherently non-equilibrium process, where the effect of the vapor generated by the liquid has almost no influence on the separation factor and rate. Due to the non-existence of convection by ebullition, the distillated flow is extremely limited, requiring frequent renovation. However, the process presents a simple construction, low resistance to the liquid discharge and high separation ability. As a consequence of the construction and phenomenological characteristics of this process, its effectiveness is intrinsically related to the feeding system.

In recent years, there has been considerable academic and industrial interest in the use of computational fluid dynamics (CFD) to model two phase flows in some chemical engineering processes. The volume-of-fluid (VOF) technique can be used for an initial determination of multiphase flows on structured packing. Szulczewska et al. [2] simulated the gas-liquid counter-current flow on plate-type structured packing. Gu et al.

[3] developed a two-phase flow CFD model using the VOF method to predict the hydrodynamics of falling film flow in structured packing. Ataki et al. [4] simulated the liquid flow structure in a structured packing element and liquid redistribution at the node of structured packing with the VOF model.
The hydrodynamics of the liquid-vapor contact has an essential function in the falling liquid film distillation design, since it determines the column fluid dynamics limits and controls the mass transfer rates. Computational fluid dynamics (CFD) has been used successfully to model the multiphase discharge in many chemical engineering systems [5-7]. It has become a powerful tool for the design and analysis of chemical processes. Due to the characteristics of the falling film distillation process, it is necessary to use feeding devices that allow a uniform distribution and adequate formation of a liquid film on the entire wall area of the unit. The simulations carried out allowed the evaluation of two different systems, one static and another with rotational movement using two rotation frequencies. The aim of this study is to evaluate the influence of the feeding system (rotational or static cone) on the film formation. The CFD technique was used as an auxiliary design tool due to its notable ability to represent systems. It is important to note that in this study only the flow of the water/air system will be analyzed. However, this is sufficient to characterize the flow as a whole, where the liquid mixture is represented by water vapor and the gas mixture is represented by air. Thus, an analysis of the fluid dynamics of the gas/liquid flow was carried out. The mass and heat transfer will the subject of a future study.

2. Methodology

This section is divided into three subsections. The first contains a brief description of the pilot distillation unit; the second describes the mathematical model used in these simulations; and the third presents the boundary conditions.

2.1. Geometric Characteristics of the System

The geometry for the feeding distribution system was proposed based on a study by Batistella [1]. Figure 1 shows the experimental apparatus which consists of a vertical tube and a mesh. Figure 1 (a) shows the liquid inlet at the top of the distillation tube and the design initially used to run the experimental tests with the rotational and static cones. The distribution system consists of a hollow steel cone which promotes a liquid film near the glass tube wall. Gas flows up through the inner part from the base.

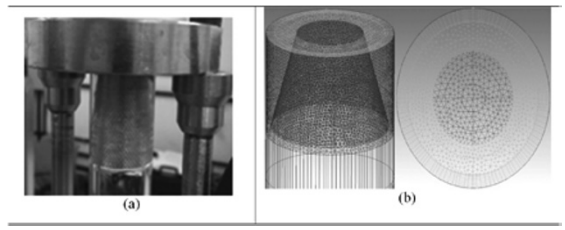

Figure 1. (a) Distribution and feeding part and (b) Hybrid mesh.

Figure 1(b) shows a hybrid mesh (with tetrahedral and prismatic volumes) built to represent the equipment and power distribution system used to perform the simulations. It should be noted that this mesh configuration gave the best numerical results with respect to convergence and time required to perform the simulations. It was built with a refined hybrid mesh comprising the prismatic walls of the distillation tube since this is the region of greatest interest in the study, *i.e.*, the area where formation of the film occurs.

2.2. Mathematical Model

The model considers the flows of gas and liquid in a Eulerian-Eulerian framework, where the phases are treated with transport equations. The equations used to solve this problem were the mass continuity and momentum equations. In order to solve these the equation of momentum flow was also required [7]. It was considered that the fluctuation (turbulence) consists of the formation and dispersion of small swarms of bubbles, and that the Reynolds stresses can be linearly related to the mean velocity gradients (eddy viscosity hypothesis), as in the case of the relation between the stress and strain tensors in laminar Newtonian flow. The shear stress transport (SST) turbulence model for multiphase flow was assumed [6].

2.3. Boundary Conditions

Dirichlet boundary conditions were used in these simulations, as follows:

1) Liquid inlet: Inlet conditions, with normal flow to the surface. A uniform liquid inlet velocity profile is recommended. Only liquid enters through the liquid inlet area, so the liquid volume fraction is taken as unity;

2) Liquid outlet: outlet condition, with normal flow to the surface. The liquid outlet boundaries were specified as pressure boundaries with volume fraction specifications. The specifications assumed that only liquid or gas leaves the simulation geometry;

3) Opening of the upper part of the cone: open condition, that is, it allows the air and/or liquid to enter and exit at the top of the cone. Entry/exit is determined by the pressure equalization;

4) Wall: All walls for the two phases are specified as no-slip wall boundaries;

5) The values of the variables of interest, such as liquid volumetric fraction, and air and water superficial velocities, were investigated at three different heights of the distillation unit and horizontal lines were drawn for this purpose. Considering the lower base of the feeding cone as zero (0) the lines were drawn at 10, 65 and 165 mm from the cone bottom. The studies were focused on the analysis of the water volumetric fraction, liquid film uniformity and thickness and formation of dry points throughout the distillation unit. The simulation conditions analyzed in this paper are listed in Table 1.

Table 1. Simulation Conditions

	Mixture water/air		
Mass Flow	50 ($kg.h^{-1}$)	50 ($kg.h^{-1}$)	50 ($kg.h^{-1}$)
Rotational Speed	-	750 rpm	1000 rpm
Wall Temperature	25ºC	25ºC	25ºC

The code used to model the computational fluid dynamics was CFX 12.0. The finite volume numeric method was used for the discretization of the equations, with a high-order interpolation scheme (high resolution) in order to avoid problems of oscillation and numerical diffusion. The pressure-velocity coupling was obtained using the phase-coupled SIMPLE algorithm. The total number of unstructured cells within the computational space was 1135238 and these are shown in Figure 1(b). Air and water were used as the gas and liquid phases, respectively, at ambient pressure. The time step was 0.01 s and the convergence criterion adopted was an average error of 10^{-5}.

3. Results and Discussions

In this section the main results obtained in the simulations carried out using the CFX 12.0 software will be reported. In Figure 2 the development of the liquid volumetric fraction profiles across the entire radius for the three height levels is shown.

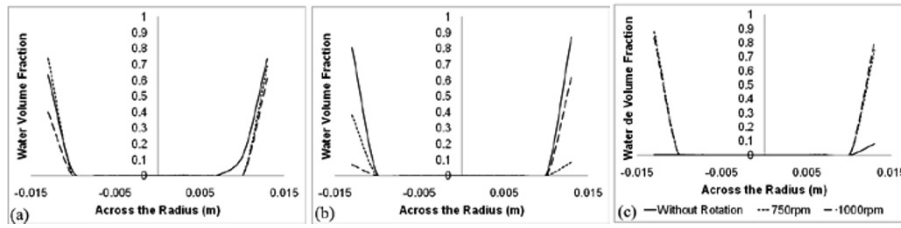

Figure 2. Liquid volumetric fraction profiles (a) 10 mm (b) 65 mm and (c) 156 mm below the feeding cone for a 50 (kg.h^{-1}) mass flow with tetrahedral mesh, cone with 750 and 1000 rpm rotation.

As can be observed in Figure 2, there were no significant differences between the liquid volumetric fractions, that is, the profiles followed a pattern formation related to the liquid volumetric fraction on the walls. On further analyzing Figure 2 it can be observed that the thickness of the film formed varies as the discharge takes place.
Figure 3 shows the Reynolds values found for each of the simulations with the power supply off and rotating at 750 and 1000 rpm.

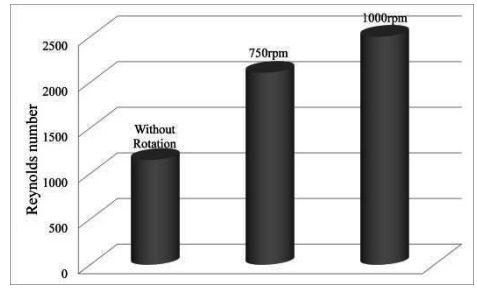

Figure 3. Average Reynolds number for each of the simulations.

It can be observed in Figure 3 that the Reynolds number increases on moving from a stationary power system to a rotation of up to 1000 rpm. This occurs because the liquid undergoes a centripetal acceleration due to the rotation of the cone and the flow has a greater velocity when in contact with the walls of the distillation tube. Figure 4 shows the volume fraction of the liquid on the distillation tube wall, over its entire length for the three simulated cases. Observing the volume fraction of the liquid on the walls of the tube distillation shown in Figure 4 (a, b and c), there is the formation of some preferential paths and also some dry spots as previously observed in experimental studies.

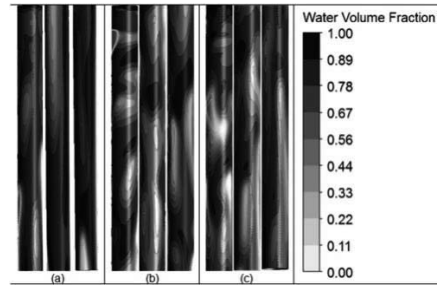

Figure 4. Profile of the volume fraction of liquid on the walls of the distillation tube for a feed flow rate of 50 (kg.h^{-1}), (a) cone without rotation, (b) cone rotating at 750 rpm and (c) cone rotating at 1000 rpm.

The formation of dry spots is not desirable from the standpoint of the distillation process by descending liquid film, because in places where there is no evaporating liquid film in contact with the steam that rises inside the tube the processes of heat and mass transfer will not occur. From the liquid volumetric fraction on the distillation unit walls in Figure 4 a slight difference can be perceived between the distributions in different parts of the unit. However, it is not possible to state that the rotational system provided a significant gain or improvement in the film formation on the distillation unit walls, and thus its use cannot be recommended.

4. Conclusions

In a rotational system the film formation is more uniform throughout the distillation unit compared with a static system. However, the formation of dry spots occurs in a similar way in both the static and rotational systems. Thus, we can conclude that this system has an impact on the film renovation. This difference becomes more evident in the case of viscous fluids. For a system with the characteristics of an air/water mixture the feeding carried out through the static device was found to be more appropriate. Studies are being carried out in order to evaluate the use of this feeding distribution system for a highly viscous mixture. The processes of heat and mass transfer through distillation using a falling liquid film are also currently being analyzed. With respect to the flow regime, two regimes were observed in full flow with a transition in the range of turbulent flow which, according to the literature, is good for the process as mass transfer can occur in a laminar flow because the film is stagnant. Regarding the maintenance of the film, it is not possible to state that the use of a rotational system substantially improved the quality of the film.

Abstract

Wood is considered one of the main future feedstocks in the production of second generation biofuels in Europe. While feedstock cost has a major impact on production cost, wood prices are expected to change significantly once biorefineries enter the raw material market as new high volume consumers. Therefore, wood market dynamics and approximate price forecasting should be integrated into decision-making during the design phase. In this contribution we show how such an integration could be realized by combining a preliminary process model to determine the raw material demand and a spatial partial equilibrium model of the wood market to predict the price development. This approach is illustrated on a case study examining the production of 2-methyltetrahydrofuran (MTHF) as a novel biofuel component, which is converted from deciduous wood grown in Germany.

Keywords: biorenewables processing, process design, partial equilibrium model, biofuel

1. Introduction

New ways of using wood as a raw material in the chemical and fuel industries would contribute to crucial changes in the fuel as well as in the wood-based sectors. The availability of wood is characterized by seasonal differences and long-term re-growth patterns such that a sustainable supply can only be adapted over extended time intervals. As such, supply constraints and an increased demand would significantly affect the wood market price dynamics. Furthermore, the relatively low energy density and organic nature of wood leads to high transportation costs and expensive supply logistics. Different methods used in process systems engineering have been utilized to address some of these issues. Especially, supply chain optimization strategies have been applied recently to examine various aspects of the new bio-economy (see [1] for an overview). Most of the case studies focus on the identification of the ideal location, number and capacity for (biofuel) production facilities based on economic or sustainability criteria. Sometimes connections to scheduling and decision making frameworks are included, but long-term changes in raw material costs induced by an increasing installed capacity of bio-based processes are mostly neglected. Other research concentrates on the modeling of biomass cultivation (e.g. [2]) to enable the estimation of feedstock prices. Moreover, partial equilibrium models are widely used to describe the wood market primarily to support policy making [3] by providing a rough prediction of wood price dynamics. However, price developments are usually not considered in conceptual

process design. Steady-state market conditions are assumed instead, irrespectively of the impact a new technology may have on resource availability and cost. Yet, especially in terms of biorenewables processing, the price of the raw material often dominates the profitability of the entire production and at the same time might vary massively in cases where biorefineries enter the raw material market as new high volume consumers. In this paper, we show how wood market and process models could be combined to overcome the above mentioned shortcomings. A better understanding of the mutual influence of markets and technologies can also facilitate enterprise-wide optimization and portfolio management [4].

2. Modeling approach

A spatial partial equilibrium model is implemented to represent the wood market, while reaction network flux analysis (RNFA) is chosen for preliminary process modeling because of few required input data. In the following sections we briefly introduce the main features of these models, highlight the necessary adaptations and show the results of their integration.

The market model has to account for all industries competing for wood resources, incorporate a realistic raw wood supply and endogenously predict the evolution of wood price dynamics over the planning horizon. In addition, the modeling framework has to allow for the introduction of future wood-based technologies. A spatial partial equilibrium model has therefore been chosen, which expresses the interaction across final product markets and resources via the simultaneous maximization of a "quasi-welfare" objective function of three representative agents (consumer, producer and trade agent) spread across regions endowed with different resources and production facilities [5]. Following the notation of Kallio *et al.* [6], the optimization problem results in

$$\max_{q,h,y,e} \sum_{i,f} \int_0^{q_{i,f}} \left(\alpha_{i,f} + \beta_{i,f} q_{i,f}\right) \mathrm{d}q_{i,f} - \sum_{i,w} \int_0^{h_{i,w}} \left(\alpha_{i,w} + \beta_{i,w} h_{i,w}^{\gamma_{i,w}}\right) \mathrm{d}h_{i,w} - \sum_{i,l} c_{i,l} y_{i,l} - \sum_{i,j,k} D_{i,j,k} e_{i,j,k} \quad (1)$$

$$s.t. \quad \mathbf{\Gamma}(\mathbf{q},\mathbf{h},\mathbf{y},\mathbf{e}) \geq 0,$$

where the dependence on time t has been dropped for clarity. The first term is a linear approximation of consumers' inverse demand function for quantity $q_{i,f}$ of final product f in region i; $h_{i,w}$ refers to the supply of wood type w in region i; $c_{i,l}$ measures the unit marginal cost for a given production level $y_{i,l}$ of technology l in region i (though it excludes raw wood, intermediate wood product inputs and marginal transport costs, which are endogenously accounted for by the model); and $D_{i,j,k}$ refers to the transportation cost for shipping the amount $e_{i,j,k}$ of commodity k from region i to region j. The production and supply of the final commodities are included in the set of constraints $\boldsymbol{\Gamma}$, which ensures material balances and reflects current production capacity limitations for all model variables ***q, h, y, e***. The evolution in time t is represented by a discrete-time recursion [6], where the next period's wood growing stock $g_{i,w,t+1}$ is affected by the growth rate $\delta_{i,w}$ of its current stock level and the wood harvest $h_{i,w,t}$ at time t

$$g_{i,w,t+1} = \left(1 + \delta_{i,w}\right) g_{i,w,t} - h_{i,w,t}. \quad (2)$$

The availability of wood resources affects in turn the tightness of the wood supply, and hence its prices. In each period the model parameters related to prices, supply and demand are then re-calibrated based on the outcome of the previous period. Even though such models already exist ([7], [8]), they fail to represent the current German

market with sufficient detail, and instead aggregate it into a larger block of countries (i.e. Western Europe). The more detailed model of the German wood market developed in this work is divided into three regions, namely West, North and South. It distinguishes between coniferous and deciduous wood and includes the main wood consuming sectors by accounting for the production and consumption of sawnwood, wood-based panels (chipboard, oriented strand board and medium density fiberboard), pulp (mechanical, sulphite and sulphate), fuel wood and, ultimately, biofuels. The model accounts for the current and forecasted production capacity of the German wood-based industry [9], while data concerning the available wood growing stock and the corresponding growing rates are taken from the National Forest Inventory [10]. In order to summarize the raw material demand of all the different sectors, so called input-output tables are used to represent the production sectors and to relate the amount of feedstock required per unit of product ([11], [12]), and are included in the material balance conditions $\boldsymbol{\Gamma}$.

The input-output relation for fuel production, a novel technology to be introduced into the market, is calculated by a separate optimization problem via RNFA, which is an optimization-based screening method for the selection of reaction routes in the early stage of design focusing on the entire value chain rather than on an individual process plant ([13], [14]). In this methodology, all possible reaction steps are summarized in a network such that linear material balances can be formulated easily for each substance. Optimal reaction pathways can be detected by solving the optimization problem

$$\begin{aligned} &\min_{\boldsymbol{f},\boldsymbol{b}} \ \phi \\ &s.t.\ \boldsymbol{A}\cdot\boldsymbol{f} = \boldsymbol{b}, \\ &\quad \boldsymbol{f},\boldsymbol{b} \geq 0. \end{aligned} \tag{3}$$

The matrix $\boldsymbol{A}$ contains the stoichiometric coefficients of all reactions, while $\boldsymbol{f}$ represents the reactive molar flows through the network (including the amount of the raw material wood, an aggregate of the supplies $h_{i,w}$ for fuel production) and $\boldsymbol{b}$ indicates product and by-product formation. If desired, yield constraints and additional performance criteria can also be considered. In fact, a rough economic evaluation can be integrated by balancing raw material costs and product sales. In addition, investment costs can be estimated according to a correlation estimated by Lange [15] based on the energy loss of the process. The objective function ϕ can be chosen according to the actual application; here, the minimization of the amount of biomass feedstock is targeted. In order to cover the evolution of price and also demand, the RNFA model has to be solved repeatedly on a receding planning horizon (embedded into the market model).

The optimization of both the RNFA and the forest market models is performed as bi-level optimization problem via the General Algebraic Modeling System (GAMS) platform. Overall, the interaction between the two models is as follows: the market model predicts the raw material cost for RNFA (i.e. the cost of deciduous wood and changes thereof after the introduction of biorefineries), while RNFA determines the flux distribution of the input-output requirements of the new biorefinery technology implemented in the partial equilibrium model. The RNFA model is solved as a subproblem of the market model at discrete times t, where the net present value (NPV) of a representative biorefinery is calculated for the most favorable processing route at fixed plant capacities in relation to the varying raw material prices.

3. Case study: the production of MTHF from deciduous wood

2-methyltetrahydrofuran (MTHF) is considered as a novel biofuel component, which could potentially replace standard fuel. It can be produced from woody biomass (e.g. beech wood) via levulinic acid followed by a consecutive series of hydrogenations and dehydrations [16]. In this case study, deciduous wood chips are used as raw material inputs of the fuel synthesis for a plant in West Germany with an expected lifetime of 20 years including a building phase of 5 years. For simplicity, fuel demand and fuel price are not yet calculated by a market model, but instead assigned according to reasonable estimates. In particular, the plant capacity is varied between $50 \cdot 10^3$ and $500 \cdot 10^3$ tons of biofuel per year in order to identify the influence of different production scales on the wood market. The pre-tax fuel price of MTHF is fixed to 0.59 €/l based on current diesel prices in Germany under the assumption of fuel price parity based on energy content. Moreover, the price of (deciduous) wood chips is calculated to be 13 €/m^3 in the base case scenario. If we assume fixed price levels, the NPVs would range between 13 Mio € for the smallest facility and 598 Mio € for the largest one. In the alternative scenarios, the price of the raw materials changes over time according to the response of the wood market model to the introduction of the new biofuel technology. The price predictions for each period are then included in the updated NPV estimation of the plant. As it can be seen in Fig. 1, the price of wood chips increases significantly due to the high demand depending on the plant capacity. These changes in raw material cost affect the profitability of the production process even more strongly. Most notably, none of the production facilities can retain a positive NPV after the cost increase, whereas the impact on large production is more severe.

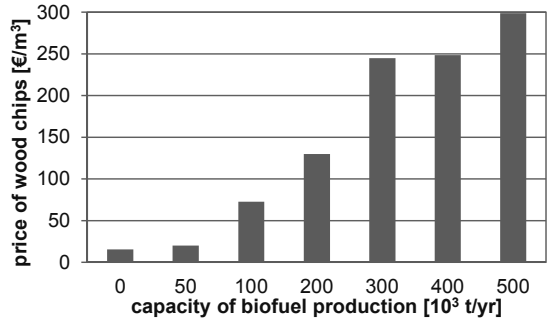

Figure 1: Prices of wood chips after the introduction of biofuel plants with different capacities.

4. Conclusions

The case study presented clearly indicates that the development of biorefineries has an enormous impact on wood market dynamics, which in turn affect the profitability of wood-based biofuel production. Consequently, market dynamics must be considered during conceptual process design and product portfolio management. The combination of RNFA and a spatial partial equilibrium model of the wood market provides a feasible framework to assess these mutual influences, even though the results are based on a rather coarse model of the German wood industry, which still needs further validation. Currently, the main drawback of the study is the lack of an adequate representation of international trade in wood products. As a consequence, on the one hand, the supply of wood is limited to the available national resources, thus possibly presenting steeper price responses to an increased demand for wood products. On the other hand, the market is also isolated from demand or supply shocks originating from abroad. At the

moment we are looking for alternatives to integrate the German market model into a larger framework to account for international trade. In addition, both the wood market and the process models incorporate several (uncertain) parameters, which call for a comprehensive sensitivity analysis to assess the validity and robustness of the results.

Abstract

A systematic design methodology is developed for producing two main products plus side products starting with one or more bio-based renewable source. A superstructure that includes all possible reaction and separation operations is generated through thermodynamic insights and available data. The number of alternative processes is systematically reduced through a screening procedure until only feasible alternatives are obtained. As part of the methodology, process intensification involving reaction-separation tasks is also considered to improve the design by shifting the equilibrium reactions. Economic analysis and net present value are determined to find the best economically and operationally feasible process. The application of the methodology is presented through a case study involving biodiesel and fatty alcohol productions.

Keywords: Methodology, Superstructure, Process intensification, Biodiesel, Fatty alcohol production

1. Introduction

Various methods for synthesis and design of chemical processes are available. The most commonly used method is heuristic by nature. Seider *et al*. (2004) proposed a step by step method for design of chemical processes. Since the physical and chemical properties of the involved chemical system play a very important role for the design/synthesis of a process, a thermodynamic insights based hybrid method was proposed by Jaksland *et al*. (1995). Hostrup *et al*. (2001) further developed this method by including a reverse design approach where process design variables are "back-calculated" for known design targets. The proposed method was applied to methyl acetate and cyclohexane productions. All these methods, however, focus on processes with one main product for a fixed reaction-catalyst and do not consider process alternatives in terms of diversion of resources to another product within the same overall process. In this paper, a systematic step by step methodology is developed for design, synthesis and analysis of a flexible process that can economically produce multiple main products plus side products according to demand and economic states. According to this methodology, all possible flowsheet configurations are first generated from a generic superstructure. Then through a systematic screening procedure, applying constraints in a hierarchical manner, the number of alternatives is reduced to identify only the feasible ones. These are further reduced in terms of productivity, consumption of raw material and process intensification. For the remaining alternatives, the optimal fractions (diversion of source) to produce multiple products is determined by solving a non-linear optimization problem. The application of design methodology is presented

through a case study involving the production of biodiesel integrated with fatty alcohol, that is, two main products and waste edible oil is employed as a feed source.

2. Methodology

The objective of the methodology is to design a chemical process to convert a renewable source to multiple main products with associated side products. The main-steps of the methodology are shown in Fig. 1, where the work-flow is structured in terms of levels (0-5) after problem definition. The starting point is problem definition where the number of available renewable sources, the number of desired main products, the qualities of the products, the performance criteria for the desired process, among others, is defined. At level-0, search of available data (in a database as well as open literature) is made, and based on this, the generic superstructure is created. Levels 1-4 involve screening of alternatives, where constraints are ordered in a hierarchical manner; the computationally easier constraints are considered first. Consequently, as the number of alternatives reduces, computationally more intensive constraints are considered. In level-0, the full set of alternatives available in the superstructure is generated, while, at the end of level-4, only a few (5-10) alternatives are considered for further analysis (for example, economic). The methodology is generic in nature (can handle any number of main products); flexible (method of solution can be changed through another order of constraints, including all at the same time). Note, however, in this paper the option for two main products and a fixed hierarchical order for constraints is used.

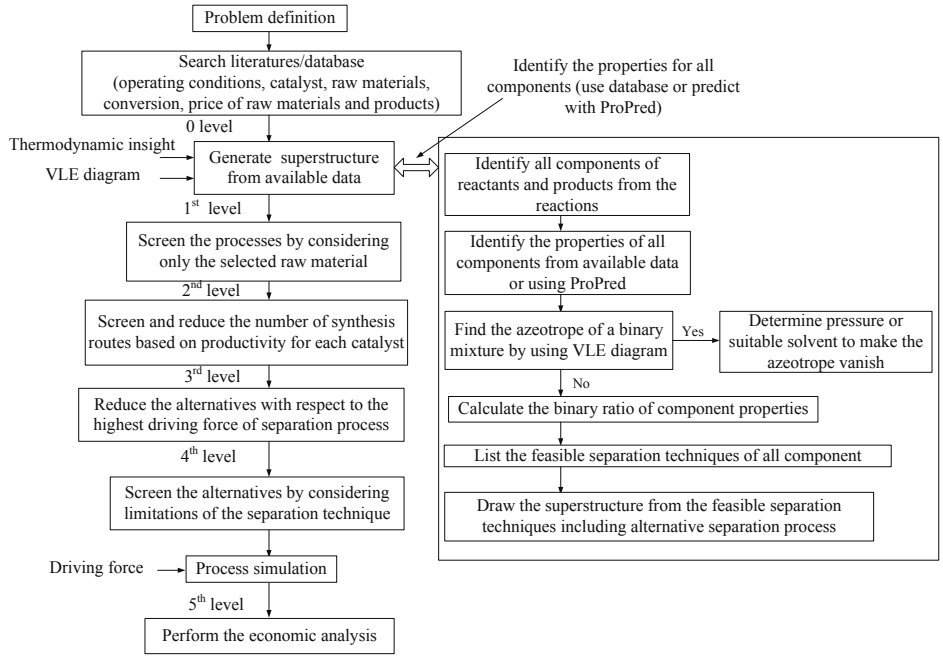

Fig. 1 Work-flow diagram for methodology for producing two main products plus side products.

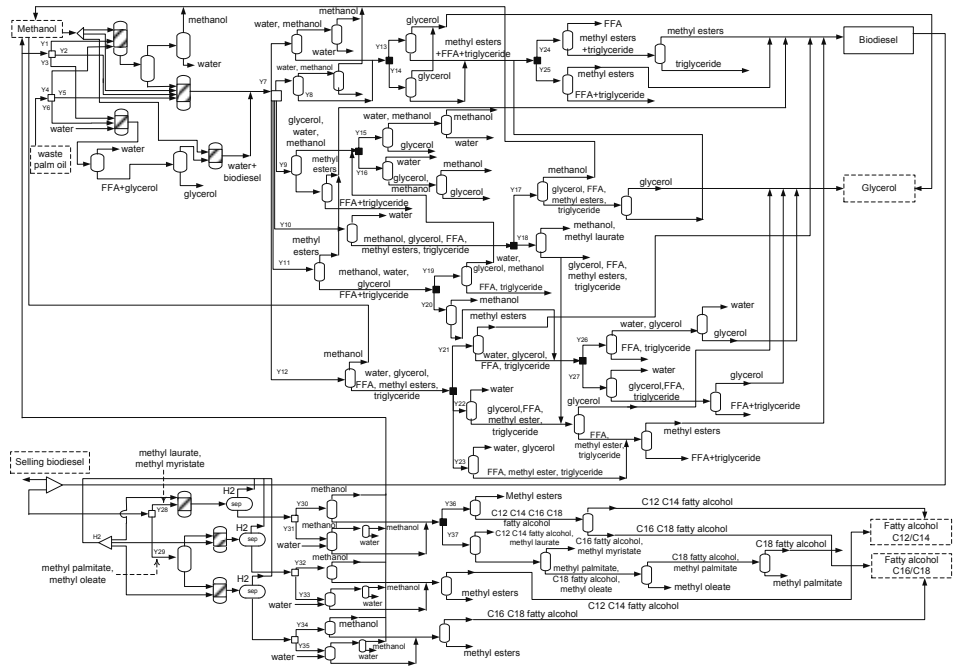

Fig. 2 Superstructure of biodiesel production process integrated with fatty alcohol production.

3. Case study

The application of the design methodology is presented through a case study involving the production of biodiesel integrated with fatty alcohol, that is, the problem defined is to produce biodiesel and fatty alcohol at a purity of 99.5 wt.%, respectively. The performance criterion is to maximize the net present value (NPV) of the process.

$$\text{Max NPV} = f(\underline{X}, \underline{Y}) \quad (1)$$

subject to design variables $\underline{X}$, binary integer (decision) variables $\underline{Y}$, process model equations (*i.e.*, mass and energy balance equations), product purities and other design targets. NPV in Eq. 1 is the summation of total capital investment, revenues, and depreciation and operating costs with interest rate (15% assumed) and lifetime (20 years assumed). In level-0, information on the type of catalysts, operating conditions, conversions for biodiesel from waste palm oil are collected. For the identified chemicals present in the system, binary ratios of properties for all components are computed and using this information and the collected data, a superstructure for the production of biodiesel integrated with fatty alcohol is generated (Fig. 2). The superstructure contains 6 separation operation types (such as flash separator, decanter, distillation, stripper and absorber) and conversion reactors (one for each type of catalyst considered; 7 types of catalysts have been considered).The number of alternatives is reduced at level-1 for the given renewable source (waste palm oil); at level-2 for the highest productivity (the reactor and catalyst that give the highest product yields); at level-3 for the easiest separations (the separation techniques employing the maximum driving force); at level-4 for the limitations on separation tasks. At the end of level-4, 7 process alternatives (such as alkali catalyzed process, acid catalyzed process, heterogeneous catalyzed process, enzyme catalyzed process, supercritical process and hydrolysis of triglyceride then esterification of free fatty acid) are obtained and then, rigorous steady-state process

simulations are performed before their performance are computed in level-5 for economic analysis and final selection. In the simulation step, the UNIQUAC model is used for phase equilibrium calculations, while the percentage recoveries of separators and distillations are specified at 90% and 99%, respectively. The driving force technique is used to design distillation columns by considering the energy consumption and total capital cost and using the reverse approach, the number of stages and the feed location that matches the driving force target are determined. The driving force diagram for separating methyl oleate from palmitic acid is shown in Fig. 3. The results for screening procedure are given in Table 1. In the last step of the methodology, seven processes are analyzed through profitability indicators such as NPV and ROI (return on investment). At the end, the best process is found to be the heterogeneous acid catalyzed process and the suitable fraction of biodiesel to produce fatty alcohol is 1. That is, most of biodiesel should be diverted to fatty alcohol because currently the price of fatty alcohol is higher than biodiesel (note that this is a constrained optimal solution and by adding a maximum amount of allowed diversion of biodiesel, both main products are obtained). Process intensification (reactive distillation) combining separation of water and methanol from biodiesel with the reaction step to improve the conversion of equilibrium-limited reaction is considered. Methanol and water are obtained at the top of the column, while methyl esters and glycerol are obtained at the bottom. The results with and without process intensification are compared in Table 2. Due to its low fraction, water derived from the esterification process (the pre-treatment section of waste palm oil) is assumed to be an inert component. From the element concept, there are 4 components with 3 elements. The ternary reactive phase diagram of the transesterification process for a biodiesel production system at 438 K is shown in Fig. 4. It shows that pure methyl ester is obtained at W_A and W_B of 50%, at AB point, while pure triglyceride is obtained at W_A and W_C of 50% at AC point. This implies that methyl ester, methanol and glycerol are found at the bottom of the reactive distillation column. As the W_A and W_B do not equal to 50% at the end of the liquid line, the bottom product is not pure methyl ester; methanol is mixed with the biodiesel product.

4. Conclusions

The systematic design of processes for multiple main products plus side products has been presented and applied for biodiesel production integrated with fatty alcohol production. Although the methodology has been highlighted in this work for two main products, it is generic, in principle. By increasing the number of renewable sources and main products, the model for an optimal biorefinery is obtained. The mathematically complex problem has been managed by decomposing it into different hierarchical levels. This technique, in principle, also includes the simultaneous approach. Current and future work will incorporate the simultaneous approach at different levels. According to the methodology, a heterogeneous acid catalyzed process for biodiesel production integrated with fatty alcohol production is better than other process alternatives. Process intensification improves the process by reducing heat duties and production costs.

Multi-objective Optimization of a Fermentation Process Integrated with Cell Recycling and Inter-stage Extraction

Shivom Sharma,[a] G.P. Rangaiah[a]

[a]Department of Chemical & Biomolecular Engineering
National University of Singapore, Singapore 117576, Singapore

Abstract

Bio-fuels are clean, renewable energy with potential to replace fossil fuels. Bio-ethanol is the widely used bio-fuel, which can be produced from a variety of agricultural feed-stocks. Its production from fermentable sugars is well established. Production of bio-ethanol from starchy and cellulosic materials requires hydrolysis as an additional step to produce fermentable sugars. In SHF (separate hydrolysis and fermentation) process, hydrolysis and fermentation are performed at their respective optimal temperatures, but end products (i.e., glucose and cellobiose) inhibit hydrolysis. SSF (simultaneous saccharification and fermentation) process removes product inhibition by immediate consumption of end products of hydrolysis. Ethanol concentration also inhibits glucose to ethanol conversion in the fermentor, which results in low ethanol productivity and yield. To avoid this, ethanol can be continuously removed from the fermentor using either extraction or perm-selective membrane. In this study, a three-stage fermentation process integrated with cell recycling and inter-stage extraction is considered, for producing ethanol from the lignocellulosic feed-stocks. The integrated process is optimized using a multi-objective differential evolution algorithm for two objectives simultaneously. Finally, improvement in the performance of the fermentation process due to inter-stage extraction is evaluated quantitatively.
Keywords: Fermentation Process; Inter-stage Extraction; Multi-objective Optimization.

1. Introduction

Cellulosic ethanol production can use non-food crops and inedible waste products to produce bio-ethanol that causes less air pollution compared to conventional fuels. Cellulosic bio-ethanol production requires hydrolysis as an additional step to produce fermentable sugars. Lignocellulosic feed-stocks produce both glucose and xylose after hydrolysis. Feed concentration, fermentation temperature and time affect the conversion of these feed-stocks into glucose and xylose. Hydrolysis is faster in SSF than in SHF due to reduced end-products inhibition. Furthermore, conversion of fermentable sugars (i.e., glucose and xylose) into ethanol is inhibited by ethanol concentration inside the fermentor. Hence, several researchers have improved the fermentation process by in-situ removal of ethanol using different processes (e.g., extraction, pervaporation, etc.).

Bio-ethanol production using first generation feed-stocks (e.g., glucose, xylose, etc.) has been optimized in the recent years. Silva et al. (1999) used solvent extraction for partial removal of ethanol from the fermentor; they have maximized both yield and productivity using response surface analysis. Wang and Lin (2010) studied fuzzy multi-objective optimization (MOO) of a three-stage fermentation process with cell recycling using glucose as feed. Chen and Wang (2010a) optimized a fermentation process using lignocellulosic feed-stocks, which involves co-fermentation of glucose and xylose. Chen and Wang (2010b) have studied a three-stage fermentation process coupled with cell recycling and inter-stage extraction, and solved a fuzzy multi-objective

optimization (MOO) problem as a single objective optimization (SOO) problem using hybrid differential evolution.

Fuzzy MOO approach requires prior knowledge, such as preference interval for each objective and constraint; and also its solution as SOO problem gives single solution. Further, in the literature, several Pareto-optimal front generating techniques are available to find the trade-offs among conflicting objectives. Hence, in this work, a three-stage fermentation process integrated with cell recycling and inter-stage extraction is optimized for ethanol productivity and xylose conversion using multi-objective differential evolution (MODE) algorithm. In order to assess the usefulness of inter-stage extraction for three-stage fermentation process with cell recycling, a three-stage fermentation process with cell recycling only (base case) is also optimized for ethanol productivity and xylose conversion using MODE algorithm.

The rest of this article is organized as follows. Next section of this article briefly presents the integrated fermentation process and its mathematical model. Section 3 describes the MOO problem formulation, whereas MODE algorithm is briefly described in Section 4. Section 5 presents and discusses the optimization results. Useful insights from this study are drawn at the end of this article.

2. Integrated Fermentation Process and its Model

A schematic diagram of the three-stage fermentation process coupled with cell recycling and inter-stage extraction is presented in Figure 1. Three fermentors are placed in series, and feed enters the first fermentor. A small part of mother liquor from a fermentor goes directly to the next fermentor while remaining mother liquor goes through a cell separator and an extractor. A cell separator is used after each fermentor to separate the cell mass and recycle it to the fermentor, whereas an extractor is used to remove ethanol using a solvent.

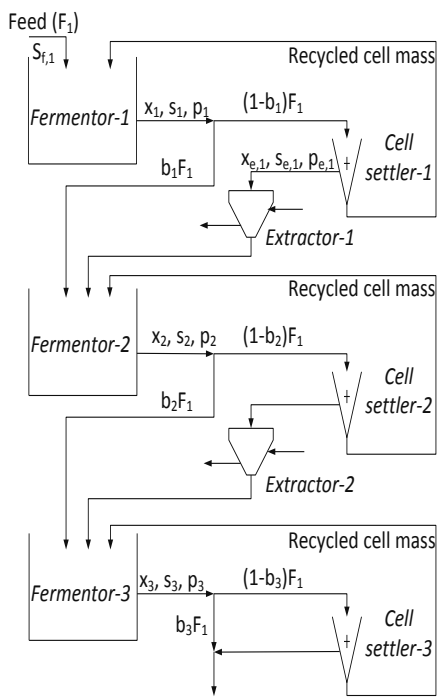

Figure 1: a schematic diagram of a 3-stage fermentation process coupled with cell recycling

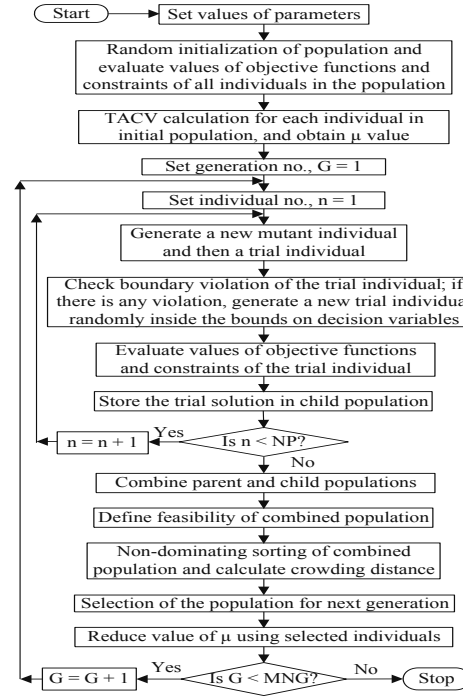

Figure 2: flowchart of the MODE algorithm

The model of the three-stage fermentation process integrated with cell recycling and extraction is taken from Chen and Wang (2010b). Steady-state material balances for cell mass, glucose, xylose and ethanol around k^{th} stage are given by equations 1-4 respectively.

$$D[b_{k-1} + (1 - b_{k-1})\zeta_x]x_{k-1} - D[b_k + (1 - b_n)\zeta_x]x_k + r_{x,k} = 0 \quad (1)$$

$$D\lambda s_{f,k} + D[b_{k-1} + (1 - b_{k-1})\zeta_s]s_{g,k-1} - D[b_k + (1 - b_k)\zeta_s]s_{g,k} - r_{sg,k} = 0 \quad (2)$$

$$D(1 - \lambda)s_{f,k} + D[b_{k-1} + (1 - b_{k-1})\zeta_s]s_{x,k-1} - D[b_k + (1 - b_k)\zeta_s]s_{x,k} - r_{sx,k} = 0 \quad (3)$$

$$D\left[b_{k-1} + (1 - b_{k-1})\frac{\zeta_p}{1+E_{k-1}}\right]p_{k-1} - D[b_k + (1 - b_k)\zeta_p]p_k + r_{p,k} = 0 \quad (4)$$

Here, D is the dilution rate. x, s_g, s_x and p are respectively cell mass, glucose, xylose and ethanol concentration (kg/m^3) in the fermentor indicated by the subscript. b_k, E_k and $s_{f,k}$ are bleed ratio, extraction efficiency and substrate concentration in feed to k^{th} stage. λ is the mass fraction of glucose in substrate, and remaining is xylose. ζ_x, ζ_s and ζ_p are cell discard/separation factor ($= x_{e,1}/x_1$), substrate condensed factor ($= s_{e,1}/s_1$) and ethanol condensed factor ($= p_{e,1}/p_1$) respectively (see Figure 1). The rate expressions for cell mass growth (r_x), glucose consumption (r_{sg}), xylose consumption (r_{sx}) and ethanol production (r_p) can be found in Chen and Wang (2010b). The kinetic parameters used in this study are taken from Krishnan et al. (1999).

3. Multi-objective Optimization Problem Formulation

In this study, ethanol productivity and xylose conversion are used as two objectives, which ensure efficient utilization of production capacity and substrate respectively. Glucose conversion is not considered as an objective since it is higher than xylose conversion (Chen and Wang, 2010b).

$$\text{Ethanol productivity}, \frac{D}{3}\left[b_3 + (1 - b_3)\zeta_p\right]p_3 + \sum_{k=1}^{2}(1 - b_k)\frac{\zeta_p E_k}{(1+E_k)}p_k \text{ [kg/(m3.h)]} \quad (5)$$

$$\text{Xylose conversion}, 1 - \frac{[b_3 + (1-b_3)\zeta_s]s_{x,3}}{(1-\lambda)s_{f,1}} \quad (6)$$

Decision variables for this optimization include dilution rate, substrate concentration in feed and cell mass recycling for different stages.

$$0.3 \le D \le 0.8 \text{ [1/h]}; \; 40 \le s_{f,1} \le 130 \text{ [kg/m}^3\text{]}; \; 0.1 \le b_k \le 0.2 \text{ for } k = 1, 2, 3 \quad (7)$$

In addition to mass balances for different stages (Equations 1 to 4), positive values of ethanol productivity of each stage (π_k), glucose and xylose conversions ($\chi_{g,k}$ and $\chi_{x,k}$) in each stage are physical constraints. Other constraints are total sugar supply (s_T) and limits on the residual glucose and xylose concentrations ($s_{g,3} < 0.1$ and $s_{x,3} < 1$) in the mother liquor from the third fermentor. These constraints can be obtained from Chen and Wang (2010b).

4. Multi-objective Differential Evolution Algorithm

Integrated fermentation process is optimized for multiple objectives using MODE, which is similar to GDE3 presented by Kukkonen and Lampinen (2009). Figure 2 presents the flowchart of this algorithm. An initial population of NP individuals is randomly generated inside the bounds on decision variables, and values of objectives and constraints are calculated for them. In each generation, for each target individual in the current population, a mutant individual is generated by mutation using three random individuals from the current population. Then, a trial individual is produced by crossover of mutant and target individuals. Similarly, NP trial individuals are generated,

and each trial individual is evaluated for its values of objectives and constraints. These trial individuals are mixed with the current population, and non-dominated sorting of the combined population followed by crowding distance calculations are performed to select NP individuals as the population for the next generation. Constrained dominance or feasibility approach (Deb et al., 2002) is used for handling inequality constraints in the optimization problem; this approach modifies the selection rule for individuals in MODE algorithm, to give higher priority for feasible individuals over infeasible individuals with better objective values. MODE algorithm has been implemented in MS-Excel (for user interface and model calculations) and VBA (for optimization steps).

5. Results and Discussion

MODE parameters used in this study are: population size = 100, crossover probability = 0.3, mutation rate = 0.5, DE/rand/1 mutation strategy and maximum number of generations (MNG) = 200. The steady state model for each stage of fermentation process (equations 1 to 4) has to be solved numerically to compute values of objectives and constraints for each decision variable vector (or individual) provided by the MODE algorithm. In this work, 'Solver' in MS-Excel has been used to solve the steady state model equations by minimizing sum of squares. Feed to the fermentation process contains 65% glucose and 35% xylose, and extraction efficiency of solvent is assumed to be 6.93 (Chen and Wang, 2010b).

Initially, a three-stage fermentation process with cell recycling but without extraction (base case) has been optimized for ethanol productivity and xylose conversion simultaneously, for the same range of decision variables stated in Equation 7. Figure 3(a) shows the Pareto-optimal front obtained for this base case. The obtained Pareto-optimal front is well distributed, which means MODE performs well and successful for this problem. As expected, ethanol productivity and xylose conversion are conflicting in nature. The quantitative trade-off in Figure 3(a) is interesting and useful. The obtained Pareto-optimal front can be analysed into two parts: (i) a steep increase in ethanol productivity from 2.6 to 5.5 kg/(m^3.h) with little decrease in xylose conversion, and (ii) a nearly linear decrease in conversion from 0.995 to 0.955 as ethanol productivity increases from 5.5 to 7 kg/(m^3.h). The significant improvement in ethanol productivity in the first part is due to steady increase in substrate concentration in feed and followed by increase in dilution rate (Figures 3c and 3e). In the second part, variation in ethanol productivity is mainly due to dilution rate. All the bleed ratios are nearly constant at their lower bounds (i.e., 0.1), and so these are not shown for brevity.

Pareto-optimal front obtained for three-stage fermentation process integrated with both cell recycling and inter-stage extraction, using MODE algorithm is shown in Figure 3(b). In this case too, optimal values of dilution rate and substrate concentration in feed vary with the objectives (see Figures 3d and 3f), and all the bleed ratios are nearly constant at their lower bounds. The obtained Pareto-optimal front in Figure 3(b) shows some discontinuity near ethanol productivity of 5 kg/(m^3.h), due to changes in dilution rate and substrate concentration (Figures 3d and 3f). In order to check the global optimality of the obtained solution, this case has been run several times with fixed bleed ratios (= 0.1 as these are nearly constant); the Pareto-optimal solutions obtained in different runs are practically same. This indicates that MODE algorithm has converged to the global Pareto-optimal front.

In the fermentation process integrated with both cell cycling and extraction, ethanol productivity has improved significantly compared to the base case (Figures 3a and 3b); maximum value of productivity has increased from 7 to 13.3 kg/(m^3.h). Furthermore,

xylose conversion has also improved, closer to one. In both cases (i.e., with and without extraction), optimal dilution rate is varying between its bounds. In the extraction case, substrate concentration in feed is mostly near to its upper bound (130 kg/m^3), which means three-stage fermentors integrated with inter-stage ethanol removal can convert larger amount of fermentable sugars into bio-ethanol, for the same capacity of plant.

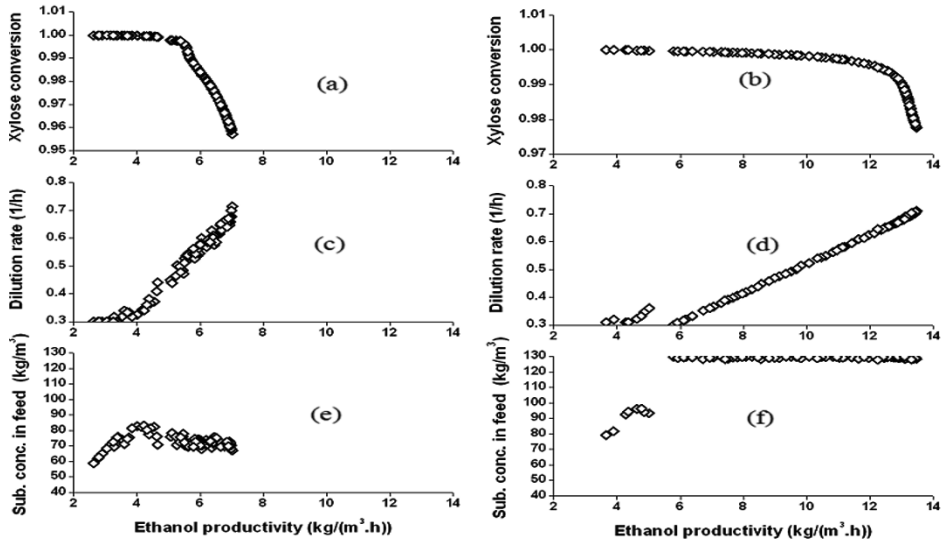

Figure 3: Selected optimization results for the three-stage fermentation process integrated with cell recycling only (plots a, c and e in the left column), and with cell recycling and inter-stage extraction (plots b, d and f in the right column)

6. Conclusions

This study optimizes a three-stage fermentation process with cell recycling and inter-stage extraction, and using glucose and xylose as the feed-stocks. The MODE algorithm is used to generate the trade-off solutions. The obtained Pareto-optimal front gives better insights by providing a range of alternatives with different ethanol productivity and substrate conversion. Low values of bleed ratios are favorable for both objectives. Finally, optimization results show that inclusion of inter-stage extraction improves the fermentation process significantly (e.g., ethanol productivity nearly doubles).

Abstract

This work addresses the integrated design of the High Temperature Steam Electrolysis (HTSE) and Biomass to Liquid (BtL) hybrid process.
The comprehensive gate-to-gate analysis includes BtL and hydrogen production on-site operations. Simulations are carried out using a commercial process simulation software – ProSimPlus® – to allow physical modeling and mass and energy balances; modeling is based on standard elementary and user modules and supported by various CEA (French Atomic Energy and Alternative Energies Commission) previous works.
The framework for assessment is proposed. Considering productivity, efficiency, cost and environmental issues, five criteria have been chosen: carbon matter yield; energy efficiency; greenhouse gas emissions; water use; levelized biofuels production cost.
Preliminary results verify that hydrogen input is almost doubling the productivity (biofuels/biomass). They bring out significant secondary energy saving for HTSE compared to standard process; and clear advantages over alkaline electrolysis considering technical and environmental criteria.

Keywords: integrated design, Biomass to Liquid, High Temperature Steam Electrolysis, hybrid, multicriteria.

1. Introduction

1.1. Context: enhanced BtL processes with extra hydrogen input

The second generation liquid biofuels are promising regarding substitution of petroleum: they offer both interesting energy efficiency and potential for GreenHouse Gas Emissions (GHGE) cut. The Biomass to Liquid (BtL) thermochemical route – based on biomass gasification then Fischer-Tropsch Synthesis (FTS) – is the most often considered, because it can produce fuels similar (even of higher quality) to conventional liquid fuels. However, lignocellulosic resources are significant but not plentiful: in Europe, the primary energy feedstock is about the third of the final energy consumption [1]. As a consequence advanced use of biogenic carbon is necessary. This increase in productivity is possible with optimized efficiency of the standard process, but also by providing extra hydrogen input, therefore coupled hydrogen production is studied [2–4].
Referring to chemical equations, biomass gasification is roughly $C_6H_9O_4 + 3\ O_2 + H_2O \rightarrow 4\ CO + 2.5\ H_2 + 2\ CO_2 + 3\ H_2O$ while FTS is ($n \in [5, 20]$), $n\ CO + (2n+1)\ H_2 \rightarrow C_nH_{2n+2} + n\ H_2O \approx n\ (CH_2) + n\ H_2O$. With extra hydrogen input the process equation is then roughly $C_6H_9O_4 + 3\ O_2 + H_2O + 6H_2 \rightarrow 4\ (CH_2) + 2\ CO_2 + 7\ H_2O$ instead of $C_6H_9O_4 + 3\ O_2 + 3\ H_2O \rightarrow 2\ (CH_2) + 4\ CO_2 + 5\ H_2O$.

1.2. Objective: the relevance of High Temperature Steam Electrolysis

Water electrolysis produces both hydrogen for extra input and oxygen for gasification – in the required *3:6* ratio shown above –: $H_2O \rightarrow H_2 + ½\ O_2$. Furthermore, water recycling could theoretically lead to $C_6H_9O_4 \rightarrow 4\ (CH_2) + 2\ CO_2$ for the integrated process. High Temperature Steam Electrolysis (HTSE) is notably relevant because it puts free heat (from BtL) to work, as well as it offers high energy efficiency [3] (Fig. 1).

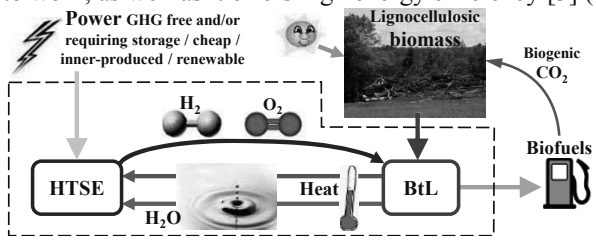

Fig. 1: Principle and interest of BtL and HTSE hybrid process to produce biofuels.

This paper aims at defining the framework for assessment, validation and quantification of the relevance of the HTSE and BtL hybrid process. Both optimal coupling of the two processes and comprehensive optimization of the new process require a detailed modeling: the selected technologies and method used are presented in §2. Challenges of energy system – and particularly second-generation biofuels processes – lead to select several criteria which are presented in §3. These modeling and criteria are suitable for multicriteria optimization.

2. Process description

2.1. BtL process

The BtL process rests on two main steps: gasification of the biomass into syngas then FTS of naphtha, gasoline, kerosene and diesel. In addition, the complete process includes preparation or recovery operations that impact process performance data and therefore the criteria. Operations involving heat or matter are simulated, from raw biomass to liquid fuels (in bold in Fig. 2).

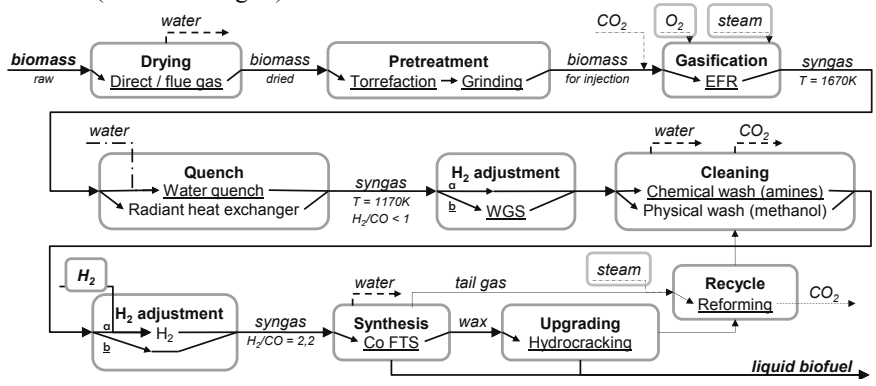

Fig. 2: Block diagram of the BtL process.

Simulations are carried out using a commercial process simulation software (ProSimPlus®) to allow physical modeling, mass and energy balances; it also generates data for complete heat integration. The process model is built from standard elementary and user modules, supported by various CEA (French Atomic Energy and Alternative Energies Commission) previous works, including modeling work [5,6] and selection of relevant

elementary processes and technologies [4]. This selection is mainly based on cost and productivity for high capacity BtL plants, e.g. adiabatic pressurized oxygen-blown Entrained Flow Reactor (EFR) is used for biomass gasification. Selected technologies are shown in the block diagram (Fig. 2, WGS: Water Gas Shift; Co FTS: cobalt catalyzed FTS. Base case is underlined). Concerning reaction models, equilibrium is considered when possible (gasification, WGS – with methane as an inert – and reforming); in case of non-standard kinetics (torrefaction, FTS) conditions and conversions are fixed; electrolysis are user-built modules.

In this paper only base case simulation results and a preliminary comparison are proposed. Three options for hydrogen ratio adaptation are presented: HTSE, Alkaline Electrolysis (AE) and WGS.

2.2. Hydrogen ratio adaptation

Adaptation is required to bring H_2/CO ratio of the syngas (<1) to stoichiometric conditions (>2) for FTS. Hydrogen can come either from a conversion of a part of the syngas using WGS reaction ($CO + H_2O \rightarrow H_2 + CO_2$) or an extra hydrogen input in order to increase carbon yield; in this case the hybrid process obtained uses both biomass and another raw energy. Using steam reforming of Natural Gas (NG) to produce hydrogen creates GHGE. With low-carbon content electricity (e.g. renewable or nuclear power), the AE (consuming only electricity) can reduce these GHGE, but with an increase in production cost and a poor equivalent primary energy efficiency. Finally, HTSE (using heat both to vaporize water and to maintain the electrochemical reaction at 1000-1200 K) brings the advantage of better energy efficiency of the process, but along with an increase in cost. WGS, NG reforming and AE are touchstones for HTSE performance and suitability. Scope, coupling issues, computing input/output and parameters are summarized in Fig. 3.

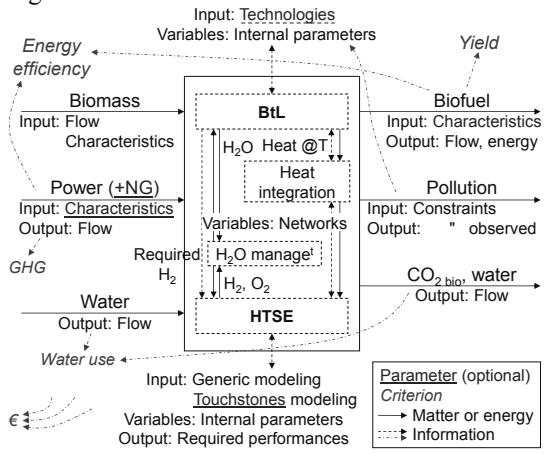

Fig. 3: Framework for BtL and HTSE hybrid process evaluation.

2.3. Heat integration

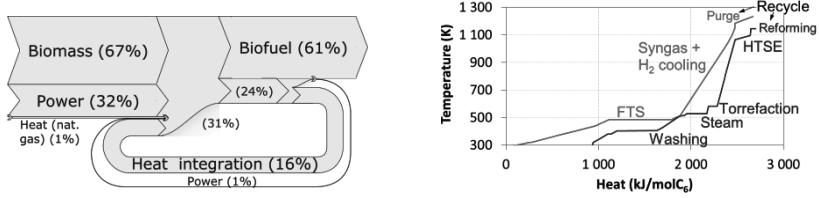

Fig. 4: Heat integration (case HTSE): Grassmann (exergy flow) diagram and composite curves.

Complete heat integration is performed after each simulation (so it does not impact the operations shown in Fig. 2). Temperatures are corrected using half matching typical ΔT_{min} (minimum temperature difference in exchangers) values [7] (Fig. 4).

3. Criteria and preliminary results

Issues of energy system – and particularly second-generation biofuels – lead to select several criteria as performance data or compliance constraints. Two technical criteria (yield or efficiency; to maximize) are used for the two main functions of the process and three other criteria (expressed per unit of energy in the liquid biofuels; to minimize) are selected: the standard economic criterion (not described for space limitation) and two environmental criteria. Criteria are italicized in Fig. 3.

3.1. Biogenic carbon criterion

The main function of the coupling is to enhance the conversion of biogenic carbon into liquid biofuels. Biogenic carbon yield is therefore selected as a technical performance criterion. Flow diagrams are presented for WGS and both electrolysis (HTSE and AE) cases. CO_2 (including part of CO_2 in the gas) is shown in grey; CO_2 formations – that are losses of biogenic carbon – are framed in Fig. 5: *6%* of the input biogenic carbon is lost at torrefaction, *12%* at the EFR, *16%* at the quench and possibly *31%* at WGS.

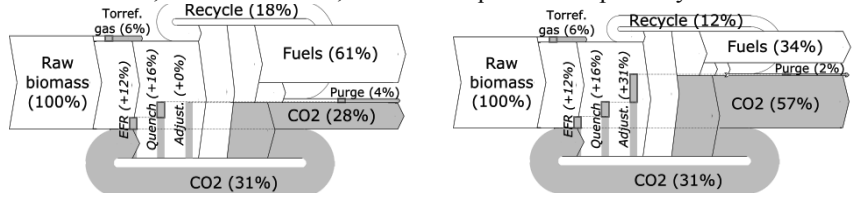

Fig. 5: Biogenic carbon flow diagrams: HTSE and AE cases (left) and WGS case (right).

3.2. Energy criterion

Energy criterion is expressed as exergy (work equivalent) efficiency in recent papers [8–10]. Exergy is particularly useful to consider heat value, that is why it is used in Fig. 4. However, secondary (i.e. without power production yield) exergy results do not provide relevant input/output data given that exergy of fuels is higher than Lower Heating Value (LHV) – biomass: 113%, liquid fuels: 107% [11] – but exergy equals power for electricity. On the contrary, we must account for upstream power production and inferred technical energy efficiency of this prior conversion. That is why the energy criterion is expressed as the yield of equivalent primary energy (heat equivalent: $[\sum(flowrates_{in} \times LHV_{in}) + power \times 2.6] / \sum(flowrates_{out} \times LHV_{out})$) in this work*.

3.3. Greenhouse gas emissions criterion

GHGE are calculated for the process (from NG consumption for hot utility), including indirect emissions for power production (French electricity mix for industrial applications: $55 g_{\text{equivalent of fossil } CO2} / kWh$); indirect GHGE for forestry is not counted due to high variability. Avoided emissions are directly related to productivity, therefore raw emissions are preferred.

3.4. Electrolysis water use criterion

Fresh water consumption is used in life cycle analysis, but it is not calculated in studies using a process engineering approach. As electrolysis uses water as raw material, the additional fresh water consumption due to electrolysis is counted in this study.

* Primary energy is found in nature (e.g. wind, biomass or NG); secondary energy has been converted (e.g. electricity) and thus it has been affected at least once by a conversion efficiency.

First results show that the process is always globally a net producer of water (due to moisture of raw biomass) and that consumption of fresh water by HTSE can be notably reduced (almost by half) using the water byproduced by the FTS. This water meets specifications for HTSE catalysts (simulations carried out using specifications for FTS from [12]) and hydrocarbons are harmless for HTSE.

3.5. Discussion

First results (Table 1) are consistent with expectations: electrolysis can nearly double the biogenic carbon conversion, but this leads to lower performance data regarding other criteria; HTSE can limit this drop compared to the AE.

It appears that characterization of power strongly impacts the results. Concerning energy, the secondary energy efficiency increases with HTSE but the equivalent primary energy efficiency is still lower than with WGS. This is due to poor efficiency of power production: the criterion in equivalent primary energy is indeed necessary. Concerning GHGE, they are strongly linked to power consumption in case of electrolysis, given that little NG is used compared to power.

Table 1: Criteria values of BtL processes for different hydrogen adaptation options.

	WGS	AE	HTSE
Biogenic carbon (Fig. 5)	34%	61%	61%
Secondary energy ($\frac{\sum(flowrates_{in} \times LHV_{in}) + power}{\sum(flowrates_{out} \times LHV_{out})}$)	50%	51%	62%
Equivalent primary energy	46%	30%	41%
GHGE (in $g_{\text{equivalent of fossil } CO2} / kWh_{\text{liquid biofuels}}$)	10	50	35
Water (in $kg / GJ_{\text{liquid biofuels}}$)	no extra	+43	+11

4. Conclusion

The first concluding elements in studying integrated HTSE-BtL process verify that hydrogen input is almost doubling the biogenic carbon conversion compared to the standard BtL process. They bring out significant secondary energy saving for HTSE; and clear advantages over AE considering technical and environmental criteria. HTSE is therefore suitable and promising, although its performance data is strongly linked to power characterization.

Next step is implementation and use of multicriteria optimization. In addition to trade-offs, multicriteria parametric optimization is expected to make the proposed structural comparison more accurate by providing adapted operating points for the integrated design under study.

Model-based assessment of algal ponds for biomass production under temperate climates

Mohammed K Mohammed, Aidong Yang, Adel Sharif

Division of Civil, Chemical, and Environmental Engineering, Faculty of Engineering and Physical Sciences, University of Surrey, UK

Abstract

Computer modelling of open ponds for producing algal biomass in wastewater was utilised to evaluate the potential of such algal ponds in a temperate climate. Simulations were performed with the solar radiation and temperature regime of a UK location representing temperate regions, in comparison with a Qatar location representing hot regions. Simulation results indicated low cold season performance at the UK location although a peak of algal biomass production in the summer was observed. In contrast, the Qatar location was shown to have consistently high biomass productivity all year round. Further simulations suggested that the enhancement of light supply is very likely more effective than increasing temperature for improving the algal pond productivity in a temperate climate.

Keywords: algal pond, biomass yield, temperate climate, mathematical modelling.

1. Introduction

Cultivation and utilisation of microalgae have recently received much attention due to their potential roles in the production of renewable fuels as well as chemical, health and medical products, and in environmental mitigation (Demirbas, 2010). Cultivation of algae currently occurs in open ponds and closed photobioreactor (PBR) systems (Chisti and Yan, 2011). The latter is preferable as it allows for more control and vitally reduces the possibility of contamination. However, the high cost of this technology still prevents it from being economically viable for large-scale production (Kovacevic and Wesseler, 2010). Currently, open ponds are the more economic option, although they suffer from various problems stemming from the nature of being open to the environment. These particularly include the effect of natural conditions, most notably temperature and solar radiation. Generally, open ponds tend to be more productive when located in warm areas with plenty of sunlight; their performance under temperate climatic conditions is still a matter that requires investigation.

The aim of this paper is to utilise a mathematical model to evaluate algal ponds located in temperate climates, by means of a comparison with those in warm regions. Specifically, two different geographical regions were chosen: Camborne (UK) and Al Kharsaah (Qatar), representing a temperate region and a warm region, respectively. Data for each area was obtained from the Atmospheric Science Data Centre (ASDC) at NASA Langley Research Centre (NASA, 2012). This paper will report the key mathematical model components and the climatic data utilised in the simulations, as well as the observations made based on the simulation results.

2. Mathematical Model

A mathematical model was created to assess algal biomass production in a continuously operated open pond fed with wastewater, where photosynthetic algae and aerobic

bacteria co-exist with symbiosic exchange of CO_2 (produced by bacteria and utilised by algae) and O_2 (produced by algae and utilised by bacteria). A raceway type of design has been assumed for the algal pond. Key design and operation parameters such as pond volume and depth, wasterwater flow rate and nutrient level were taken into consideration (Table 1).

Table 1 Design and Operating Parameters of Simulated Algal Pond

Parameter	Nominal Value
Pond Depth (m)	0.4
Pond Volume (m^3)	350
Influent Flow Rate (m^3/day)	50
Influent BOD (g/m^3)	500

In terms of the supply of CO_2, two sources were considered by the model, namely the atmosphere and aerobic digestion of the nutrients in the wastewater. Additional CO_2 supply by gas sparging was not considered in this paper as it represents a separate level of complexity in terms of the design and operation of the pond. Other nutrients were assumed to be at levels which have no limiting or inhibitory effects. The modelling framework previously developed by Yang (2011) has been used, which particularly includes kinetic modelling of algal growth affected by temperature and light supply:

$$r_{gA} = \mu_A X_A \tag{1}$$

$$\mu_A = \hat{\mu_A}\left(\frac{CO_{2_D}}{K_c + CO_{2_D}}\right)\left(\frac{N_T}{K_{NA} + N_T}\right)f_I \tag{2}$$

$$f_I = \frac{I_a}{I_s}\exp\left(1 - \frac{I_a}{I_s}\right) \tag{3}$$

$$\hat{\mu_A} = 9.46 \times 10^5 \exp\left(\frac{-4034}{T}\right) \tag{4}$$

$$I_a = \frac{1}{Z}\int_0^Z I_0 \exp(-K_e z)\,dz \tag{5}$$

$$I_0(t) = \left(\frac{\pi}{2}\frac{I_d}{f_P}\right)\sin\left(\frac{\pi t}{f_P}\right) \tag{6}$$

The notations are explained below:

r_{gA}	Growth Rate
μ_A	Specifc Growth Rate
X_A	Mass Concentration of Algae
CO_{2D}	Dissolved CO_2
N_T	Total Nitrogen
$\hat{\mu}_A$	Constant
K_C	Constant
K_{NA}	Constant
f_I	Light Intensity Factor
I_a	Average Light Intensity in the Pond
I_s	Saturated Light Intensity (350Cal/cm^3)
T	Temperature
I_0	Surface Light Intensity
K_e	Extinction Coefficient
Z	Depth of Pond
I_d	Daily Total Light Intensity at Pond Surface
f_p	Fraction of the Photoperiod in a Day
t	Time in Days

3. Selected Locations and Climate Conditions

To avoid extremes, a relatively warm area in the UK (Camborne, latitude: 50.22; longitude; -5.33) was selected to represent temperate regions where open pond based algal cultivation might be practical. To offer a contrast, an area in central Qatar (Al Kharsaah, latitude: 25.5; longitude: 51.25) was also selected to represent hot regions, which are normally considered ideal for operating algal ponds. Data for each territory was gathered from ASDC (NASA, 2012), which provided averaging months over a 22-year period from 1983 to 2005 based on data gathered from various Earth orbiting satellites. To conduct a preliminary test on the reliability of the NASA data, a comparison was made with the measurement data collected by the Met Office in the UK for Camborne (WRDC, 2012), averaged over the period of 2005-10. This comparison gave only an average difference of 1.69%, suggesting reasonable reliability of the NASA data set. The NASA data for both sites is shown in Figure 1. It can be seen that there is an expected variation in temperature within the year with a predictable difference between the two selected locations (Fig 1c). With respect to solar radiation data, the Direct Normal Radiation follows a seasonal pattern similar to temperature with regards to variation and the expected difference (Fig 1b). Greater variation in Daily Photoperiod is apparent between the two localities, with the UK location being lower during the colder seasons and eclipsing the Qatar location during the summer period (Fig 1a).

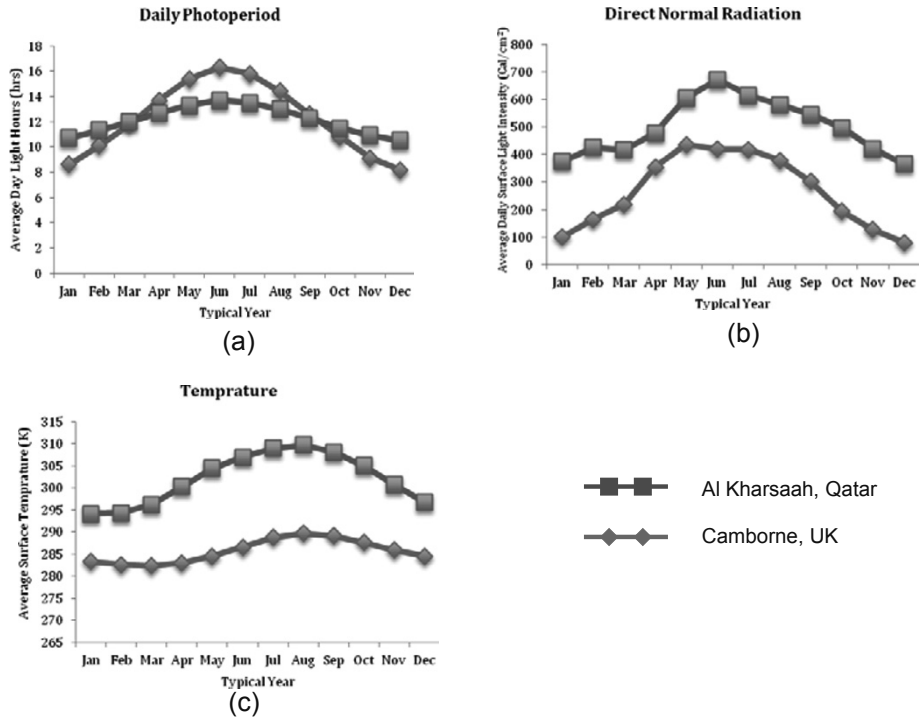

Figure 1. Comparison of (a) Daily Photoperiod, (b) Direct Normal Radiation and (c) Temperature between Camborne (UK) and Al Kharsaah (Qatar).

4. Simulation Results and Discussion

The process modelling software gPROMS was used to carry out a number of simulations, with all results presented in Figure 2. Each simulation covered a two year period and the result of the second year was taken for analysis. This is to allow for stabilisation of the (simulated) pond in the first year and subsequently to achieve in the second year a more accurate representative estimation of what would be expected in a typical year of operation.

The first two simulations were dedicated to the climate conditions of the two locations respectively, without any modification to the data presented in Section 3. The results clearly show that algal biomass production is much more favoured in the Qatar location than the UK location overall in a typical year. It can be seen that during the mid summer period the algal biomass concentration in the pond was almost identical for both countries with average figures of 301g/m^3 and 299g/m^3, respectively, for the month of June. However, gaps appear significantly in the performance between the two locations during the UK's cold seasons, suggesting inadequate solar radiation and/or temperature conditions for high biomass yield during these periods in a typical year within the UK.

The pond at the Qatar location on the other hand was shown to have a stable and relatively high level of algal biomass concentration throughout the year, suggesting the region being a good location for algal biomass production via open ponds.

To further understand the relative importance of temperature and light supply for operating open algal ponds under a temperate climate, further simulations were performed using modified climate data for the UK location. These include: (1) two tests with UK's real temperature data coupled with year-round light supply at the level of UK's April (photoperiod = 13.7 hrs, average surface light intensity = 355.20 Cal/cm^2) and June (photoperiod = 16.3 hrs, average surface light intensity = 419.71 Cal/cm^2), respectively; and (2) two tests with UK's real light data coupled with year-round temperature of 20^{o}C and 30^{o}C, respectively. As shown in Figure 2, for simulations carried out with June light data, the algal biomass concentration was similar to that obtained within Qatar throughout the year, hovering around a biomass concentration of 295g/m^3. Results for April light data showed a similarly stable but lower concentration of biomass with a peak of 275g/m^3, which however, still represent a significant improvement during the cold seasons. On the other hand, temperature at both 20^{o}C and 30^{o}C saw medium improvement of the overall productivity compared to the performance under the real temperature profile, however still with low biomass concentration yielded during the cold periods of a year. Furthermore, the improvement brought by increasing temperature from 20^{o}C to 30^{o}C is visible but not significant. The above results of these additional simulations together tend to suggest that light supply is a factor more important than temperature for improving the performance of algal ponds located in a temperate region like the UK location studied in this work.

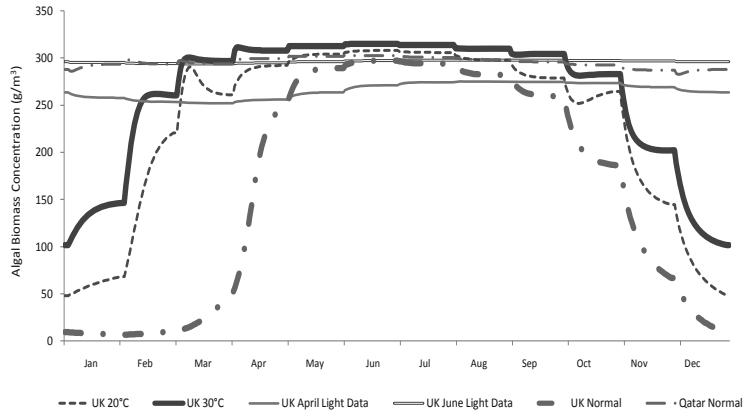

Figure 2. Model-predicted algal biomass concentration in a typical year temperature conditions at constant solar data taken from April, June as well as constant temperature of 20^{o}C and 30^{o}C.

5. Conclusion

Computer simulations were carried out to assess and compare the algal biomass production by an open pond at two geographical locations selected within the UK and Qatar to represent the temperate and hot climates respectively. Both original (i.e. actual) and modified climate data sets have been used as the input to the simulations. Results showed that in comparison to a hot region, a temperate region possesses a much inferior viability for open pond based algal biomass production. It was further shown that the importance of light supply is greater than temperature for improving the performance of an open algal pond operated in a temperate region, suggesting that additional light supply rather than heating is likely a more effective direction of intervention. It should be noted that experimental validation of the kinetic parameters currently taken from the literature is a critical step to follow, which is the ongoing work.

PSE opportunities in biocatalytic process design and development

Pär Tufvesson,[a] Ulrich Krühne,[a] Krist V. Gernaey,[a] John M. Woodley[a]
[a]*PROCESS, Department of Chemical and Biochemical Engineering, Technical University of Denmark, DK-2800 Lyngby, Denmark*

Abstract

Biocatalysis (the use of one or more isolated enzymes in soluble or immobilized form, as well as enzymes contained within resting whole-cells) is a rapidly growing area of process technology. The introduction of biocatalysis presents new opportunities to develop 'green' synthetic routes to pharmaceuticals and other chemical products, since enzymes usually work in an aqueous solution and under mild conditions. Nevertheless the implementation of a biocatalytic reaction and the integration of a biocatalytic reaction into an otherwise chemical catalytic sequence is a complex task where PSE tools have a particularly important role to play. In this paper we will present a variety of PSE tools including computational fluid dynamics (CFD), operating windows, kinetic modelling, economic analysis and environmental assessment to support the development of economically viable biocatalytic processes.

Keywords: process template, substrate adoption, methodology, pharmaceutical.

1. Introduction

Biocatalysis, the use of cells, enzymes (or parts thereof), is increasingly used in industry for the production of chemicals [1,2]. The technology is primarily used in the pharmaceutical and fine chemicals industries, but increasingly also in the production of lower value chemicals where high reaction selectivity can be exploited to yield a more competitive process. The main limitations are the limited operating space (e.g. temperature < 100°C) and potentially low productivity (kg product / kg catalyst). Successful processes need to be carefully balanced to give optimal process performance, while at the same time exploiting the capability of the biocatalyst to the maximum extent possible. Consequently, when developing a biocatalytic reaction or process it is necessary to have an understanding of the factors that determine the activity, stability and selectivity of the biocatalyst as well as the process requirements and constraints, and the interconnection between the biocatalyst and process performance. A number of biocatalytic processes have been successfully implemented in industry. Commonly these are developed on a case-by-case basis. However, for biocatalysis to achieve its full potential it would be highly desirable to introduce systematic process design methodologies and tools similar to those that are widely used in the development of conventional chemical catalytic processes. Further, although modern biotechnology offers huge possibilities to improve the biocatalyst, e.g. by directed evolution, to increase tolerance to solvents and temperature, as well as increasing the activity, this is a time consuming and expensive activity. Therefore, clear targets for the catalyst and the process are very important in order to develop an effective and competitive process. This is a complex task due to the many factors influencing the effectiveness of the catalyst and the process. In this paper we will illustrate how a Process Systems

Engineering (PSE) approach, and associated tools, can be used to facilitate this development.

2. The development procedure

The purpose of a structured framework for the development procedure is to simplify decision making and to direct work towards collecting the data required for these decisions as efficiently as possible. A simplified development procedure is shown in Figure 1 indicating the interactions between the process and catalyst development efforts and the PSE tools that could potentially be used. For example, CFD investigations in microfluidic reactor systems, offer excellent opportunities for assessment of kinetic parameters, material characteristics and in understanding of transport and reaction details [3,4]. The understanding gained by the virtual experiments can then be used in simulations of large-scale designs of new reactor layouts or operating strategies. The framework can address challenges such as what type of product removal system to integrate, how to supply reactant, how to choose the biocatalyst format, when to integrate operations and most importantly, how to set targets for protein engineering [5]. It is this latter challenge in particular which presents a new and exciting opportunity for PSE.

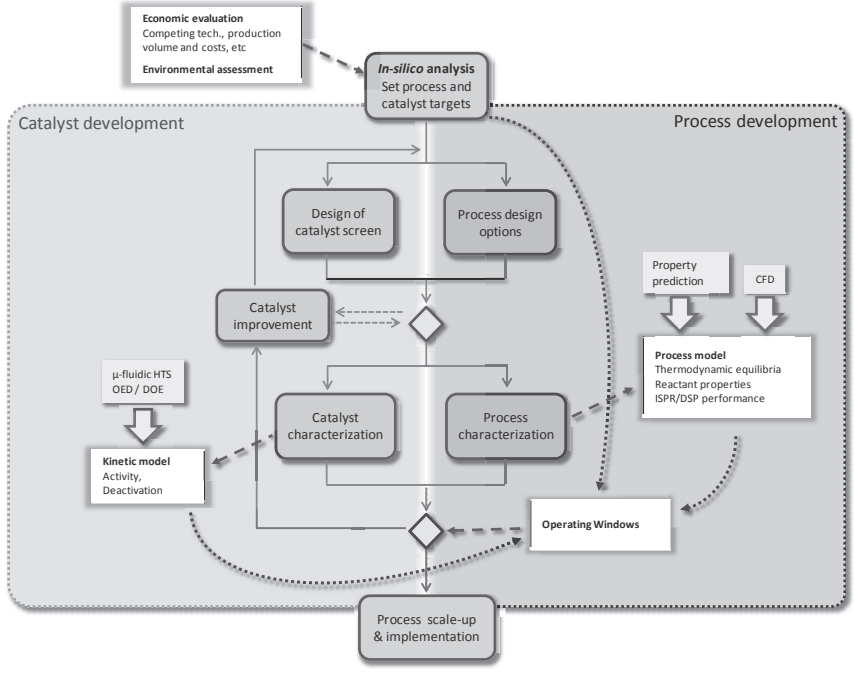

Figure 1. Biocatalytic process development procedure.

The procedure consists of different stages of development and strategic points, where a decision has to be made concerning: (1) whether to go on (or discontinue the project); and/or (2) if the catalyst needs to be developed further instead of spending additional efforts on the process. The so called 'Operating Windows' form a useful and easy to understand tool in order to facilitate the decision-making, to visualize the interactions between the biocatalyst and the process and to identify knowledge gaps [6].

3. Operating windows

An operating window is a tool to illustrate the interaction of multiple constraints on the feasibility of a process. There are four main classes of constraints that will define the operating window in the processes discussed here: (1) Economic – Allowed process cost; (2) Physico-chemical –Solubilities, reaction thermodynamics, etc.; (3) Biocatalyst – Activity and stability under different conditions, etc.; (4) Process – Separation, mixing, mass transfer. An example is given in Figure 2, indicating some of the limits for operation based on reaction product and co-product concentration, in this case for a transaminase catalyzed reaction.

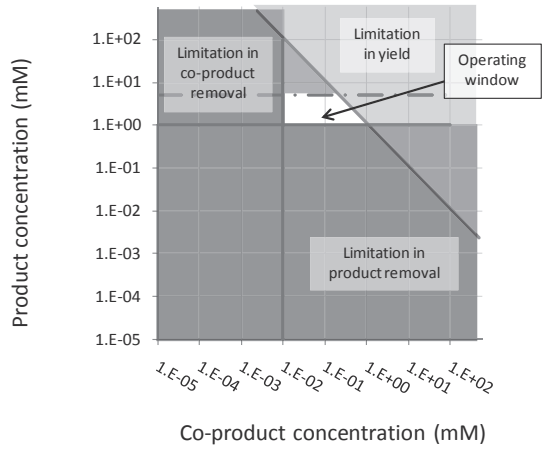

Figure 2. Operating window for the synthesis of an optically pure chiral amine based on simultaneous removal of product and co-product from the reactor.

Windows such as this can be used to dictate the requirements on the biocatalyst in an individual case - information that will be very valuable in early development. The data required for building the window will depend on the development stage. In order to be effective in choosing between the many different process options in early development, being able to make decisions based on rapidly available data is crucial. Experimental data are by their nature time consuming to acquire, which is why prediction tools for physico-chemical properties (e.g. thermodynamic equilibrium), computational fluid dynamics (CFD) simulations, as well as automated microreactor platforms and experimental protocols for rapidly collecting the relevant biocatalyst, as well as process data, would be highly valuable. Once sufficient data are available, the operating window can be refined on the basis of mechanistic process models [7,8].

4. Property prediction

Reaction and process characteristics such as the solubility of the compounds involved, the reaction equilibrium and stability of the compounds involved are independent of the biocatalyst but constitute essential information for selection of biocatalysts and operating methods. However, frequently reaction characteristics cannot be obtained from literature since the compounds involved when developing a new biocatalytic process are most often new compounds which frequently have not been studied before. Hence the required data must be obtained via experimentation. As the number of reaction and process options might be very large, the idea of property prediction is therefore to assist in narrowing down the search space for experimentation. For

biocatalytic reactions we have identified that predictive tools for water-solubility and thermodynamic properties are amongst the most important. The conditions under which a specific biocatalytic step operates make such predictions particularly challenging. In a recent study, a group contribution methodology for predicting metabolic fluxes *in-vivo* was developed, which could potentially be applied also for *in-vitro* biocatalytic reactions run in aqueous media [9]. However, this method proved to yield estimates with an unacceptable accuracy in a study of reaction sets relevant to biocatalytic transamination reactions, thereby clearly showing the need for substantial further research in this area [10].

5. Micro-scale reactors and Computational Fluid Dynamics (CFD)

The use of miniaturized systems to collect experimental data enables the benefits of parallelisation to save time. Indeed an increasing number of applications can be found in the scientific literature based on microfluidic principles. Miniaturized systems offer a range of important characteristics: (1) Use minute amount of samples and other expensive process materials (enzyme, substrate, etc.); (2) perform the experimental investigations faster than bench scale setups; (3) introduce favourable effects for the detailed investigation of material properties like diffusion coefficients or reaction kinetics due to the laminar nature of the fluid dynamic conditions; (4) can be easily automated; (5) can be more easily analysed numerically due to the absence of turbulence in the microchannels. An example of high content screening and numerical analysis by use of CFD is given in Figure 3a and b.

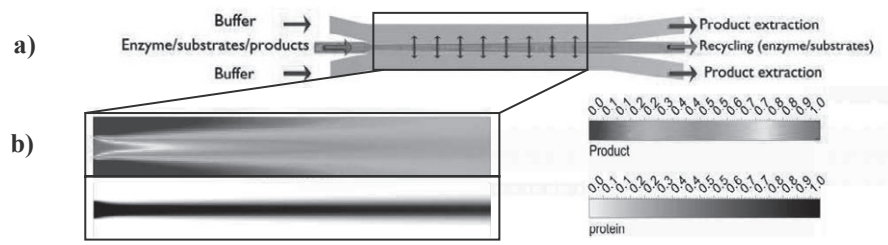

Figure 3 a) Principle of hydrodynamic focussing. Channel width 250 µm, depth 50 µm. **b)** CFD calculated concentration profiles for different components. Diffusion coefficients: Protein $1 \cdot 10^{-10}$ m^2/s Product $2 \cdot 10^{-9}$ m^2/s

Figure 3a shows an example of a miniaturized system in which the process stream of an upstream biocatalytic reactor is guided in between two buffer flows. By choosing the appropriate flowrates the residence time in the total system can be adjusted, as well as the sample width in the main channel. When the liquids flow through the channel a perpendicular material transport will take place due to concentration gradients (diffusion). The reaction medium will be composed of the enzyme, the reaction substrates and products. Each component will most likely have different diffusion characteristics, which commonly are poorly documented and might be different in an environment with changing liquid characteristics. According to the different diffusion rates different amounts of the respective substances will therefore be found in the three outlet channels. Varying the total flowrate and hence the residence time, the diffusion rates can thereby be determined. In Figure 3b a CFD simulation is shown for the investigated product, which is assumed to have a diffusion coefficient which is one order of magnitude larger than the diffusion coefficient of the biocatalyst. Selecting the

appropriate channel geometries along with the flowrate for the biocatalyst to be recycled into the reactor, a part of the product can be directly extracted through the side channels. This demonstrates one of the advantages of miniaturized systems in the field of accessing the process characteristic information. Setting up the systems with automated analytical equipment will furthermore contribute to the rapid assessment of key design information.

6. Economic assessment

For effective process development the use of economic assessment tools should be considered. Although full cost assessment is not possible at early process development stages due to a lack of reliable information about the final process, it is possible to identify critical process parameters and set development targets for the process and biocatalyst based on previous experience or literature data for similar processes. It has previously been shown how such an assessment could be used to set biocatalyst productivity targets for different types of biocatalytic reactions, ranging from small scale high value processes (pharmaceuticals) to high volume low value processes (bulk) [11]. The guidelines developed in such analyses have great value in serving as a first approximation for the process and biocatalyst development.

7. Future perspectives

In this paper we have discussed a number of PSE tools to potentially assist in the development of biocatalytic processes. The future will see the integration of such PSE tools which will enable more rapid and effective implementation of new biocatalytic processes. Collaborative efforts will be essential to further develop the tools. The testing of new methodologies will also be an important activity together with those that implement changes to the biocatalyst and those that design and implement new and retrofit processes.

Optimal Design of an Algae Oil Transesterification Process

C. Silva[a], L. A. Fabiano[a], G. Cameron[a], and W. D. Seider[a]

[a]*Department of Chemical & Biomolecular Engineering, University of Pennsylvania, 220 South 33rd St, Philadelphia 19103, USA*

Abstract

An optimization strategy for designing processes to convert algae oils to biodiesel is introduced. In this brief paper, just a typical oil sample is used, grown experimentally using *Nannochloropsis salina* algae in salt water by Solix and transesterified using the Catilin solid T-300 acid catalyst. NIST thermophysical property data in ASPEN PLUS and literature data were used to estimate the properties of the chemical species. Approximate group contribution methods were used to estimate missing properties.

A transesterification process was synthesized and simulated using ASPEN PLUS. For the transesterification reactor design, three reversible reactions were assumed. Because kinetic data were unavailable, pre-exponential factors and activation energies for the transesterification of palm oil were used, adjusted using residence-time data from Catilin for transesterification of an algal oil[1]. A USER2 FORTRAN subroutine was written to solve the CSTR mass balances.

The process was heat integrated to reduce energy consumption. Next, the Aspen Process Economic Evaluator was used to estimate equipment sizes and purchase and installation costs. In this brief paper, just the results for a single case study are presented. In a full manuscript, the optimization strategy for selecting the best algal oil is presented.

Keywords: Biodiesel, *Nannochloropsis salina*, Transesterification

1. Introduction

1.1 Background

Because of their compatibility with conventional combustion engines, biofuels are being considered as replacements for petroleum-based, liquid transportation fuels. Originally, beef tallow, plant-derived oils, and waste oils, were transesterified to biodiesel; however, in recent years, various strains of algae have been explored as sources of oil because algae grow in much higher density, using land and water that are unfit for terrestrial plant cultivation.

Because salt water is significantly cheaper and more plentiful than fresh water, the *Nannochloropsis salina* strain of algae, which is cultivated in salt water, is an excellent candidate for the production of biodiesel. This strain yields oil levels in excess of 50% (on a dry basis[2]), using mixotrophic conditions[3].

After the algae are grown, they can either be transesterified directly under super-critical conditions, or the oil can be extracted from the cells and converted at milder conditions using an acidic or basic catalyst; we have chosen the latter approach for this initial study. During the extraction, the triglycerides are separated from an algae-sludge using a standard hexane extraction procedure, yielding relatively pure triglycerides and a byproduct of residual algae biomass.

1.2 Transesterification Kinetics

One kinetic model for converting triglycerides to biodiesel is the three-reaction mechanism in Figure 1. In each reaction step, a fatty-acid group, attached to the glycerol backbone, is reacted with methanol to form a fatty-acid, methyl ester (FAME). First, the triglycerides are converted to diglycerides, which become monoglycerides, finally yielding glycerin.

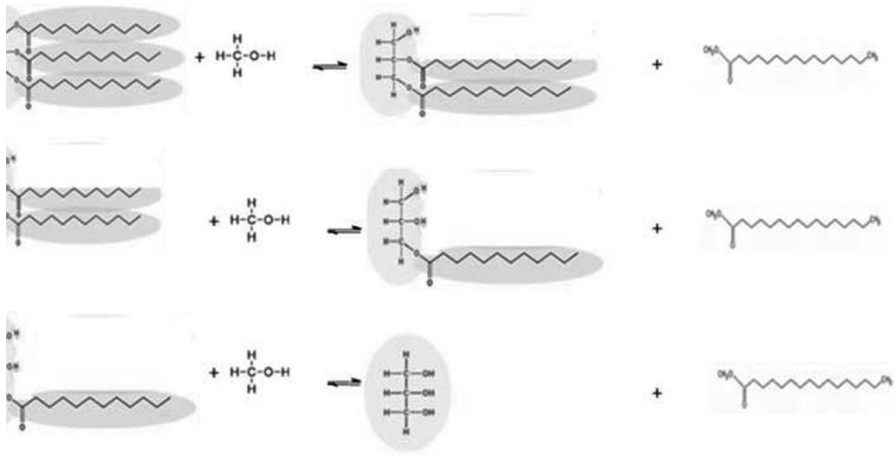

Figure 1. Transesterification Kinetics

This kinetic model is based upon the bench-scale Catilin process, which uses their proprietary T-300 solid-metal, acid catalyst for the conversion of triglyceride to FAME. We are using kinetic data for palm oil[1] (with modified activation energies to match Catilin-reported conversions for the transesterification of algae oil) to size the reactors.

1.3 Species Data

The thermophysical property data for triglycerides and their derivatives within ASPEN PLUS were extremely limited. ASPEN's databanks were supplemented with information from the NIST databank, which is interfaced with ASPEN PLUS for easy data-sharing; however, many important properties remained absent for key chemical species. Therefore, an extensive literature search was performed to obtain the missing properties.

Three sources were used for the Antoine equation parameters for the triglyceride and FAME molecules[4,5,6]; these data were nonexistent for the monoglycerides and diglycerides. Unsaturated bonds were assumed not to affect the Antoine constants or boiling points. When Antoine constants could not be found or regressed, boiling-point data were used[10,11]. When there was a disparity between two sources, the more recent source was used.

A similar search was conducted for density data, returning five sources[7,8,9,10,11]. Because ASPEN PLUS only accepts the density data at 60°C, whenever possible, the density was adjusted using linear interpolation. If an adjustment was not possible, and the data were at temperatures within 20°C of 60°C, the density was assumed constant over this range.

When pure component data were unavailable, they were estimated by ASPEN PLUS using the JOBACK group-contribution method[12]. Liquid-Liquid interaction parameters were calculated using the UNIFAC-LL group-contribution method, and

vapor-liquid interaction parameters were calculated using the traditional UNIFAC group-contribution method.

2. Process Analysis

2.1. Process Description

A process flowsheet based upon the Catilin bench-scale process is shown in Figure 2. Eventually, alternative syntheses will be considered. Algal-extracted triglycerides are mixed with excess methanol (7 mol methanol/mol triglycerides – containing catalyst pellets), heated, and sent to a CSTR, where they are converted to the FAME product and glycerol byproduct. The effluent is filtered to remove the catalyst (which is recycled to the reactor) before being sent to a decanter. The decanter separates the FAME (light phase) and glycerol (heavy phase) by gravity; methanol distributes itself between the two phases.

The light phase is sent to a second CSTR for further conversion. Its effluent is subjected to the same separation techniques, and is then sent to a distillation column, where the FAME (biodiesel) is recovered from methanol. The glycerol effluents from the decanters are combined and sent to a distillation column, where nearly-pure glycerol is recovered from methanol. The methanol effluents are recycled.

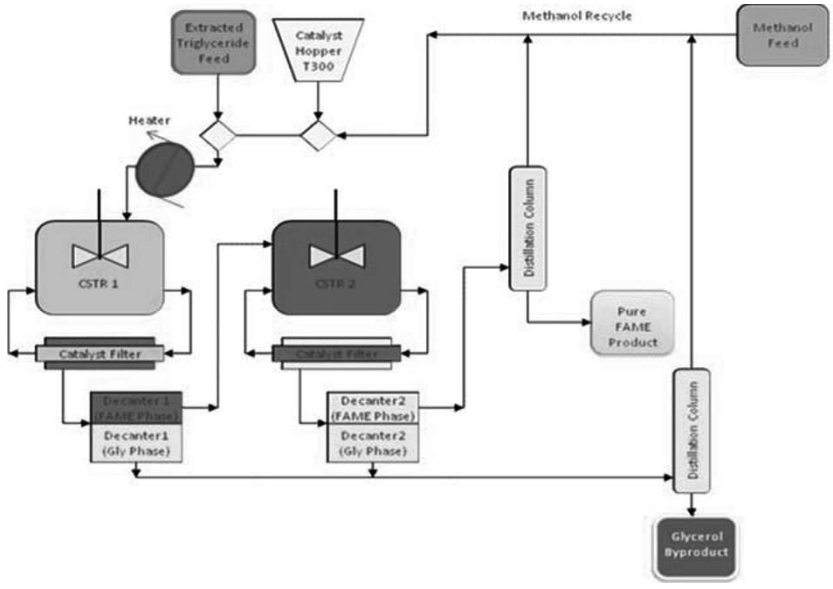

Figure 2. Modified Catilin Transesterification Process

The major material inputs and outputs from the process are shown in Table 1. Due to space limitations, stream data (temperatures, compositions, heat capacities, etc.) computed by ASPEN PLUS must be obtained from the authors. Note that 39,993 kg/hr is 0.003% of the biodiesel consumed daily in the United States in 2010[17].

Table 1. Major Process Inlet and Outlet Flow Rates

Stream	Triglyceride Inlet	Methanol Inlet	FAME Outlet	Glycerol Outlet
Flowrate (kg/hr)	39,735	4,623	39,993	4,364

2.2. Heat Integration

The heat capacities were averaged between the source and target temperatures for each stream, and then assumed constant. A pinch-analysis spreadsheet, produced by ICHEME, was used to determine the minimum utility targets. Stream matching was done using methods described in the literature[13]. Although the glycerol and FAME product streams were a source of heat for the "cold" streams, they were not cooled to room temperature (77°F); therefore, cooling water was not used to cool them.

The resulting system has 14 heat exchangers, including the condensers and reboilers for the two distillation columns: yielding hot and cold utility requirements of 2,450 KW and 1,820 KW, respectively.

2.3. Process Economics

Using Aspen's Economic Process Evaluator (AEPE), cost estimates for the transesterification process were computed. The total depreciable capital was estimated to be approximately 9 million USD. The key results are in Tables 1 and 2. The auxiliary costs include the costs of concrete and setting, structural steel, instrumentation, piping, insulation, electrical wiring, and paint.

Table 2. Costing Results for Process Equipment.

Equipment	# of items	Purchase Cost	Auxiliary Cost	Installation	Total Cost
Centrifugal Pumps	5	$ 22,700	$ 93,400	$ 67,200	$ 183,300
Decanters	2	$ 46,300	$ 213,500	$ 63,900	$ 323,700
Distillation Towers	2	$ 95,200	$ 286,000	$ 112,200	$ 493,400
Heat Exchangers	14	$ 192,700	$ 670,100	$ 327,500	$ 1,190,300
Pressure Vessels	2	$ 46,300	$ 213,500	$ 63,900	$ 323,700
Reactors	2	$ 178,200	$ 509,900	$ 103,500	$ 791,600
Total Cost of Equipment		**$ 581,400**	**$ 1,986,400**	**$ 738,200**	**$ 3,306,000**

Table 3. Costing Results for Yearly Recurring Costs.

Utilities per year		**Labor Costs per Year**	
Cooling Water	$ 15,300	Operating Labor	$ 320,000
Electricity	$ 35,900	Maintenance	$ 21,300
Heating Oil	$ 709,000	Supervision	$ 280,000
Total Utilities	**$ 760,200**	**Total Cost of Labor**	**$ 621,300**

Shell-and-tube heat exchangers, with surface areas estimated using overall heat-transfer coefficients of 730.87 kcal/hr-m^2-K (default in ASPEN PLUS), were used. The CSTR's were 95 m^3 (using a 1-hr residence time provided by Catilin). No costs for the T-300 catalyst were available. Also, the filter costs were neglected.

Cooling water (at 90°F, heated to 120°F) and heating oil were provided by a nearby utilities plant. Costs were \$0.075/1000gal and \$1.50/gal, respectively. A heating value of 146,100 kJ/gal was used to determine the amount of oil needed[14].

The hourly labor costs for operators and supervisors were estimated at \$20/hr and \$35/hr, respectively, with 330 operating days per year.

In terms of product and raw material costs, the diesel price (\$1.90/gal) was set at the wholesale price in 2009[15], and the price of methanol (\$1.16/gal) was extrapolated from a graph provided for 2008 and 2009[16]. The glycerol by-product is assumed to yield no profit; it is recycled to the cultivation process as feed for the mixotrophic algae. At

an investor's rate of return (IRR) of 20%, a triglyceride purchase price of $1.78/gal was estimated, very close to the diesel wholesale price, $1.90/gal. Clearly, to obtain diesel, this transesterication process adds a small increment to the cost of triglyceride oil.

3. Conclusion

In this brief paper, a strategy for designing transesterification processes is presented. In a full manuscript, the strategy is applied to select the best algal oil for production of biodiesel. The design optimization is based upon data for the transesterification of various algae strains using the Catilin T-300 acid catalyst. A combination of the ASPEN PLUS database, the NIST database, and an extensive literature search was used to obtain data to rigorously estimate thermophysical and transport data of the triglycerides and fatty-acid methyl esters (FAMEs). Herein, results for just a typical process are illustrated, prior to optimization. This process was heat integrated to reduce its utilities cost. Lastly, a profitability analysis shows that this transesterification process, using the T-300 catalyst, doesn't add significant capital or utilities costs.

Abstract

Singapore's petrochemical industry plays an integral part in the nation's economy. The industry is highly dependent on crude oil as the major feedstock. This could prove increasingly unsustainable with depleting fossil fuels resources and growing environmental concerns over greenhouse gases emissions. Using renewable feedstocks such as biomass is one possible solution. This paper evaluates the potential for bio-based chemicals production in Singapore's petrochemical cluster, focusing on polylactic acid (PLA). Cost and carbon footprint assessment of the PLA supply chain using various bio-renewable feedstocks sourced from the region is presented.

Keywords: sustainability, biomass, renewable materials, supply chain, carbon footprint.

1. Introduction

Singapore is one of the major centers for oil, gas, and petrochemicals in the world. This sector of industry has played an integral part in the growth of Singapore's economy. The centerpiece of Singapore's petrochemical industry is Jurong Island complex, which houses many of the world's leading petroleum and petrochemical companies. As of today, the total refining capacity of Singapore is 1.3 million bpd [1] and projected to increase by 300,000 to 500,000 bpd in the near future [2]. The current ethylene capacity is 2.1 million tons per year and projected to reach 4 million tons by 2014 [3]. The petrochemical industry in Singapore is heavily dependent on fossil fuel-based feedstock, mostly crude oil and natural gas. While Jurong Island is undergoing continual growth and expansion, depleting fossil fuels resources and increasing environmental concerns over the emissions (such as greenhouse gases) leads to a perception that, in the long run, a petrochemical industry solely reliant on fossil fuels is unsustainable.

The negative environmental impact the use of fossil fuels has on our earth is well-known. When fossil fuels are burned, carbon dioxide is emitted. As carbon dioxide is a gas which traps heat in the earth's atmosphere, the intensive use of fossil fuels is believed to have contributed to the increase in global surface temperatures over the past century. Another crisis arising from overdependence on fossil fuels is their rapid depletion. Fossil fuels are non-renewable, which means they are finite and might well run out in the near future – a study found that fossil fuels reserve depletion times for oil, coal, and gas are approximately 35, 107, and 37 years, respectively [4]. This rapid depletion might render petrochemical production increasingly unsustainable as fossil fuels prices continue to rise. Thus, alternative sources have to be found for continued production and growth of the petrochemical industry.

One possible solution is renewable feedstock such as biomass. This is due to the following reasons. Firstly, biomass in the forms of plants and organisms is abundantly available on earth. Secondly, biomass is considered to be carbon neutral [5]. Finally, due to the complex carbon backbone and existing chemical functionality, the processing of biomass along the chemical synthesis chain can significantly reduce the energy requirement as compared with the fossil fuels-based feedstock [6]. In this paper, we investigate the feasibility of incorporating renewables into the slate of feedstocks available for chemicals production in Jurong Island. We survey the chemicals currently produced in the cluster and identify potential bio-based chemicals that can be produced. A techno-economic assessment based on current technology is then conducted taking into account production quantities, costs, and conversion yields. The necessary supply chain is established and its cost and carbon footprints estimated.

2. Bio-based chemicals production

First generation feedstocks for bio-based chemical production are mainly derived from food biomass. Feedstocks used to produce bio-chemicals include vegetable oils/fats and sugars/starches. Examples include corn, sugarcane, cassava, soybean oil, castor oil, etc. Many of the bio-products derived from these first generation feedstocks are already in the market. Examples include NatureWorks' Polylactic Acid (PLA) and Cargill's BiOH® soy-based polyols. There was concern over first generation feedstocks due to their competition with food and land as food prices have been on the rise, and it was seen as irresponsible to grow food crops for energy or chemical use [7]. Hence, second generation feedstocks looked into lignocellulosic biomass, which can be found in plants, including crop residues. Examples include corn stover, sugarcane bagasse, and pulp and paper waste. Lignocellulosic crops are seen as better alternatives to first generation feedstocks as they not only have higher crop productivities, but are also widely available and do not compete with human food products. The main problem with lignocellulosic feedstocks, however, is in breaking down the chemical and structural biomass complex into sugars required for fermentation [8]. Most of the initiatives in producing bio-chemicals from second-generation feedstocks are currently only in advanced R&D or pilot scale [9].

The chemicals currently produced in Jurong Island were surveyed to determine which can be produced from biomass. This can be achieved in two ways:

1. Bio-based chemicals directly supplement existing chemicals derived from petroleum, e.g. bio-ethylene from sugarcane ethanol vs. ethylene from naphtha.
2. Bio-based chemicals possess new and improved properties for replacement of existing functionality or new applications, e.g. PLA derived from glucose sources vs. polyethylene from petroleum-based ethylene.

The shortlisted chemicals from the survey and their possible bio-alternatives are listed in Table 1. Due to space constraint, this paper focuses on PLA, which supplements petroleum-based polyethylene and polypropylene. PLA compares favorably to high density/low density polyethylene (HDPE/LDPE) and polypropylene (PP) in terms of its aroma barrier and grease resistance. It is also stiffer and has a higher modulus, but is more expensive. PLA compares unfavorably in terms of its water barrier. The two bulk producers of PLA, NatureWorks and PURAC, agree that PLA is likely to have partial technical substitution for HDPE, LDPE, and PP in terms of applications for resultant products. PLA also has potential for applications in other areas that do not commonly utilize polyethylene or polypropylene [10].

Table 1. Possible bio-alternatives for chemicals produced in Jurong Island [11]

Chemical	Current Route	Bio-alternative(s)
Acetic acid	Syngas	Converting biomass feedstock (e.g. cassava) to ethanol (using yeast) then to acetic acid
Ethylene	Cracking of naphtha/LPG	Distillation of ethanol derived from sugar/starch sources
Polyethylene (PE) and Polypropylene (PP)	Ethylene derived from naphtha/ LPG	a. Cellulosic plastics – from cellulosic biomass b. Polylactic acid (PLA) – from polymerization of lactic acid derived from glucose c. Polyhydroxyalkanoates (PHA) – from fermentation of naturally-occurring carbon substrate (e.g. cane sugar, corn, tapioca etc) d. PE from bio-ethylene
Polyurethane systems and Polyols	Ethylene glycol derived from naphtha-obtained ethylene	Vegetable oil-based polyols

Table 2. Yields of various feedstocks, in mass unit [11]

Feedstock (Intermediate)	Yields (in mass unit)			
	Feedstock	Intermediate	Glucose	PLA
Sugarcane (Molasses)	1000	43	23	17.2
Fresh cassava roots (Dry chips)	1000	450	299	227
Corn whole (Kernels)	1000	636	433	329
Sweet sorghum whole (Syrup)	1000	793	325	247

3. PLA production

PLA is an aliphatic polyester produced via polymerization of lactide, produced from lactic acid, which can be produced from sugars through fermentation. The physical and mechanical properties of PLA make it a good candidate for replacing petrochemical thermoplastics from polyethylene and polypropylene [10]. Raw materials that can be used include sugars and starches. Table 2 lists the yields from the various feedstocks to their intermediates, glucose, and PLA.

Lactic acid is produced from the fermentation of sugars. Sugar or starch is first extracted from the feedstock intermediates and then fermented by microorganisms. Fermentation of the obtained glucose produces lactic acid. The efficiency of this conversion is typically greater than 95% on carbohydrate substrate and can be either a batch or continuous process. The obtained lactic acid will then be purified to yield the product quality required for chemical synthesis [10].

There are two main routes to convert lactic acid to PLA. The first one is by direct polycondensation of lactic acid, and is carried out under high vacuum and high temperature. The product obtained tends to have low to intermediate molecular weight (MW 10,000 – 20,000) due to difficulties in removing water and impurities. The second method, utilized by NatureWorks and PURAC, the two largest producers of lactic acid, is a continuous process using ring-opening polymerization (ROP) of lactide. This method results in a higher molecular weight polymer and uses milder conditions [10].

4. PLA supply chain economic and environmental assessment

In this section, the supply chain for producing PLA in Jurong Island is established and the associated cost and carbon footprint estimated. Ten different combinations of feedstock and sourcing locations are considered: 1) cassava-Thailand, 2) cassava-Vietnam, 3) cassava-Indonesia, 4) cassava-China, 5) sugarcane-Thailand, 6) sugarcane-India, 7) sugarcane-Philippines, 8) sweet sorghum-China, 9) sweet sorghum-India, and 10) corn-China. For each, two different supply chain configurations are evaluated: A) Local (in the country of origin) processing of crops to intermediates, which are transported to Singapore via ocean freight, and converted to PLA in Jurong Island; and B) Crops are transported to Singapore via ocean freight, and converted to intermediates and then to PLA in Jurong Island.

Cost and CO_2 emission from each stage in the supply chain (i.e. cultivation, transport of crop, processing to intermediate, transport of intermediate, ocean transport to Singapore, and PLA production) are estimated using data gathered from literature sources [11, 12]. For carbon footprint, the CO_2 absorbed by the crops during their cultivation (carbon sink effect) is also included in the assessment [13].

Figure 1 shows the overall carbon footprint of the PLA supply chains from the 10 different feedstock sources. The carbon footprint of conventional petroleum-based PP is 5.43 kg CO_2/kg PP [12]. All the supply chains have better carbon footprint than the conventional PP. Furthermore, supply chains 5-10 (sugarcane, sweet sorghum, and corn) are carbon-neutral with negative carbon footprint. In Case B, the crops are transported instead of the intermediates, so more materials are transported and the carbon footprint is higher than Case A. Sugarcane has the lowest overall carbon footprint due to its low yield (Table 2); more sugarcane is required to make the same amount of PLA, thus resulting in a higher carbon sink effect.

Figure 2 shows the overall PLA supply chain cost from the 10 different feedstock sources, compared to the conventional petroleum-based PP cost of SGD1.94/kg [12]. It can be seen that under current conditions, PLA costs almost double the conventional PP and is not cost-competitive. It may become competitive if crude oil price increases or better technology gives higher PLA yield.

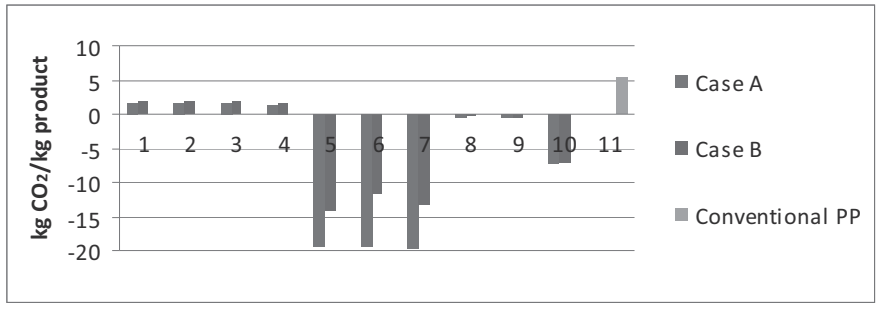

Figure 1. Carbon footprint of PLA supply chain with various feedstock sources

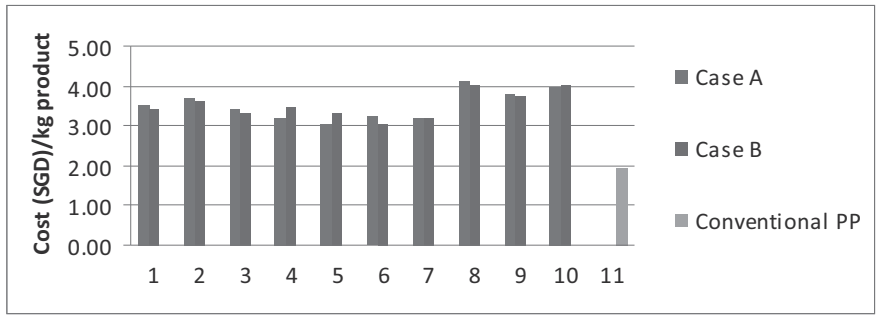

Figure 2. Cost of PLA supply chain with various feedstock sources

5. Conclusions

Bio-based chemicals production is a potential solution for increasing the sustainability of Singapore's petrochemical cluster. This paper particularly evaluates the potential for PLA production in Jurong Island using various feedstocks sourced from the region and assesses the overall cost and carbon footprint of the supply chain. It is found to be environmentally favorable but not economically competitive under current conditions. Further studies could involve other first and second-generation feedstocks and higher added-value chemicals. Also, the role of parametric uncertainty (such as conversion yields and processing costs) on the overall supply chain cost and the carbon footprint needs to be explored, given that most of the necessary technologies are in early stages of development.

Abstract

In the present work a systematic procedure, including process design and integration techniques, for sizing and operation optimization of a poly-generation plant integrated with heat storage systems is presented.
The storage system is used to balance energy demand fluctuation during 24 hours of a day. Adding thermal storage capacity allows for better utilization of equipments and avoiding over estimation of installed capacity. The integration of heat storage systems with poly-generation technologies in a multi objective and multi-period optimization model is the novelty of this work.

Keywords: Heat storage, Mixed Integer Linear Programming, Evolutionary algorithm, Renewable conversion technologies, CO_2 mitigation

1. Introduction

Poly-generation technologies, joined with the storage system, have a good potential for CO_2 emissions reduction in the district heating networks. A systematic optimization procedure is needed to select and size equipments and storage tanks.
The optimization of energy systems that include one or more technologies is extensively studied by many authors. It is referred to D.Connolly et al. (2010) for a detailed review. Most of these publications carried out only simulations, while system design optimization is neglected. For a detailed overview, the role of optimization modeling techniques in power generation is reviewed in Bazmi and Zahedi (2011). However, most of these optimization models only consider a mono economic objective function, completed with environmental and energetic targets as constraints.
On the other side, the integration of heat storage devices and conversion technologies in the energy system is studied in several publications. Soderman and Pettersson (2006) proposed a mixed integer linear model with mono objective function to integrate the storage tank with the cogeneration units in a district energy system. The MIP optimization model for sizing the heat storage tanks and a combine heat and power plant with mono

*samira.fazlollahi@epfl.ch

objective function is presented by Christidis et al. (2011) and Collazos et al. (2009), while long-term thermal storage is studied by Tveit et al. (2009).
To sum up, the energy system optimization with storage systems are studied by many authors. However, a systematic procedure including the heat storage systems and energy integration techniques with simultaneous consideration of multi-periods and multi-objectives aspects for optimizing a district energy system is needed. A multi-objective optimization model with evolutionary algorithms (EMOO) and MILP based on the decomposition approach was developed by Fazlollahi and Marechal (2011). It is extended with the integration of the thermal storage optimization model in the present work. The goal is to integrate heat storage system with other conversion technologies for optimizing a district energy system design.

2. Methodology

The multi-objective optimization techniques are used in order to investigate sizing and operating effects of poly-generation technologies and heat storage systems on CO_2 emissions. The basic concept of the developed model is the decomposition of the problem into several parts, as illustrated in Figure 1. Three major parts (Weber et al. (2006)) are; a **Structuring phase** in which required data will be collected and manipulated. Secondly the **Multi-objective nonlinear optimization phase** will solve the system configuration and produce results in the form of a Pareto frontier. In the third step, the **Post-Processing phase**, the Pareto frontier and associated results will be studied in details by doing a more details process operation simulation.

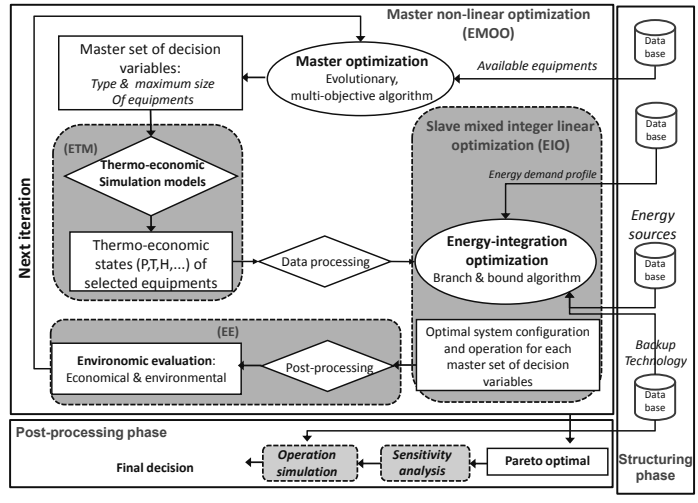

Figure 1. Illustration of the process optimization strategy

2.1. Multi-objective nonlinear optimization phase

The optimization algorithm has the aim of solving a complex non linear problem consisting of minimizing the investment costs (CAPEX), operational costs (OPEX) and CO_2 emissions simultaneously. The goal of this step is to optimize the system configuration and size the selected equipments including the storage system. This phase is decomposed in four major parts, a **master optimization (MOO)**, a **thermo-economic simulation (ETM)**, a **slave optimization (EIO)** where the best usage of equipments in the selected superstructure is calculated, and the **environomic evaluation (EE)**. For detail explanation on these steps, it is refer to the previous work of authors Fazlollahi and Marechal (2011). In the present work the slave optimization is extended by adding the heat storage model (Part.3). The storage model is considered as an equipment option to optimize the operation schedule.

3. Storage optimisation model

Heat for the district heating can be stored in heat storage tanks. The storage is used to manage the energy demand fluctuation during 24 hours of a day. Adding thermal storage capacity allows for better utilization of equipments and avoiding over estimation of installed capacity. There should be a trade off between the investment cost of additional capacity of conversion technologies and the storage system. Economical data of storage system were taken from Becker and Marechal (2012).

In the present work the thermal storage is divided into several temperature intervals, $S = 1,...,N_S$, between its maximum and minimum temperature limits. Each intervals is going to charge with the available excess heat by considering its corresponding temperature level during each time periods. When there is a heat deficit in the district networks the tank will be discharged to supply the heat requirement. For the heat storage tanks, it has been assumed that the total volume of the storage tanks is constant (Q^{max}) and the losses from radiation are negligible. Charging or discharging flow are activated throw the following two equations:

$$Fmin_S * \mathbf{y}_{S_c,t} \leq \mathbf{f}_{S_c,t} \leq Fmax_S * \mathbf{y}_{S_c,t} \qquad \forall S = 1,...,N_S \quad , \quad \forall t = 1,...,T \tag{1}$$

$$Fmin_S * \mathbf{y}_{S_h,t} \leq \mathbf{f}_{S_h,t} \leq Fmax_S * \mathbf{y}_{S_h,t} \qquad \forall S = 1,...,N_S \quad , \quad \forall t = 1,...,T \tag{2}$$

Where $Fmin_S$ and $Fmax_S$ are two parameters for showing the minimum and the maximum available capacity of each interval S. $\mathbf{y_{S_c,t}}$ and $\mathbf{y_{S_h,t}}$ are binary variables for activating the inlet flow and outlet flow of each storage's interval S in time t. $\mathbf{f_{S_c,t}}$ and $\mathbf{f_{S_h,t}}$ are continuous variables for showing the filling rate and discharging rate of each interval S in time t.

Input and output flows of each interval S should not be activated at the same time, as the heat content in the storage can vary. Eq.3 is used to present this condition:

$$1 - \mathbf{y}_{S_h,t} - \mathbf{y}_{S_c,t} >= 0, \qquad \forall S = 1,...,N_S \quad , \quad \forall t = 1,...,T \tag{3}$$

The net heat flow into each storage interval S at time t is shown by $(\mathbf{f}_{S_c,t}\dot{Q}^{-}_{S_c,t} - \mathbf{f}_{S_h,t}\dot{Q}^{+}_{S_h,t})$. Where $\dot{Q}^{+}_{S_h,t}$ is a parameter for representing the reference heat discharging of each storage interval, while $\dot{Q}^{-}_{S_c,t}$ shows the reference heat charging of the storage interval S at time t. The total charging load of the storage in the interval S is shown by $\mathbf{f}_{S_c,t}\dot{Q}^{-}_{S_c,t}$.

In this work a daily storage with 24 operating hours is defined. The heat content in the

storage must be the same at the beginning and the end of a day. This cyclic constraint is shown as following:

$$\sum_{t}^{N_t}\sum_{S}^{N_S}(\mathbf{f}_{S_c,t}\dot{Q}^{-}_{S_c,t} - \mathbf{f}_{S_h,t}\dot{Q}^{+}_{S_h,t}) * \triangle t = 0 \tag{4}$$

The heat load available in each storage interval S during each time period t, should be positive:

$$\mathbf{Q^0_S} + \sum_{p=1}^{t}(\mathbf{f}_{S_c,t}\dot{Q}^{-}_{S_c,t} - \mathbf{f}_{S_h,t}\dot{Q}^{+}_{S_h,t}) * \triangle t >= 0, \qquad \forall S = 1,...,N_S \quad , \quad \forall t = 1,...,T \tag{5}$$

Where $\mathbf{Q^0_S}$ shows the initial heat load (MWh) of each storage interval S. It is optimized by the optimization model. As mentioned before, the maximum size of the storage is constant and set by the user as an input data, while the size of each interval S is optimized through the optimization model.

$$\sum_{S}\mathbf{Q^0_S} =< Q^{max}, \tag{6}$$

3.1. Illustrative example

The proposed model is demonstrated by means of a case study, where the district heating demand should be supplied by a central plant. Available equipments in the central plant are; fuel-oil, biomass, coal and natural gas boilers, gas turbine and incinerator. Economical and technical data of each technology were taken from Fazlollahi and Marechal (2011). The first graph in Fig.2 gives the optimal outlet power of each equipments with-

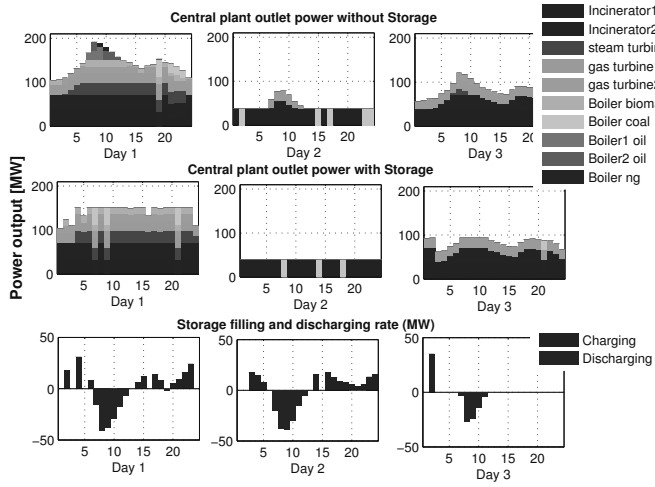

Figure 2. Comparison between a plant's operation condition with and without storage tank

out storage tanks for 3 typical days of a selected year. While the second graph shows

the optimal outlet power of each equipments integrated with storage tanks. Finally, The third graph gives the storage tank level for the second situation. The number of tanks, the volume and the initial level of storage tank are optimized by using the developed model. From the results it appears adding thermal storage capacity allows for better utilization of equipments, avoiding over estimation of installed capacity and managing the energy demand fluctuation during 24 hours of a day.

4. Conclusion

A systematic procedure including the storage system, process design and energy integration techniques with simultaneous consideration of multi-periods and multi-objective aspects, economic and environment targets, for energy system design and operation is explained. A decomposition approach is used to deal with this complexity. The heat storage optimization model is introduced in the optimization phase in order to manage the energy demand fluctuation during 24 hours of a day. Adding thermal storage capacity allows for better utilization of equipments and avoiding over estimation of installed capacity.

Improved Strains for Biological Treatment of Wastewater

Shilpi Aggarwal[a], Chia Pei Lyn[a], I A Karimi[a]

[a]*Dept. of Chemical & Biomolecular Engineering, National University of Singapore, Singapore 117576*

Abstract

Nitrogen is one of the most abundant nutrients present in wastewater. The removal of excess nitrogen is a crucial step in wastewater treatment because of its detrimental effects on the human health and environment. Biological nitrogen removal processes are widely used owing to their flexibility and lower operating costs. *Nitrosomonas europaea* is widely used in the nitrification step of the biological nitrogen removal process. However, these biological treatments are unable to efficiently reduce nitrogen content to the desired low levels required to meet the discharge quality standards that are becoming stringent over time. Two of the main reasons for the lower efficiency of these processes are the low growth and nitrogen removal rates exhibited by *N. europaea*. Efforts to improve the efficiency of *N. europaea* are hindered by the lack of information about its integrated metabolic network. In this work we report the first genome-scale metabolic network of *N. europaea*. The model consists of various metabolic pathways and activities based on the organism's genome annotations and biochemical literature. The model has been validated using growth and nitrite production data taken from the existing literature.

Keywords: Wastewater Treatment, *Nitrosomonas europaea*, Metabolic Model.

1. Introduction

The stringent water quality standards prescribed by the environmental agencies for safe disposal of wastewater have made its pretreatment an essential operation. The increasing population and industrialization have further intensified the problem of wastewater generation and the need for its intensive treatment. Nitrogen is one of the most abundant nutrients present in waste water (Zhu et al., 2008). It occurs commonly in the form of ammonium ions resulting from the degradation of organic nitrogen (such as urea and fecal material) and other nitrogenous substrates. The wastewater treatment to reduce nitrogen content to safer levels is crucial as any excess of it can exert harmful effects on both the human health and environment. One of the main concerns of the presence of nitrogen in wastewater is eutrophication – a natural phenomenon in which water bodies, such as lakes and ponds, becomes eutrophic typically due to runoff of minerals and organics (Abeliovich, 1992). Nitrogen has been identified as one of the important rate-limiting nutrients in the eutrophication process. Further, if wastewater is recycled for potable purposes, the presence of excessive nitrogen in drinking water can initiate a variety of health issues in humans such as methemoglobinemia or blue-baby syndrome, a condition in which the presence of nitrates interferes with the body's ability to take up oxygen from the bloodstream. This can lead to neurologic and cardiac symptoms, and even brain damage or death under severe conditions. Considering these harmful impacts of excess nitrogen in wastewater, several biological and physiochemical processes have been devised for nitrogen removal. Of them, biological

treatments for nitrogen removal are preferentially used owing to their flexibility and low cost.

The biological process for nitrogen removal from wastewater is carried out in two steps i.e., nitrification followed by denitrification (Zhu et al., 2008). The nitrification step in turn involves two steps. The first step in nitrification involves oxidation of ammonium to nitrite via the intermediate compound hydroxylamine while the subsequent step is the oxidation of nitrite to nitrate. The denitrification step involves conversion of the nitrate to nitrogen gas that is released in the air. The first step of nitrification i.e., oxidation of ammonium to nitrite is carried out by ammonia oxidizing bacteria (AOB). *N. europaea* is identified as the one of the most suitable and widely employed bacteria owing to its relatively higher growth rates than other possible AOB such as *Nitrospira* (Wells et al., 2009). However, the nitrification and growth rates exhibited by *N. europaea* are usually lower than the desired levels which lead to inefficient nitrogen removal. Moreover, the low growth rates and long generation times prevent detailed biochemical studies of *N. europaea*'s metabolic network. Since the various cellular phenotypes arise as a result of integrated functioning of various biochemical activities, it is essential to study the entire metabolism as a whole. The complexity of metabolic networks makes it difficult to study and comprehend their integrated properties intuitively. Genome-scale modelling provides an easy way to study the properties of complex metabolic networks and biochemical activities of an organism using mathematical modelling. However, any such model or a holistic study of *N. europaea* is unavailable in literature.

In this work, we present the first genome-scale metabolic model of *N. europaea*. It incorporates the information about *N. europaea*'s metabolic network based on its genome annotations and other biochemical literature. It has been successfully validated using the data available in literature (Schmidt, 2009) for growth on two different carbon sources namely pyruvate and lactate. It also successfully predicts the nitrite production data taken from a published article (Güven and Schmidt, 2009). We have used the model to compare effects of different carbon sources on its growth.

2. Model Development

Generation of an *in silico* metabolic model requires the complete information on metabolites and their associated reactions relevant to the domain of the model, inclusion of transport reactions, biomass composition of the microorganism under consideration and a gene-enzyme association (Suthers et al., 2009). The reported model is based on the stoichiometry and biochemistry of reactions that describe the overall metabolic and biosynthetic functions of *N. europaea*. The KEGG (Kanehisa and Goto, 2000) and MetaCyc (Caspi et al., 2008) biochemical database were used to obtain genome annotations and the associated reactions for the first draft of the model. Due to the unavailability of biomass composition for *N. europaea* in literature, we have adapted the biomass equation from *E. coli*, the model organism (Edwards et al., 2001). Transport reactions are included to account for the uptake and release of nutrients from the medium. Constraints on these transport reactions are applied by restricting the uptake or release of the metabolites into or out of the metabolic system respectively. However, due to gaps and broken pathways several reactions are included from literature to bridge these gaps and enable *in silico* growth. During model reconstruction several possible new genome annotations are identified during the gap filling process. The final reconstructed model accounts for 516 open reading frames (ORFs)

corresponding to 651 reactions (633 intercellular, 18 transport) associated with 332 genes. Flux balance analysis (Raman and Chandra, 2009) is used to solve the model using the metabolic network management software tool MetaFluxNet (Lee et al., 2003).

3. Model Validation

Experimental data is indispensable for model validation. The reconstructed genome-scale model of *N. europaea* is validated by simulating the experiments of Schmidt (2009) and Güven et al.(2009). The model has been solved by simulating the various experimental conditions defined in above studies and the model predictions are compared against the reported experimental observations.

Schmidt (2009) studied the growth of *N. europaea* on pyruvate and lactate as the sole carbon sources under anoxic conditions. During their experiments they measured the carbon source and nitrate uptake rates, cell growth and CO_2 excretion rates at different times. We used their data to measure the specific uptake, excretion and growth rates. We simulated their anoxic conditions in the experiments by constraining the supply of oxygen to zero. Further, the model was solved by constraining the specific carbon source uptake and specific growth rates while maximizing the CO_2 production rates. As seen in Figures 1 and 2, the model predictions are in close agreement with the experimental data for both carbon sources.

In another study (Güven and Schmidt, 2009), the authors have investigated the nitrite formation under aerobic conditions using carbon dioxide as the sole carbon source. We inferred that the nitrogen source, ammonium was limiting as its depletion triggered the stationary phase in their experiments. Therefore, we simulated their experiment by constraining the specific ammonium uptake rate at their experimental values while allowing unrestricted supply of CO_2. We solved the model by setting the maximization of nitrite formation as the objective function. It was also reported by the authors that all of the ammonia supplied was not converted to nitrite. According to them, approximately 20% of nitrogen was lost in the form of gaseous nitrogen compounds which the model predictions do not account for. Thus, the results predicted by the model were adjusted to account for these losses and are found to be in comparable to the experimental data as seen in Figure 3.

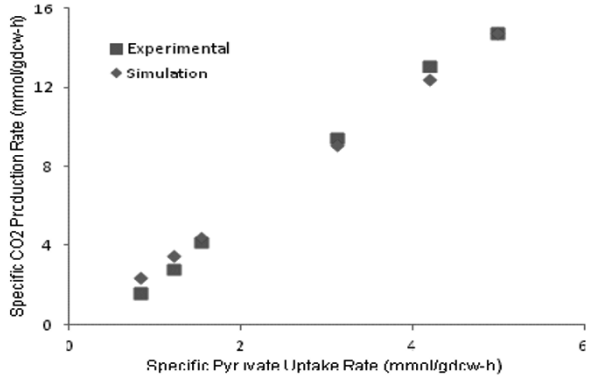

Figure 1: Specific carbon dioxide production rate vs. specific pyruvate uptake rate based on experimental data from Schmidt (2009)

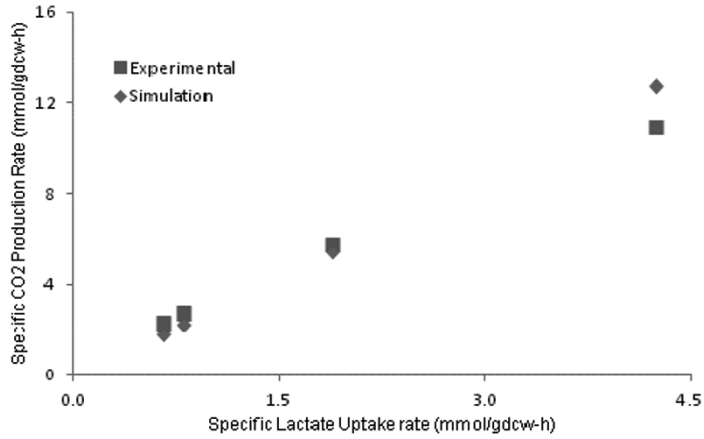

Figure 2: Specific carbon dioxide production rate vs. specific lactate uptake rate based on experimental data from Schmidt (2009)

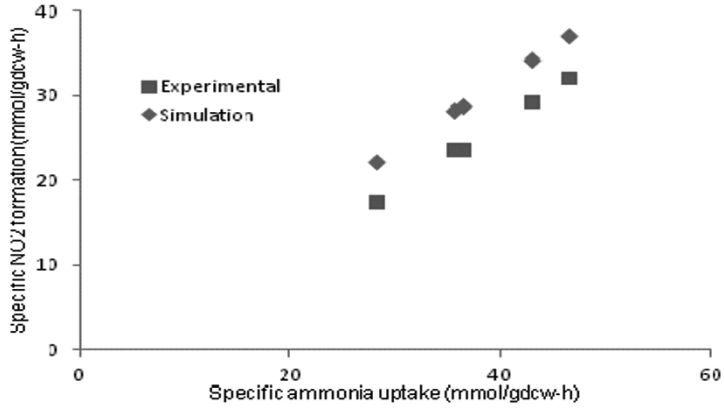

Figure 3: Specific NO_2 formation rate vs. specific ammonia uptake rate based on experimental data from Güven et al.(2009)

4. Model Analysis

Consistent with the findings of Schmidt (2009), the model exhibits growth under anaerobic conditions with nitrite as an electron acceptor using pyruvate, lactate, acetate, serine, succinate or α-ketoglutarate and fructose as the sole carbon source. It also shows that serine can replace ammonia as a nitrogen source by conversion to pyruvate and ammonia, in which the latter is liberated into the medium, as postulated by Schmidt (2009). We used our reconstructed model to compare the effects of various carbon sources on the growth of *N. europaea* under experimental conditions described by Schmidt (2009). We calculated maximum specific growth rate obtained for fixed uptake rate (20mg/gdcw-h) of each carbon source. The model predicted the suitability of carbon sources for growth per carbon atom in the following order, pyruvate (0.058 1/h-C atom as 100%) > lactate (97.7%) > serine (83.8%) > succinate (74.6%) > α-ketoglutarate (60.2%) > fructose (48.8%). This trend is fairly consistent with the published data(Schmidt 2009). We also noticed that under unrestricted conditions when

biomass maximization is used as the objective function, there is no excretion of CO_2 by the model. However, in the experiments, *N. europaea* has been found to excrete considerable amounts of CO_2 as a byproduct of respiration while growing on any of these carbon sources. This shows that there is a considerable diversion of carbon flux towards undesirable CO_2 formation than the desired growth. This observation is of high importance and can be used to improve *N. europaea*'s growth rate by altering or redesigning its respiration.

5. Conclusion

This work presents the first genome-scale metabolic model of the nitrifying bacterial strain, *N. europaea* and provides key information on the organism's cellular metabolism. Several possible new genome annotations have been identified that account for the missing functionalities in the existing annotations. The model is successfully validated using the experimental data available in literature. The proposed genome-scale model of *N. europaea* can greatly complement experimental efforts by providing concise explanations for the observed metabolic phenotypes and establishing links between metabolic entities on a genomic level. More importantly, the versatility of the reconstructed model gives it the potential to serve as a reliable platform for proposing new hypotheses and devising metabolic engineering strategies to redesign the interactions among the various host functions in *N. europaea*. It can therefore, aid the design of improved strains with enhanced nitrogen removal.

Abstract

The anaerobic *Zymomonas mobilis* has been acknowledged as a promising microorganism for bioethanol production due to its numerous advantages over the popular bioethanol producer, *Saccharomyces cerevisiae. Z. mobilis* has higher sugar uptake, higher ethanol yield, and tolerance to higher ethanol concentration. Despite of many advantages of *Z. mobilis*, the wild strain ferments only glucose, fructose, and sucrose. Nevertheless, recent studies have successfully engineered strains, which were capable of fermenting xylose and arabinose. Several advanced studies were conducted to acquire more information regarding the physiology data that can be used to improve the production yield. These studies have so far been limited to time and resources consuming experimental work. Therefore, the use of biological model can enable a systematic approach for *Z. mobilis* strain improvement

To this end, we developed a complete model of *Z. mobilis* by reconstructing a genome-scale metabolic network. We built the stoichiometric model of *Z. mobilis* ATCC31821 (ZM4), based on its annotated genome and biochemical information. The reconstructed model successfully predicts the experimental observations of *Z. mobilis* ZM4 growht on glucose. The intracellular flux distribution obtained from the model analysis is in close agreement with NMR-measured fluxes in engineered strain fueled by various carbon sources (glucose, fructose and xylose). Further, comparative performance analysis with other ethanol producers (*E. coli* and *S. cerevisiae*) and gene essentiality analysis have also allowed us to confirm the functional role of *pdc* and *adh* genes in the ethanologenic activity of *Z. mobilis*, thus leading to better understanding of this natural ethanol producer.

Subsequently, we explored the *Z. mobilis* metabolic capacity for organic acids production, particularly lactic acid, acetic acid, and succinic acid. We performed gene deletion analysis on central metabolic reactions and the results suggested that pyuvate is the key metabolite in *Z. mobilis* fermentation and knocking out the competing pyruvate-consuming reactions could lead to increased production of desired product. Thus, this finding could be used as assistance for conducting strain improvement to enhance organic acids production in Z. mobilis.

Keywords: Genome-scale metabolic network, *Zymomonas mobilis*, acetic acid, lactic acid, succinic acid, systems biotechnology

1. Introduction

Zymomonas mobilis is known to have high catabolic rate and high glucose uptake rate for anaerobic fermentation. It produces ethanol as its main fermentation product and

several organic acids, such as acetic acid, lactic acid, and succinic acid as a minor fermentation product under anaerobic conditions (Johns et al., 1991). As minor by-products, the aforementioned organic acids are typically produced at the yield of 0.0025-0.014 (g/g). The high catabolic rate and high glucose uptake rate of *Z. mobilis* is expected to tackle the low organic acid productivity issue in anaerobic fermentation. Moreover, the low biomass yield of *Z. mobilis* could also benefit the production process, as most carbon fluxes would be directed for metabolites production instead of biomass growth.

As *Z. mobilis* produces low yield of organic acids, it requires strain improvement to increase its production. Recent studies have shown that genome-scale models could be useful to investigate the metabolic behavior of the strain of interest, to formulate hypothesis, and to evaluate *in silico* the potential genetic modification for strain improvements (Blazeck and Alper, 2010; Patil et al., 2004). Several methods have been designed to select the genes candidates that could give the best result in metabolite production target, namely OptKnock (Anthony P. Burgard, 2003), OptStrain (Pharkya et al., 2004), OptFlux (Rocha et al., 2010), OptForce (Ranganathan et al., 2010). The achievement of those studies utilizing genome-scale model to assist experimental studies for genetic engineering has prompted us to explore the possibilities of employing genome-scale model of *Z. mobilis* to provide metabolic engineering strategis to enhance *Z. mobilis* capability as an organic acids producer. In this study, we evaluated *Z. mobilis* metabolism for organic acids production, using constraint-based flux analysis of the genome-scale metabolic model. In particular, we carried out the knockout simulation to propose optimization strategies for overproducing organic acids in *Z. mobilis*.

2. Materials and Methods

2.1 Genome-Scale In silico Z. mobilis Metabolic Model

We have developed the genome-scale metabolic model for *Z. mobilis* ZM4 (ATCC31821), *iZM*411 based on its genome annotations (Widiastuti et al., 2011). This model comprises of 748 reactions and 704 metabolites, classified into 48 specific pathways or subsystems based on their functional role. It includes the metabolic pathways i.e. central metabolism, amino acid metabolism, lipid metabolism, cell wall metabolism, and vitamin and cofactor metabolism along with the necessary transport reactions for extracellular metabolites. Biomass equation is derived from the drain of various biosynthetic precursors and relevant cofactors into *Z. mobilis* biomass at their appropriate ratios to quantify the cell specific growth rate.

2.2 Constraint-Based Flux Analysis

Mass balance on various metabolites under the steady state assumption gives a set of linear equations with reactions fluxes as unknown quantities. It leads to an underdetermined system, as the number of metabolites constraints is less than the number of unknown fluxes to be determined. Thus, unknown flux distribution can then be evaluated by applying linear programming to find optimum value for a given cellular objective by using known uptake rates as the constraints in the model. In this study, the objective function considered was maximization of biomass growth. The modeling and simulation for flux distribution calculation were carried out by using the metabolic

network management program MetaFluxNet (Lee et al., 2003) and General Algebraic Modeling System (GAMS) 23.2 platform (McCarl, 2009). For the simulation, we assumed anaerobic growth by setting oxygen uptake to zero and set glucose uptake rate to be 10 mmol/gDCW/hr.

2.3 Gene Deletion Analysis

Gene deletion analysis was performed by applying additional constraints to the current linear flux model. This analysis was carried by deleting individual reactions associated with the genes from *in silico* models, and the alteration in flux distribution as the consequence of the absence reaction was evaluated. For the simulation, we assumed anaerobic growth on glucose by setting glucose and oxygen uptake rates at 10 mmol/gDCW/h and zero, respectively. Biomass maximization for a steady-state metabolic network, comprised of a set N = {1,…, *N*} of metabolites and a set M = {1,…, *M*} of reactions, can be expressed in the following linear program ,

maximize $v_{biomass}$

$$\text{subject to} \quad \sum S_{ij} v_j = 0 \qquad \forall\, i \in \text{N},\ \forall\, j \in \text{M}$$

$$y_j.lb_j \le v_j \le y_j.ub_j,\ \forall\, j \in \text{M},\ y_j = \{0,1\}$$

$$M - \sum_{j=1}^{M} y_j = n \quad \forall\, \text{j} \in \text{M},\ \text{n} = \text{number of genes deleted}$$

where S_{ij} is the stoichiometric coefficient of metabolite i in reaction j, v_j is flux value reaction j, and y_j is binary variable with 0 for deleted reaction and 1 for active reaction. Gene deletion conducted in this study was for single (n=1), double (n=2), triple (n=3), and quadruple (n=4).

3. Results and Discussion

From the central metabolism (presented in Figure 1) that consists of glycolysis, pentose phosphate pathway, tricarboxylix acid (TCA), and anaplerotic reactions, we narrowed down the genes candidate for disruption and further enumerated the gene deletion analysis on metabolite reactions of the central carbon metabolism of *Z. mobilis*. The 59 genes corresponded to 66 central metabolite reactions was sequentially disrupted in gene deletion analysis (as described in Method). The simulation results are presented in Figure 2. The maximum yield obtained for acetic acid, formic acid, lactic acid, and succinic acid was 0.98, 0.8, 1.9, and 1.4 mol/mol respectively. it is interesting to see that different number of genes knockout required for oveproducing each organic acid. Maximum acetic acid yield was resulting from three genes knockout of pyrucate decarboxylase (*pdc*), acetaldehyde dehydrogenase (*adh*), and lactate dehydrogenase (*ldh*) while maximum lactic acid yield could be obtained by double knockout of pyrucate decarboxylase (*pdc*) and acetaldehyde dehydrogenase (*adh*). Succinic acid overproduction required higher number of knockout genes as its maximum yield could be reached by quadruple genes knockout of acetaldehyde dehydrogenase (*adh*), pyruvate formate lyase (*pfl*), lactate dehydrogenase (*ldh*), and citrate lyase (*cl*) and slight increase of production could be obtained by additional knockout of pyruvate decarboxylase (*pdc*) gene.

From these results, we could also observe the simulated fermentation profile of *Z. mobilis*. Knocking out one of two genes required for ethanol production (*pdc* or *adh*), which is *Z. mobilis* main fermentation product, was the first step to overproduce other fermentation products. Next preferred fermentation product after ethanol was lactic acid that could be produced at its maximum yield by inactivation of ethanol production related genes (*pdc* and *adh*). This observation could be explained by similar fermentation profile of ethanol and lactic acid. Both ethanol and lactic acid production required one mol NADH for every mol product. .

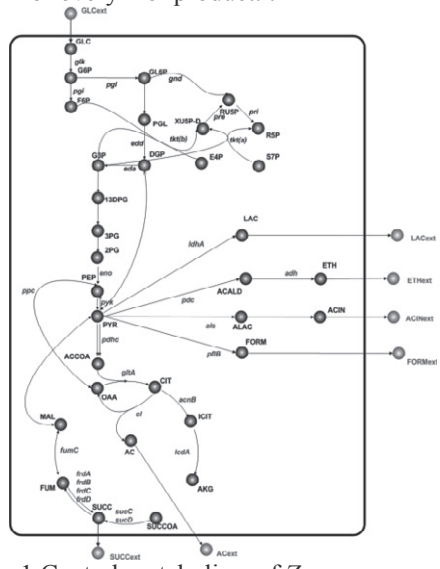

Figure 1 Central metabolism of *Zymomonas mobilis*

Different observation could be seen from the formic acid fermentation. Eventhough formic acid is also a direct product conversion from pyruvate, its maximum yield is lower than lactic acid. Formic acid production involved ACCOA and OAA in the conversion reaction from pyruvate. Thus, these two cofactors balancing in the cell might be the reason why formic acid cannot be produced in high amount as lactic acid.

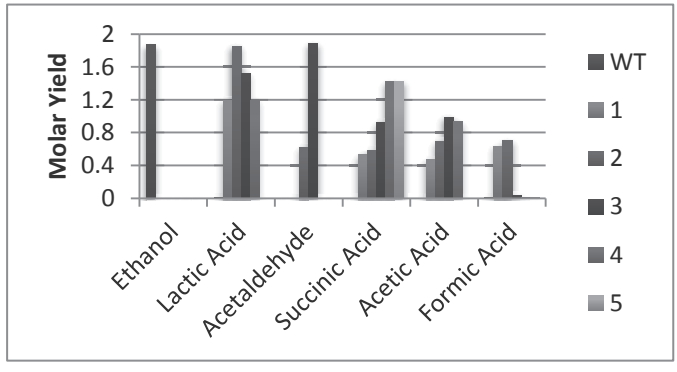

Figure 2 Simulation results for gene deletion analysis on central metabolism reactions of *Zymomonas mobilis*

Cofactor balancing might also pay important roles in acetic acid and succinic acid production as these two acids could only be produced in lower yield than lactic acid. Moreover, these two acids production required more reaction steps compared to lactic acid production.

It was concluded from the gene deletion analysis that all overproducing of organic acids in *Z. mobilis* required the inactivation of pyruvate decarboxylase (*pdc*) gene. Therefore, the deletion of the competitive pyruvate-consuming fluxes is very important for desired organic acid acid production.

4. Concluding Remarks and Future Work

Based on the *in silico* simulation results, it was shown that competing pyruvate-consuming reactions need to be inactivated for the enhanced production of desired organic acid in *Z. mobilis*. In addition, it was also observed that cofactors might affect the *Z. mobilis* fermentation performance particularly for the switching from ethanol to organic acid production. Thus, we would further evaluate the *Z. mobilis* fermentation characteristic from the metabolites point of view by incorporating flux sum analysis in the form of attenuation analysis and intensification analysis. This analysis could be useful to investigate particular metabolites that could play important roles in organic acid production, which could then be applied for medium formulation.

CFD simulation of cracking tube with internal twisted slices

Nan Zhang, Bingzhen Chen, Tong Qiu

Institute of Process System Engineering, Chenical engineering, Tsinghua University, Beijing 100084, P. R. China

Abstract

This work investigated the effectiveness and limitation of twisted slices applied in thermal cracking process. Stiff cracking kinetics was first integrated into a 3D simulation of specially configured cracking tube with twisted slices, through a comprehensive rigorous computational fluid dynamics (CFD) approach. The CFD analysis indicates that reasonable placement of twisted slices could efficiently make changes at the micro scale and flow behaviors within a certain tube length. This leads directly to thinner boundary layer, and further increasing the capacity of cracking furnace, inhibiting coke formation, extending the operating cycle but slightly postponing reaction start-up. Simulation results can be used as scientific guide for further technical retrofit and operation improvement.

Keywords: twisted slice;CFD; cracking tube; heat transfer intensification; cracking kinetic

1. Introduction

In the radiant section of cracking furnace, the thermal cracking process is highly coupled with turbulent flow, heat transfer and mass transfer. The cracking tube is both the heating load carrier and the cracking reaction channel. The undesirable coke formation and thermal fatigue damage of tube wall are two major factors restraining operating period that have aroused concerns of heat transfer intensification. At present most cracking furnaces adopt the smooth tube design, thus methods of transfer intensification are limited to changes in tube arrangement, diameter and number. This work investigated the effectiveness and limitation of twisted slices recently applied in thermal cracking process. This technique performed well in recent pilot experiments, but the transfer and reaction behaviors are temporarily unavailable due to measurement limitations. We adopted the CFD technique to inspect the influence of twisted slices on transfer behaviors. The major difficulty is to incorporate the complete cracking kinetics into severely turbulent process gas in the 3-D simulation since the cracking mechanism is invariably stiff and computationally costly.

Simulations of smooth cracking tube were given by Joo [1] , Heynderickx et al. [2], and Oprins et al. [3]. Lan et al.[4] investigated the influence of tube diameter and spacing on ethylene furnace. As to the special tube type, Han[5] investigated the local flow field of a 2.1m tube section with one twisted slice. Yuan [6] studied the plum blossom-shape tube, mixing element and swirling element in a 5.1m tube with cracking reactions ignored.

Compared with aforementioned papers, this work first integrated the stiff kinetic cracking scheme with a rigorous CFD model of a plant level *CBL-I* cracking tube successfully. Results are compared to industrial data with verification. The effectiveness and limitations of twisted slices was illustrated. Besides the change of flow pattern and the capacity enhancement, the introduction of stiff kinetics has made it possible to analyze the mutual interaction between temperature distribution and the control of cracking reactions. Results can be used as scientific guide for further technical retrofit and operation improvement.

Fig.1. showed schematic representation of the North CBL-I Cracking Furnace. The 16-group tube design and 2-1-1-1 type are adopted. Each coil tube takes four passes through the furnace. Detailed structural Parameters of the cracking tube and feedstock composition are presented in Tab.1~2.

Tab.1. Structural Parameters of *CBL-I* cracking tube

Type	*Number of passes*	*Wall thickness* （*mm*）	*Internal tube diameter(mm)*	*Length* （*mm*）	*Tube spaces*

2. Modeling Approach

2.1. Turbulence-chemistry interaction model

We simulated the turbulent cracking gas based on a Reynolds-averaged k-ε model and used a control-volume-based method in Fluent to convert the non-linear governing equations of mass, momentum, energy, turbulence and species to discretized and linearized scheme which were further solved in implicit Gauss-Seidel linear solver. A molecular cracking mechanism[7] involves 23 reactions is implemented and it's valid over a wide range of operating conditions and feedstock especially for light hydrocarbons. Finite-rate/eddy-dissipation model is adopted to take into account of turbulence-chemistry interactions based on the work of Magnussen and Hjertager[8].

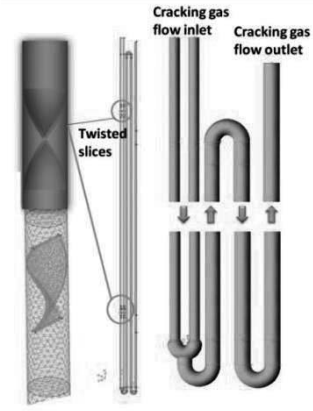

Fig.1.Schematic representation of the cracking tube and inserted twisted slices

2.2. Grid construction and boundary conditions

The platform of gambit 2.2.30 is used to create a 3D full geometry of the plant level CBL-I furnace coil tube. Unstructured tetrahedral cells are used for the complex grid around twisted slices, elbows and T-joint pieces. The number of grid varied from 0.5 to 0.7 million depending on the number of twisted slices. The inlet boundary condition is determined as mass flow inlet and specified as 24000kg/h for total 32 coils inlets. Non-slip condition is specified both on the tube wall and the surface of twisted slices. Industrial data of heat flux profiles are written in Scheme language and compiled into the Fluent solver.

2.3. Grid independent test and model validation

We utilized the initial solution and perform reasonable mesh refinement and adaption based on the work. Tab.3 represented the comparison between our simulation results of smooth tube and industrial data. They coincide well with regard to yields, cracking tube outlet temperature (COT) and inlet/outlet pressure.

Tab.3. Comparison between Industrial smooth tube data and simulation results

Yields(%)	H_2	CH_4	C_2H_4	C_2H_6	*Aromatics Others*	COT (K)	Coil Outlet/Inlet pressure (Mpa)
Simulation results	2.09	10.17	34.74	12.43	3.78	1109.78	0.1284/0.2094
Industrial data	1.85	10.60	33.13	12.67	3.56	1115.15	0.1287/0.2187
Absolute error	0.24	-0.43	1.61	-0.24	0.22	-5.37	-0.0003/-00093
Relative error(%)	12.97	-4.06	4.86	-1.89	6.18	-0.48	-0.23/-4.25

3. Result and discussion

3.1. Flow behavior of the cracking gas system

The enhancement of heat transfer inherently links to the change of flow pattern of cracking gas. Simulation results have proved the internals could efficiently turn the flow pattern

within a certain tube length. Fig.2 showed the tangential velocity distribution and effective disturbing distance. Two groups of slices (at the height of 3m and 11m, L=147.5mm, twisted ratio=2.2) were placed into the abreast tubes of the 1st pass.

It was found that the tangential velocity increased rapidly from 0.1202m/s to a peak value of 68m/s while cracking gas enters into the vortex generation area. The swirl intensity of the cracking gas comes to its maximum at the terminal of the twisted slice before the flow gradually moved out of the vortexes, with facet average tangential velocity of 20.27 m/s. Then the axial velocity augmented along the tube until almost reaches almost the same value of the scalar velocity magnitude of 144.32 m/s. At the same time the disturbance brought by the twisted slice gradually faded away while the tangential velocity returned back to 0.07924m/s. Compared with previous simulation of smooth tube, the radial velocity distribution of downstream cracking flow has a more flat shape, and larger gradients value near the tube wall region.

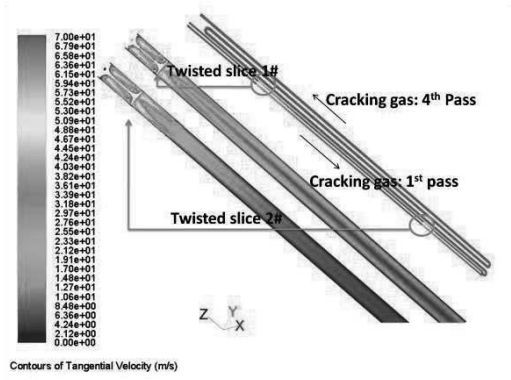

Fig.2. Tangential velocity distribution and effective distance of twisted slices

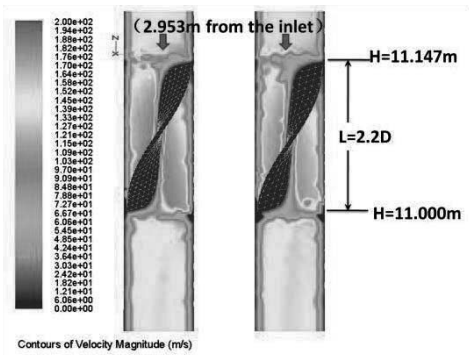

Fig.3. Velocity magnitude around the first twisted slice: (a) X=0 cross-section (b) Y=0 cross-section

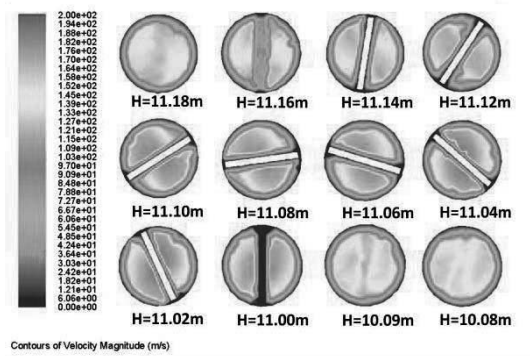

Fig.4. Distribution of velocity magnitude around the first twisted slice at different cross sections

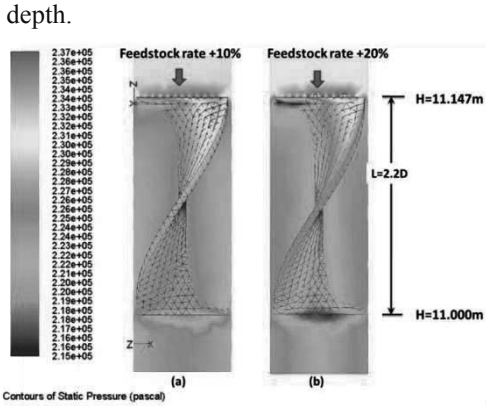
In the present simulation, the above process occurs at both two groups of twisted slices in a like manner. However, the effective distances of the two appear to be significantly different. For the slice near the inlet(1#), the downstream cracking gas undergoes longer affected distance of 3.16m (≈47D) , while in contrast, the slice near the tube joint part (2#), the effect only lasts for 1.88m (≈28D) and quickly faded away. This difference can be explained by the mutual disturbance between the slice and the T-joint part, and is partially due to a larger upstream velocity before the cracking gas flow through twisted slice 2#.

While the twisted slices efficiently change the local plunger flow to swirling pattern and brought a desirable thinner boundary layer, the undesirable body resistance is unavoidable. The gas flow become constricted as the area available for flow decreased and transformed into two transient vortex parts as depicted in Fig.4. However, in Fig.3 we notice that the gas does not undergoes obvious drop in velocity magnitude and the resistance loss is mostly reflected on the pressure drop. The sustained velocity is meaningful since it suggests twisted slices

won't increase the residence time of cracking gas, which in turn won't decrease the reaction depth.



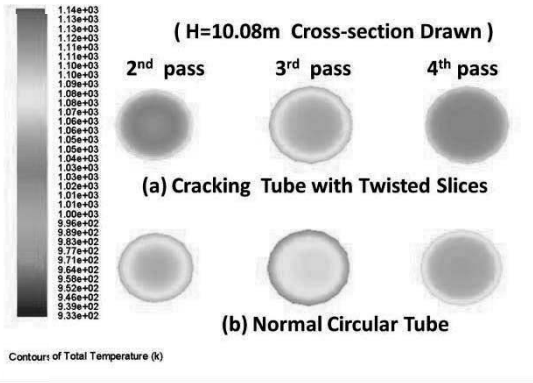


Fig.5. Pressure drop around the twisted slice section: (a) +10% feedstock rate; (b)+20% feedstock rate

Fig.6. Reduction of temperature gradient and thickness of boundary layer

3.2. Analysis of furnace capacity and pressure drop

Under the general operating conditions, the full length overall pressure drop of the base case is 0.081Mpa. The increase of the feedstock rate is accompanied with extended pressure drop (0.098Mpa for 10% more capacity and 0.110Mpa for the one of 20% more capacity). Fig.5 showed that the higher capacity case has experienced a more severe pressure loss and the low-pressure area is wider. With the existence of twisted slice, the facet averaged pressure has experienced a steep drop of 9.9Kpa in case (a), while in case (b) the pressure loss spread to 12.2Kpa. Large feed stock capacity directly brought a rise in Re number, and further increasing the pressure loss brought by the body resistance of twisted slices.

3.3. Temperature distribution and coking delay

Smaller temperature grads are of great importance of extending operating cycle and decreasing fuel consumption of the furnace. Simulation results showed a visualized alleviation in temperature distribution near the wall region. The symmetrical vertical vortexes generated by the twisted slices can serve as a source of flatting temperature distribution and the effect could last in the subsequent three passes. Fig.6 showed the comparison and the color variation revealed the sustained effect on lowering temperature grads in vicinity of tube wall. Specifically, at the cross-section of H=10.08m the coil wall with slices only have to bear a wall temperature of 1083.4K, 1106.7K and 1097.7K in following 3passes, compared with a 13.9 ~18.9 K higher wall temperature of 1102.3K, 1120.6K and 1114.0K in the absence of twisted slices. This decrease coincides with the industrial reported value of 10~20K[9].

3.4. Analysis of Kinetics Control

The integration of detailed reaction mechanism in present work makes it possible to analyze the complete interaction between heat transfer behavior and cracking reaction in a deep insight. Reactions generating C_2H_4 are the first to start up and its mass concentration reaches 0.062 at the end of 1st pass, 0.201 and 0.286 for the 2nd and the 3rd pass, respectively. At the terminal of 4th pass, the concentration of C_2H_4 is maximized with a outlet facet average value of 0.3474. Similar analysis is applied to C_3H_6 and C_4H_6. A similar trend with a initial notable start-up at the bottom of the 1st pass and an equilibrium in the middle of the 4th pass has been observed. From the perspective of technical retrofit, this analysis indicates the 1st pass hasn't been sufficiently utilized, while the 4th pass is too longer in the investigated CBL-I furnace.

A kinetic control analysis also revealed the interaction between temperature alleviation and

kinetic control. Take the consumption rate of C_3H_8 for example, among all reactions that directly involving C_3H_8 consumption, $C_3H_8 \rightarrow C_2H_4+CH_4$ and $C_3H_8 + C_2H_4 \rightarrow C_2H_6+C_3H_6$ contribute most and dominates the profile of C_3H_8 concentration along the total tube length. Fig.7 contours the reaction rate of the two reactions. We utilized the symmetric structure of 1st pass and pick off the slices in right side tube while keeping slices in left side, the results suggested that the side tube without slices insertion can start up cracking reactions prior to the other side. And a neutralization of the reaction rate is observed at the joint part. This point is in good agreement with the alleviated temperature profile and means that a trade-off between long operating cycle and quickly start-up reactions is needed.

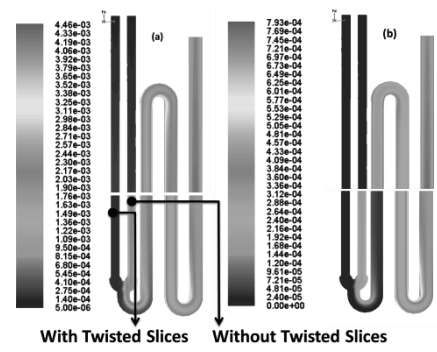

Fig.7.Reaction rate of $C_3H_8 \rightarrow C_2H_4+CH_4$ and $C_3H_8+C_2H_4 \rightarrow C_2H_6+C_3H_6$

4. Conclusion and prospect

This work presented a 3D simulation of a plant level cracking tube with twisted slices. Stiff cracking kinetic was first integrated to CFD model of this specially configured tube type. The model scheme was validated. Simulation results proves the sustainable effectiveness of twisted slices in turning flow pattern and illustrates the reasonable placement of the slices. The resistance loss brought by the slices is mostly reflected on pressure drop and the reaction depth won't be influenced. A visualized alleviation in temperature distribution near the tube wall and a sustained effect of reducing boundary layer, aiming at delayed coke formation and extended operating circles, are demonstrated. Analysis of kinetic control suggests that the 1st pass hasn't been sufficiently utilized, while the 4th pass is too longer in the investigated CBL-I furnace. The trade-off between long operating cycle and quickly start-up reactions is needed, due to the slightly delayed reaction start-up brought by the twisted slices. Multi-objective optimization of cracking tube with twisted slices could be necessary for further research.

CFD-Based Optimization of a Flooded Bed Bioreactor for Algae Production

Justin Smith,[a] Selen Cremaschi,[a] Daniel Crunkleton[a]

[a]*Department of Chemical Engineering, The University of Tulsa, 800 South Tucker Drive, Tulsa, OK 74104, USA*

Abstract

Algae show great potential for use as a feedstock for energy applications, but the cost of production must be reduced to compete with traditional feedstocks. One method of doing so is to optimize the algae production photobioreactor. This study presents the method of obtaining, and results of, such an optimization using a model derived from computational fluid dynamics simulations.

Keywords: Computational Fluid Dynamics, Optimization, Algae Bioreactor, Neural Networks

1. Introduction

Traditional biomass sources such as wood, corn, and sugarcane can be problematic as replacements for fossil fuel feedstocks because they require land currently used for other purposes. These traditional fuel crops can take from months to years to grow and be harvested, at which point the cycle must be repeated if more biomass is to be obtained. As an alternative, algae-based biofuels have been suggested because they can produce more than 100x as much oil as traditional fuel crops, while growing on low-quality land and brackish or salt water [1].

To realize algae's full potential for energy applications, it is necessary to determine the best growth methods and conditions. In principle, one can develop a mathematical programming model with the objective of maximizing algal oil production, constrained by processing and growth models to determine the optimum growth method and conditions. Algae growth could be, and has been, modeled with overall mass, momentum and energy balance equations, though using no more than these equations provides only a top-level view of the growth, which does not capture many important small-scale phenomena that may contribute to large-scale changes in algae biomass production. One such small-scale phenomenon is hydrodynamics, because many algae growth techniques, such as open ponds and photobioreactors, use geometries in which fluid flow and the resulting nutrient concentrations are important. Therefore, computational fluid dynamics (CFD) models which capture the fluid flow in an algae growth reactor, combined with algae growth models, such as the Monod equation [2], are useful tools to model the algae growth in ponds and/or photobioreactors. However, the use of CFD models as part of the optimization problem is computationally expensive, because each CFD simulation can take from several hours to several weeks on a multiprocessor workstation for convergence.

Two possible methods of large-scale algae production are open ponds and enclosed photobioreactors. While it is possible to create an open pond with a very large surface

area exposed to light, ponds, being open to the atmosphere are much easier to become contaminated, compared with enclosed photobioreactors [3]. Therefore, a column type reactor [3] was chosen as the model for algal growth in this study. Packing was included to increase the mass transfer from air to the liquid phase. We developed an artificial neural network (ANN) to replicate a packed bubble column CFD model outputs, formulated a nonlinear program with the objective of algae growth rate maximization using the developed ANN, and obtained the optimum packed bubble column design and operating conditions, which include column geometry, packing geometry, gas and liquid flow rates, and carbon dioxide (CO_2) concentration.

2. Algae Growth Model

2.1. Photobioreactors

Algae growth in the photobioreactor is modeled by the Monod equation, Eq.(1), because it is widely used to model growth of single celled organisms [4], including algae [2]. For a carbon limited environment, the molar concentration of inorganic carbon species CO_2 and H_2CO_3, *i.e.,* the total molar inorganic carbon concentration expressed as C_T, in Eq. (2), is used as the [*S*] for the Monod Equation [2]. The values for M_{max}(0.07 hr^{-1}) and k_s(2.3*10^{-6} mol/L) in Eq. (1) were chosen for *Chlorella sp.* at 27°C and 600 foot-candles of light [2].

$$M = M_{\max}([S]/([S]+k_s)) \tag{1}$$

$$[C_T]_{water} = \underbrace{0.002*[CO_2]_{water}}_{[H_2CO_3]_{water}} + \underbrace{\xi*[Air]_{water}}_{[CO_2]_{water}} \tag{2}$$

The total molar inorganic carbon concentration was calculated based on the amount of air bubbled through the photobioreactor using CFD, combined with known equilibrium relationships for the different carbon species [5]. A custom user-defined function (UDF) was developed to determine the mass transfer of air into the liquid phase separately for the packed and unpacked regions of the reactor. Specchia's [6] correlation was used for the packed region, while the correlation of Akita and Yoshida [7], was used to determine mass transfer in the unpacked regions.

2.2. CFD Simulations

The packed column photobioreactor CFD model was developed in FLUENT 6.3 as a transient 2D simulation with per-phase k-ε turbulence and full Eulerian multiphase model with a uniform mesh of 0.005 m x 0.005 m nodes. Column hydraulic diameter and boundary turbulence intensity as defined in equation 7.2-1 of the FLUENT 6.3 manual [8] were used to define turbulence boundary conditions. Gas and liquid enter the column at the bottom and exit at the top, with the packed region centered on the midline of the column. Each simulation was performed twice, once with no mass transfer to estimate the pressure drop in the packed region for use in the Specchia mass transfer correlation, and again with the diffusion UDF turned on to determine the concentrations of gas in the liquid phase. The second simulation for each case was run with second order discretization for each equation other than volume fraction and a phase coupled semi-implicit method for pressure-linked equations (SIMPLE) pressure-

velocity coupling [8]. Simulations were terminated when the volume average growth rate for the column is constant to within 5 x 10^{-5} hr^{-1} over 10 time steps, sized to ensure that the Courant number is less than one, a necessary condition for convergence.

3. Optimization Models

3.1. CFD Simulations Test Ranges

The design variables considered in this study are given in Table 1. While literature refers to the optimal column height as approximately 4 m [9], heights of 0.5 - 6 m were chosen as the minimum and maximum in this study to ensure the variable space would contain the true ideal column height. The minimum physically possible column diameter was taken to be 5 cm, with 0.5 m chosen as the maximum based on light penetration studies [10]. The ranges for the packing parameters, void fraction, and packing diameter were chosen to cover many different packing geometries. The liquid Reynolds number ($Re_L = (\rho U_L D)/\mu$) range covers both laminar and turbulent flow regimes, while the concentration of CO_2 in the gas phase ranges from atmospheric to a slightly CO_2-enriched conditions.

After the range of each input variable was determined, Latin Hypercube sampling was used to generate the test matrix for the CFD simulations to understand the impact of different levels of each variable on algae growth.

3.2. Optimization Model and Results

The concentration of air in the liquid phase ($[Air]_{water}$) for all nodes in each column was extracted from its respective FLUENT simulation and systematically reduced to the same number of nodes as the simulation with the fewest nodes. For example, if the least number of nodes was 3, and a simulation had 9 nodes, simulation nodes 3, 6, and 9 were kept and the rest were removed. The value of $[Air]_{water}$ at each node was used to calculate the maximum possible algae growth rate by Eqns. (1, 2). The concentrations of inorganic carbon species other than CO_2 and H_2CO_3 were assumed to be insignificant as they are 10^7 times smaller than $[CO_2]$ [5]. The values of M for all nodes were averaged to find the mean algae growth rate for each column.

Table 1.Minimum and Maximum Values of the Photobioreactor Design Variables

Parameter	Minimum	Maximum
Height (m)	0.623	5.89
Diameter(m)	0.093	0.5
Packing Void Fraction	0.259	1
Packing Height (as % of Column Height)	6.56	90
Liquid Reynolds Number (Re_L)	1114	25000
Superficial Gas Flow Rate (m/s)	0.013	0.149
Gas CO_2 Concentration (%)	0.127	0.889
Packing Diameter (m)	0.004	0.049

The average algae growth rate data was then used to create the vector $\boldsymbol{V}$, in which each simulation corresponds to a column. The test matrix was used to create a matrix $\boldsymbol{X}$, where each variable corresponds to a row and each sample corresponds to a column.

Both $\boldsymbol{V}$ and $\boldsymbol{X}$ were rescaled so that the entire range of each individual variable was over the range of [-1, 1].

Matlab 7.8.0 was used with vector $\boldsymbol{V}$ as targets and $\boldsymbol{X}$ as inputs for Matlab's ANN training tool with the Levenberg-Marquardt backpropagation training algorithm to train an ANN with a mean square error (MSE) of 0.0362 for the training data, and 0.1748 for the test data. Of the 23 CFD simulations, 74% was used for training the ANN, 13% was used for validation, and the remainder was used for testing. The final ANN consists of 8 inputs, 1 hidden layer consisting of 3 neurons using a tangent sigmoid function, and one output layer using a linear function. The weights and biases of the ANN are given below in Table 2.

Table 2: Weights and Biases of the trained ANN

$W_1(i,r)$	1	2	3	4	5	6	7	8
1	0.539	-1.969	0.089	-2.143	1.011	-0.576	0.454	0.257
2	-0.805	-0.740	0.626	-1.597	-0.560	-1.051	1.227	0.929
3	-0.106	-0.379	-1.192	0.425	1.207	2.776	-0.058	0.399

	W_2		B_{1r}	B_2
1	-0.911	1	-2.698	-0.459
2	0.108	2	0.012	
3	0.524	3	2.926	

The generated ANN was used to formulate a nonlinear program (NLP) (Eq. (3)) to maximize average algae growth. The NLP was formulated in GAMS version 23.6 and solved using BARON version 9.0.6.

$$\begin{aligned} &\text{Decision variables} && x_i && \forall i \in \{1,2,\ldots,8\} \\ &\text{MAX} && y = B_2 + \sum_r \left(W_{2,r} * \left\{ \frac{2}{1+\exp\left(-2 * \sum_i \left(W_{1,ir} * x_i\right) + B_{1,r}\right)} \right\} \right) && \\ &\text{Subject to} && -1 \le x_i \le 1 && \forall i \end{aligned} \tag{3}$$

where i is the index of the decision variables, B is the input bias, and W is the weight. The neurons in the hidden layer are represented by r, 1 represents the hidden layer, and 2 the output layer. The optimum solution ($M = 0.07$), indicates that the maximum algae growth occurs at the conditions given in Table 3. When a CFD simulation was run with these parameters, average growth rate was found to match the ANN to within 1.33%.

Table 3. Design Variable Values of GAMS solution

Height (m)	Diameter (m)	Porosity	Packing Height (%)	Re_L	Superficial Gas Flow Rate (m/s)	$[CO_2]_G$ (%)	Packing Diameter (m)
0.623	0.496	0.614	13.89	1114	0.149	0.889	0.049

3.3. Conclusions and Future Directions

While a solution for the "highest" growth rate is given for the tested portions of the experimental space, several of the runs gave average growth rates within less than 1% of M_{max}. As the amount of dissolved carbon dioxide, and therefore theoretical growth rate increase within a column along its height, it is plausible that algae growth rate may not have much of a dependence on the amount of carbon present or that the dependence may become much more pronounced at lower levels of carbon.

Future work will involve development of a reduced order model for algae growth which maintain the accuracy of the CFD solutions while using only a fraction of the time and computational power that would be required for a new CFD simulation, as is the case with using the average algae growth rate. Work will also be directed towards testing 3D simulations of the same columns, and determining the effects of using both light and carbon as limiting substrates.

4. Nomenclature

M	specific growth rate	M_{max}	maximum specific growth rate
[S]	limiting nutrient coefficient	k_s	half saturation coefficient
ξ	% CO2 in Air	H_2CO_3	carbonic acid
CO_2	carbon dioxide	$[C_T]$	total inorganic carbon concentration

Abstract

In general, growing particle deposit in reactor cyclone duct has caused operational safety problems as well as a decrease of the cyclone efficiency. In this paper, Computational Particle Fluid Dynamics (CPFD) simulation for forecasting the behaviors of particle deposit formation in cyclone duct in Residue Fluidized Catalytic Cracking (RFCC) process is carried out. The CPFD simulation based on Multi-Phase Particle In Cell (MP-PIC) method in which particle phase is based on a stochastic particle model using the Lagrangian method and fluid phase based on an Eulerian method. We aim at analyzing the flow patterns of both particles and fluids, depending on the different sizes and shapes of the cyclone duct. As a result, we found that low speed zone existed on the duct 90° (inlet position 0°) at the initial time. Some particles passing out of main flow path tend to stick to the wall of the cyclone duct due to its low speed. A set of regions where particle deposit formation takes place are set as a start point for CPFD simulation. The deposit grew up to the size of 90mm thick, and sometimes fell off due to scouring phenomenon, which results in plugging in the dipleg, leading to serious problems such as carryover.

Keywords: RFCC, CPFD, cyclone, deposit, MP-PIC

1. Introduction

The atmospheric distillation process of crude oil, the atmospheric residue, and valueless products are produced about 50% of the amount of crude oil. The upgrading process produces valuable liquid products such as LPG, kerosene and gasoline from the residue cracking reaction. Residue Fluidized Catalytic Cracking (RFCC) process is a typical upgrading process. The cracking reactions of the residue are done by injection of catalysts in the riser. After the cracking reactions the product gases go to the reactor cyclone with catalysts. The reactor cyclone for RFCC process is used to separate catalysts from product gas.

However, a serious problem was reported that a deposit formation took place at the duct of the reactor cyclone, which has negative effects on the efficiency of the reactor cyclone and safety of operation. The deposit formation mechanism reveals that wetted catalysts with heavy hydrocarbon stick to the wall. The catalysts usually flow along their way with clumping together. The deposit formed in the low speed zone of the cyclone duct with some escaped particles from a clump of particles.

We knew that velocity magnitude of gas-solid has a decisive effect on the deposit formation in the reactor cyclone. So we analyzed flow pattern of gas-solid. In the previous CFD-DEM model for the simulation, K.W. Chu et al. (2011) developed to describe the gas–solid flow in the gas cyclone. It is verified by its successful capturing the flow features in the cyclone such as the flow pattern of particles along the cylinder wall in strands, and the decrease of pressure drop and tangential velocity after loading solids.

We analyzed velocity magnitude of particles depending on the different design of cyclone duct. It is important that the particle velocity of the cyclone duct has consistency with the level of inlet velocity. It decreases the deposit growth rate and improves the efficiency of the cyclone. This study suggests that the effective design of the cyclone duct by CPFD simulation of particle velocity.

2. CPFD governing equations

The fluid dynamics is described by averaged Navier–Stokes equations with strong coupling with the particle phase. The particle momentum equation follows the multi-phase-particle-in-cell (MP-PIC) formulation (Andrews and O'Rourke, 1996; Snider, 2001) with the addition of a relaxation-to-the-mean term to represent damping of particle velocity fluctuations due to particle collisions (O'Rourke and Snider, 2010).
The fluid-phase mass and momentum equations (Jackson, 2000) are

$$\frac{\partial(\theta_f \rho_f)}{\partial \mathrm{t}} + \nabla \cdot \left(\theta_f \rho_f u_f\right) = \delta \dot{m}_p \tag{1}$$

and

$$\frac{\partial(\theta_f \rho_f u_f)}{\partial \mathrm{t}} + \nabla \cdot \left(\theta_f \rho_f u_f u_f\right) = -\nabla p + F + \theta_f \rho_f g + \nabla \cdot (\theta_f \tau_f) \tag{2}$$

where θ_f is the fluid volume fraction, ρ_f is fluid density, u_f is the fluid velocity vector, p is fluid pressure, τ_f is the fluid stress tensor, g is the gravitational acceleration, and F is the rate of momentum exchange per volume between the fluid and particles.
The constitutive equation for the non-hydro part of the stress,τ_f, is

$$\tau_{f,ij} = \mu\left(\frac{\partial u_i}{\partial x_j} + \frac{\partial u_j}{\partial x_i}\right) - \frac{2}{3}\mu\delta_{ij}\frac{\partial u_k}{\partial u_k} \tag{3}$$

where μ is a shear viscosity, which is the sum of laminar and turbulence shear viscosity. In CPFD scheme, an ideal gas equation of state is used, where the partial pressure of gas i and total pressure are

$$p_i = \frac{p_i RT}{MW_i} \tag{4}$$

$$\mathrm{p} = \sum_{\mathrm{i}} \mathrm{p_i} \tag{5}$$

where R is gas constant, T is temperature, and MW_i is molecular weight of gas species.
The acceleration of a particle is

$$\frac{du_p}{dt} = D_p\left(u_f - u_p\right) - \frac{1}{\rho_p}\nabla p - \frac{1}{\theta_p \rho_p}\nabla \tau_p + g + \frac{\overline{u_p} - u_p}{\tau_D} \tag{6}$$

where θ_p is the particle volume fraction, ρ_p is particle density, $\bar{u}_p$ is the local mass-averaged particle velocity, τ_p is the particle contact stress tensor D_p is the drag coefficient, τ_d is a particle collision damping time.

3. Simulation conditions

The flow pattern of the reactor cyclone is simulated for the actual operating data. Fig. 1 shows the geometry of the cyclone. The other simulation conditions are listed in Table 1. All calculations were run for the fully developed three-dimensional mesh.

Table 1. Cyclone simulation conditions

Pressure = 2.4 atm		Temperature = 520 ℃		Inlet velocity = 16 m/s	
Product gas		RFCC Catalyst		Particle size distribution	
Molecular weight	67 g/mol	Molecular weight	78 g/mol	Fraction	Size (μm)
				0.23	30.00
Density	2.85 kg/m^3	Density	1964 kg/m^3	0.35	37.50
				0.64	45.00
Viscosity	0.019 cp	Mass flow rate	1.25 kg/s	0.95	52.50
				1	62.50

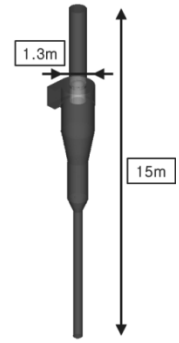

Figure 1. Cyclone geometry

4. Result and discussion

4.1. Cyclone flow pattern of the particles and fluid

In this study, we analyzed flow pattern of particles and fluid at overall and the duct in the no deposit formation case. Fig 2 shows the particles flow pattern of overall the cyclone up to 10 seconds and shows that macroscopically steady state is reached at 3.5 seconds. Fig. 2 (a) shows that the particles flow along their way with clumping together and go around the way four times and decrease their velocity magnitude. Fig. 2 (b) shows that the large-sized particles fall earlier than small-sized particles.

Fig. 3 can be seen the velocity magnitude of (a)particles and (b)fluid and (c)pressure at cross section of the duct. Escaped particles from their own way are observed in Fig. 3 (a) and the low speed zone, less than 8m/s of fluid velocity magnitude, is detected into 34mm size at duct 90° in Fig. 3 (b) When the escaped particles reach in the low speed zone, the deposit is formed. After the deposit formation, the deposit will grow backwardly on the previous formed one. That can be seen in Fig. 5 (b).

4.2. The flow pattern of the different size and shape of the expected deposit on the duct.

We found that the deposit formation started at duct 90°, so the wall was assumed the expected regions of the deposit formation for simulation. In this study, flow pattern of particles and fluid is analyzed by the duct depending on the different sizes and shapes of the expected deposit region. We knew that the deposit formed on the duct from 90° to 220° from actual the deposit shape in Fig 4 (a). Geometry of the cyclone ducts of difference maximum thickness of the expected deposit region from 30mm to 180mm can be seen in Fig. 4. Fig. 5 shows that as the deposit region gets larger, overall velocity magnitude decreases under the influence of pressure increase. There is the prospect of the hindrance of deposit growth by scouring phenomena at 90mm in Fig. 5 (d). The expected deposit region is forecasted merged (b) and (d) from Fig. 5.

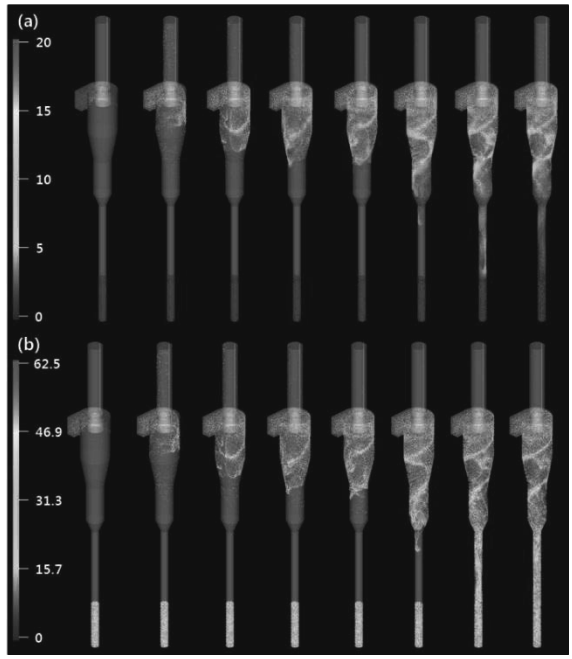

Figure 2. The dynamic flow to 10 seconds of particles in the cyclone: (a) velocity magnitude of particles (inlet velocity is 16m/s) and (b) radius of particles.

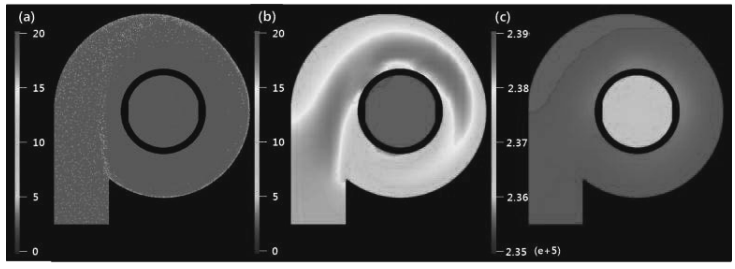

Figure 3. The flow pattern at 10seconds of duct: (a) velocity magnitude of particles, (b) velocity magnitude of fluid, and (c) pressure.

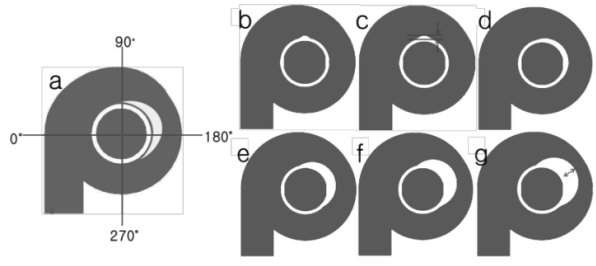

Figure 4. (a) Actual the deposit shape and Geometry of duct depending on the maximum thickness is: (b)34mm, (c)55mm, (d)30mm, (e)90mm, (f)150mm, and (g)180mm.

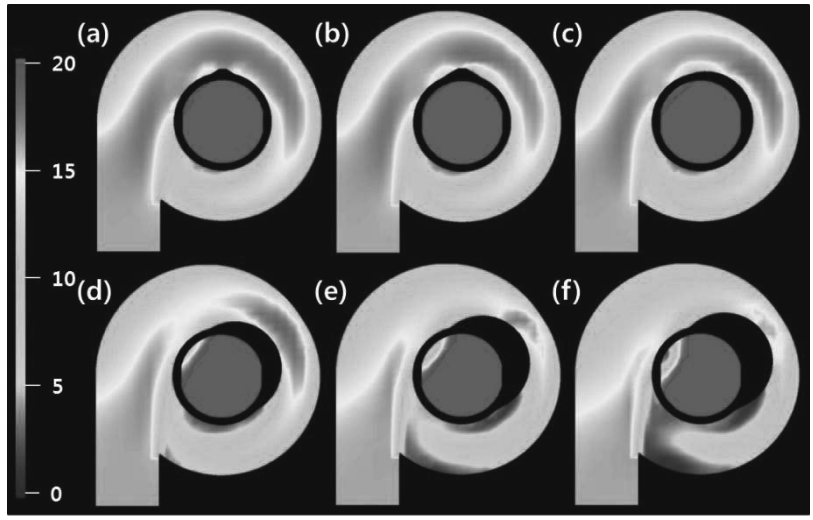

Figure 5. Velocity magnitude of fluid at 10seconds of duct depending on the maximum thickness is: (a)34mm, (b)55mm, (c)30mm, (d)90mm, (e)150mm, and (f)180mm.

5. Conclusion

We analyzed the flow pattern of particles and fluid using CPFD simulation with the actual process data. The result is verified by similarity of the overall flow features between simulation result and the cold model, and separation efficiency, 98.9%. We forecasted shape and size of the deposit formation on cyclone duct. Size and shape of expected deposit on duct was validated with the actual deposition behavior in commercial plant. We will develop a model for the deposit velocity depending on operating conditions and other parameters.

Abstract

A combined computational fluid dynamics (CFD), population balance modeling (PBM) and mass transfer code is used to simulate a rotating disc contactor pilot plant column. Droplet breakage and coalescence is accounted by a one group model and literature models for the breakage frequency, coalescence propability and efficiency. Mass transfer is described based on the two-film theory. The simulation results as droplet size, hold-up and concentration profile along the column height are compared to experimental data. The simulated droplet size shows a slight increase underneath the first compartment whereas it is in good agreement to experimental data in the active height of the column. Also the solute concentrations profiles could be good represented by the simulations.

Keywords: CFD, Mass Transfer, Extraction, RDC.

1. Introduction

Liquid-liquid extraction (LLE) is an important unit operation based on the different solubility of the components and is widely used in chemical industries, metals and nuclear industries (hydrometallurgy), petrochemical and coal industry as well as in the pharmaceutical and agricultural chemistry. The layout of LLE columns consists of the solvent and column selection as well as an appropriate description of the processes taking place in the column (hydrodynamics, breakage and coalescence of the droplets). State of the art models as the HTU-NTU model or axial dispersion model do not account for the complex droplet-droplet interactions and are of limited predictability. In the recent years, axial dispersion models were coupled with population balance modeling (PBM) to account for the droplet interactions. Nevertheless, parameters as the axial dispersion, energy dissipation and hold-up must be determined experimentally for each column type. The CFD coupled with PBM can overcome this handicap. For example Drumm et al. [1] used a coupled solver to predict the flow field and droplet size in a rotating disc contactor (RDC) column, where the computational time could be decreased by using a two dimensional rotational symmetrical case. Hlawitschka & Bart [2] investigated a more complex miniplant Kühni column, which only can be simulated using a three dimensional mesh. For an appropriate simulation, the influence of mass transfer on the system parameters (e.g. density, interfacial tension) has to be included in the simulation. Investigations on mass transfer combined with CFD were until now mainly performed for stirred vessel [3,4] and focused on the determination of the mass transfer coefficient. In this article, a CFD-PBM solver was extended to describe the concentration along the column height of an RDC column that was investigated experimentally by Garthe [5].

2. Numerical Background

The commercial CFD code FLUENT (version 12.1) is used for the simulations. The Eulerian multiphase model was chosen to simulate the two phase flow, whereas the phases are treated as interpenetrating continua and are described by the phase fraction in each cell. The used governing equations as continuity and momentum equations for each phase are described in Hlawitschka & Bart [2]. Due to the mass transfer calculations, the constant density of each phase is replaced by the mixture density $\rho_{q,m}$, which depends on the concentration of the transition component Y_q in each phase q and on the density of each component ($\rho_{q,1}$, $\rho_{q,2}$):

$$\rho_{q,m} = \rho_{q,1}\left(1 - Y_q\right) + \rho_{q,2} Y_q \tag{1}$$

As turbulence model, the standard k-ε-model is used that was also chosen by Drumm et al. [1] for the simulation of the hydrodynamics in a RDC column.

2.1. Species Transport

The concentration Y_q of each phase q is accounted by the species transport equation consisting of an accumulation term and convection term on the left hand side and of the transferred mass on the right hand side. The phase fraction of each phase is described by α_q, whereas the velocity of the phase is represented by $\vec{v}_q$:

$$\frac{\partial}{\partial t}\left(\alpha_q \rho_{q,m} Y_q\right) + \nabla\left(\alpha_q \rho_{q,m} \vec{v}_q Y_q\right) = \dot{m}_q^{\,i} \tag{2}$$

The generated mass is calculated based on the two film theory:

$$\dot{m} = A \rho_d \beta_{od}\left(m^* \cdot x_b - y_b\right), \tag{3}$$

where m^* is the distribution coefficient and A is the interfacial area, which is calculated for each cell by:

$$A = \frac{6\alpha}{d} \tag{4}$$

The overall mass transfer coefficient β_{od} is based on the individual mass transfer coefficients of the dispersed phase β_d and continuous phase β_c and the mixture densities for the dispersed phase $\rho_{d,m}$ and continuous phase $\rho_{c,m}$:

$$\frac{1}{\beta_{od}\rho_{d,m}} = \frac{1}{\beta_d \rho_{d,m}} + \frac{m}{\beta_c \rho_{c,m}} \tag{5}$$

As mass transfer model, the model of Kumar & Hartland [6] was chosen and implemented as user defined functions (UDF). The model was developed for droplet swarms and shows an overall accuracy of 14.1% to experimental data. The mass transfer models are coupled to the CFD, whereas the velocity, phase fraction and droplet size are given to the mass transfer equations and the resulted mass is given back to the CFD code to recalculate the phase fraction and density.

3. Droplet Size Calculation

The droplet size is calculated using a one-group model, called OPOSPM [1], which is based on the calculation of the volumetric diameter in each cell. The model of

Coulaloglou & Tavlarides [7] is used to describe coalescence and breakage of the droplets, whereas the breakage term is given by:

$$g(d) = c_1 \frac{\varepsilon^{1/3}}{d^{2/3}(1+\alpha)} \exp\left(-\frac{c_2 \sigma (1+\alpha)^2}{\rho_{c,m} \varepsilon^{2/3} d^{5/3}}\right) \tag{6}$$

Hereby, ε is the energy dissipation and d is the droplet size. The interfacial tension is described by σ. The coalescence term consists of the coalescence rate $h(d_1,d_2)$ and the collision efficiency $\lambda(d_1,d_2)$. Due to the use of the one group model, the droplet sizes d_1 and d_2 of the colliding droplets are equal to d .

$$h(d_1, d_2) = c_3 \frac{\varepsilon^{1/3}}{1+\alpha} (d_1 + d_1)^2 \left(d_1^{2/3} + d_2^{2/3}\right)^{1/2} \tag{7}$$

$$\lambda(d_1, d_2) = \exp\left(-c_4 \frac{\mu_c \rho_{c,m} \varepsilon}{\sigma^2 (1+\alpha)^3} \left(\frac{d_1 d_2}{d_1 + d_2}\right)^4\right) \tag{8}$$

The viscosity of the continuous phase is defined by μ_c. The four model parameters were adjusted to the test system of toluene/acetone/water (c_1=0.266, c_2=0.078, c_3=0.003, c_4=1.0e11), whereas c_2 was taken from Steinmetz [8].

4. Mesh Generation and Simulation Setup

A numerical grid was created that corresponds to the RDC pilot plant column, which was used by Garthe [5]. The grid consists of 46 896 cells and whereas the inflow and outflow region were reduced compared to the real column. The full column and a part of the column grid showing the principle flow direction of the dispersed and continuous phase is shown in Fig. 1 and the geometry data is summarized in Tab. 1. The inlet of the dispersed phase at the bottom of the column is defined as velocity inlet, whereas the outlet at the top of the column is defined as pressure outlet. The stators and the column wall were defined by the wall boundary condition, whereas the stirrer and shaft are described by the moving boundary condition. The simulation is based on the boundary conditions chosen by Garthe [5]. The inlet flow of the continuous phase flow is 40 L/h and the inlet flow of the dispersed phase is 48 L/h. The stirring speed is set to 200 rpm.

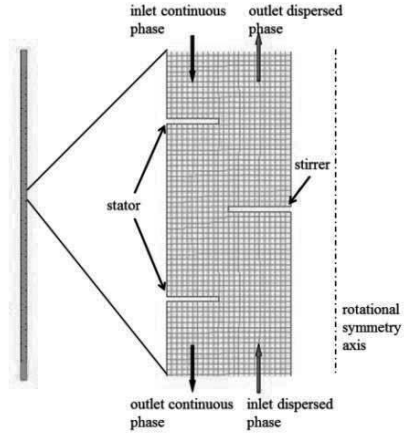

Figure 1: Mesh of the column (left) and part of the column (right) visualizing the main details of the used grid.

A detailed description of the inlet droplet size is not given. In this work, the inlet droplet size was set to 3 mm, which corresponds to the closest measured value. The acetone concentration in the continuous phase was set to the measured concentration of the continuous phase at the inlet (5.68%). The acetone concentration of the dispersed phase inside the column was set to zero. The concentration of the dispersed phase at the inlet was set to the measured value of 0.10%. The acetone concentrations at the outlets of each phase were defined as zero gradient by the use of user defined functions.

Table 1. RDC geometry

Column diameter	80 mm	Agitator diameter	45 mm
Compartment height	50 mm	Active column height	2650 mm
	10 mm	Rel. free. cross-sectional area	0.40 m²/m²

5. Simulation Results and Discussion

The simulated dispersed phase hold-up reaches a value of 6.8% in the active height (stirring zone) of the column. Compared to the results of Garthe [5], the simulated hold-up is 4.2% lower than the averaged measured value of 7.1%, which can result from an overpredicted droplet size in the inflow zone (Fig. 2, left). The simulated droplet size increases in the inflow zone due to recirculation and low energy dissipation. Due to the lack of experimental data, a direct comparison of the droplet size in the inflow zone is not possible. The increase could also be caused by an overpredicted coalescence kernel. Nevertheless, the droplet size corresponds to the experimental data in the active height. Also a slightly decreased droplet size at the column top due to a lower interfacial tension in this area can be observed. The acetone concentration in the dispersed and continuous phase is plotted versus the experimental data in Fig. 2 (right). Small deviations from the experiments can be seen for the continuous and dispersed phase acetone concentrations. The continuous phase concentration is underpredicted, whereas the dispersed phase concentration is overpredicted along the column height.

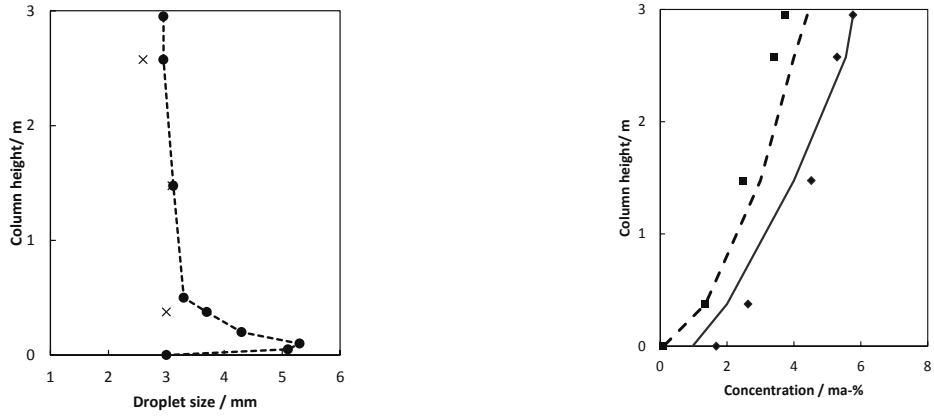

Figure 2: Left side: Droplet size (measured: **x**, simulated: ●) along the column height.
Right side: acetone concentration for the dispersed phase (measured: ■, simulated: - -) and for the continuous phase (measured: ♦, simulated: -) along the column height

The simulated values are in good agreement to the experimental data, taking the accuracy of the experimental data (higher than 5%) and the accuracy of the mass transfer coefficient model (14.1%) into account.

6. Conclusion and Outlook

A CFD-PBM simulation accounting mass transfer in a pilot plant liquid-liquid extraction column of type RDC was performed and compared to literature data. Mass transfer was described by the two-film theory and coupled to the CFD-PBM simulation. The model of Kumar and Hartland [2] was used to calculate the mass transfer coefficients. The simulation shows an over prediction of the transferred mass, which results in a lower predicted acetone concentration in the continuous phase at the column bottom and higher predicted acetone concentration in the dispersed phase at the column top. The mass transfer has an impact on the interfacial tension along the column height, which results in a slightly reduced droplet size at the column top. It can be concluded that the combination of CFD-population balance modeling with mass transfer modeling improves the accuracy of each model. Compared to state of the art models, the CFD allows a geometrical independent simulation of stirred liquid-liquid extraction columns without experimentally determined correlations for the hydrodynamics for each column type. Hence, investigation of new column types or optimizations of the geometry are possible. Further optimization of the inflow zone of each phase in the CFD simulation is required to reduce recirculation of the phases at the bottom and top of the column. Other models, as the model of Kronig and Brink [9] show a reduced mass transfer coefficient compared to the model of Kumar and Hartland [6] and could improve the prediction of the concentration along the column height in each phase.

Abstract

In this work, we propose a method to estimate the primary variables based on a combination of measurements. Our method is a reformulation of the Loss method. We will compare our method with the other well-known estimators.

Keywords: Static estimator, Loss method, Partial Least Squares, Kalman Filter

1. Introduction

It happens frequently in process control that some important variables are not measurable. Sometimes they are expensive to measure and include delay. The value of primary variable can be inferred by using some secondary variable measurements. The task of soft sensors is the maximal exploitation of transforming the information of secondary measurements into more useful process knowledge.

In multi-component distillation system, a certain temperature profile exists for a specified feed component recovery and feed condition. The idea is to use temperature measurements from several locations in order to estimate the recovery of product composition, which is also good for some variation in feed properties. In this work, we propose an approach for designing a static estimator which is inspired from the loss method by Skogestad (2000). This work is a continuation of the work done by Hori et al. (2005). Measurement noise is included. The optimal static estimator is designed for two categories: "open-loop" performance (estimator used for monitoring) and "closed-loop" performance (estimator used for control). It is optimal in the sense that it gives the smallest prediction error which is defined as the difference between the true value and the estimated value. This approach will be compared with the Partial Least Square (PLS) approach and steady-state kalman filter.

2. Loss method for estimation

The objective is to find a linear combination of measurements such that keeping these constant indirectly leads to nearly accurate estimation with a small loss $\mathbf{L}$ in spite of unknown disturbances, d, and measurement noise, n^x. Figures 1-4 show four different scenarios we have considered. Linear models are assumed for the primary variables y,

*skoge@nt.ntnu.no

measurements x, and secondary variables z. It is also assumed that $\dim(\mathrm{y}) = \dim(\mathrm{x}) = \dim(\mathrm{z})$.

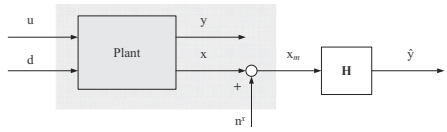

Figure 1: u is a free variable

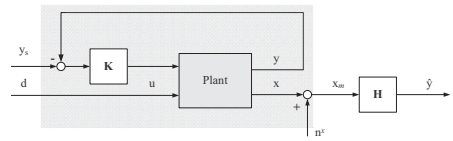

Figure 2: Control of primary variable y

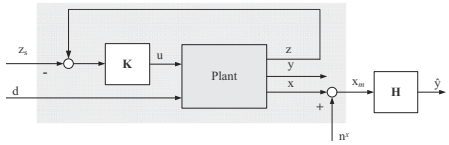

Figure 3: Control of secondary variable z

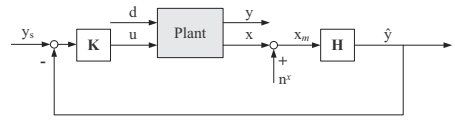

Figure 4: Control of the predicted variable $\hat{y}$

The optimal $\mathbf{H}$ is a matrix which follows the linear relationship $\hat{\mathrm{y}} = \mathbf{H}\mathrm{x}_m$, and derived by minimizing $\|\mathrm{e}(\mathbf{H})\|_{2,exp}$. We assume some expected values for disturbances and noise which come from engineering wisdom. The normalized values of disturbances and noise are used in the calculations. Table 1 shows the final expressions for obtaining $\mathbf{H}$ for different scenarios. The problem is easy for "open-loop" cases. The final expression looks like ordinary least square problems. For "close-loop" case (Figure 4), the Frobenius norm should be minimized subject to $\mathbf{H}\mathbf{G}_x = \mathbf{G}_y$ as constraint. We need to obtain the optimal sensitivity matrix $\mathbf{F}$ which is defined as $\mathbf{F} = \left(\frac{d\mathrm{x}_{opt}}{d\mathrm{d}}\right) = \mathbf{G}_x^d - \mathbf{G}_x\mathbf{G}_y^{-1}\mathbf{G}_y^d$, is simply obtained numerically by re-optimizing the model for different disturbances.

Table 1: Optimal $\mathbf{H}$ values for different scenarios

$\mathbf{H}_1 = \mathbf{Y}_1\mathbf{X}_1^{\dagger}$	$\mathbf{Y}_1 = \begin{bmatrix} \mathbf{G}_y\mathbf{W}_u & \mathbf{G}_y^d\mathbf{W}_d & 0 \end{bmatrix}$ $\mathbf{X}_1 = \begin{bmatrix} \mathbf{G}_x\mathbf{W}_u & \mathbf{G}_x^d\mathbf{W}_d & \mathbf{W}_{n^x} \end{bmatrix}$
$\mathbf{H}_2 = \mathbf{Y}_2\mathbf{X}_2^{\dagger}$	$\mathbf{Y}_2 = \begin{bmatrix} \mathbf{W}_{y_s} & 0 & 0 \end{bmatrix}$ $\mathbf{X}_2 = \begin{bmatrix} \mathbf{G}_x^{cl}\mathbf{W}_{y_s} & \mathbf{F}\mathbf{W}_d & \mathbf{W}_{n^x} \end{bmatrix}$
$\mathbf{H}_3 = \mathbf{Y}_3\mathbf{X}_3^{\dagger}$	$\mathbf{Y}_3 = \begin{bmatrix} \mathbf{G}_y^{cl}\mathbf{W}_{z_s} & \mathbf{F}_y'\mathbf{W}_d & 0 \end{bmatrix}$ $\mathbf{X}_3 = \begin{bmatrix} \mathbf{G}_x^{cl}\mathbf{W}_{z_s} & \mathbf{F}_x'\mathbf{W}_d & \mathbf{W}_{n^x} \end{bmatrix}$
$\mathbf{H}_4$	$\min_{\mathbf{H}} \left\|\mathbf{H}\begin{bmatrix} \mathbf{F}\mathbf{W}_d & \mathbf{W}_{n^x} \end{bmatrix}\right\|_F$ s.t. $\mathbf{H}\mathbf{G}_x = \mathbf{G}_y$

Note that $\mathbf{W}$'s are the diagonal scaling matrices which contain the standard deviations of the elements. We can consider u to be any variable from the process. $\mathbf{G}_y$ and $\mathbf{G}_y^d$ become so trivial if we choose $\mathrm{u} = \mathrm{y}$ ($\mathbf{G}_y = \mathbf{I}$ and $\mathbf{G}_y^d = 0$), and $\mathbf{G}_x^d$ will be equal to the sensitivity matrix $\mathbf{F}$.

3. Partial Least Square (PLS) Method

In chemometrics, Partial Least Squares (PLS) regression has become an established tool for modeling linear relations between multivariate measurements. This method is used to compress the predictor data matrix X, into a set of latent variable or factor scores. The orthogonal factor scores are used to fit a set of observations to dependent variables Y. The main attraction of the method is that it finds a parsimonious model even when the

predictors are highly collinear or linearly dependent. The final fitting equation will be

$$\mathbf{Y} = \mathbf{BX} + \mathbf{B_0} \tag{1}$$

with B and B_0 as optimization variables. B_0 is close to zero because of centering the data. The main drawback of this method is that there are several realization of the same method which do not lead to the same result for a specific problem (for PLS2 cases).

For data preparation we have two ways: If we have data, small directions in the measurement space should be deleted by SVD. We should ensure that all important directions are sufficiently exposed. We can also use exactly the same data that we get in loss method. $\mathbf{X}$ and $\mathbf{Y}$ in PLS method are the first and second row of $\mathbf{Y}_{all}$ matrix respectively.

$$\mathbf{Y}_{all} = \begin{bmatrix} \mathbf{Y} \\ \mathbf{X} \end{bmatrix} = \begin{bmatrix} \mathbf{G}_y & 0 \\ \mathbf{G}_x & \mathbf{X}_{opt} \end{bmatrix} \tag{2}$$

where $\mathbf{X_{opt}} = \begin{bmatrix} \mathbf{FW}_d & \mathbf{W}_{n^x} \end{bmatrix}$.

We need to know the expected "optimal variation" in $\mathbf{X}$ as given by the matrix $\mathbf{X}_{opt}$. Here "optimal" means that y is constant (see the second column in $\mathbf{Y}_{all}$). In addition, we also need to obtain $\mathbf{G}_x$ and $\mathbf{G}_y$ from the data, which means that the data must contain "non-optimal" variations in u, and not only contain optimal data where $\mathrm{u} = \mathrm{u}_{opt}\,(\mathrm{d})$- see the first column in $\mathbf{Y}_{all}$. This is called Closed-Loop Regressor (CLR) (Skogestad et al., 2011). CLR suffers from the same weakness as LS, giving poor results for ill-conditioned matrices and underdetermined systems. Performing a principal component analysis on the $\mathbf{X}$ data will remove the weaker directions containing noise resulting in a well-conditioned matrix. Then, CLR can be applied to the data. We call this "truncated CLR".

4. Kalman filtering

The Kalman filter estimates process states by using a form of feedback control. The linearity of state dynamics and observation process, as well as the normal distribution of noise in state dynamics and measurements are the assumptions of kalman filter. A linear difference equation $x_k = Ax_{k-1} + Bu_{k-1} + w_{k-1}$ with a measurement that is $z_k = \mathbf{C}x_k + v_k$, define the linearized process. The random variables w_k and v_k represent the process and measurement noise respectively. They are assumed to be independent of each other and with normal distributions.

$$p\,(w) \sim \mathcal{N}\,(0, Q) \tag{3}$$

$$p\,(v) \sim \mathcal{N}\,(0, R) \tag{4}$$

The objective is to minimize the estimation error. By writing a posteriori state estimate as a linear combination of an a priori estimate and the difference between actual measurement and measurement prediction weighted by kalman gain, K is calculated to minimize the a posteriori estimation error covariance. Since the focus of our work is on chemical processes, the time scales at which the sensor noise characteristics change are much larger than the time scale at which we study the system. Thus we assume the system and noise covariances are time-invariant. In addition, as mentioned previously, our proposed estimator is categorized as static estimator. So, the steady-state of kalman filter is interesting. The steady-state kalman gain is calculated as $K_\infty = P_\infty^- H^T \left(HP_\infty^- H^T + R\right)$. Figure 5 shows the block diagram of kalman filter estimation.

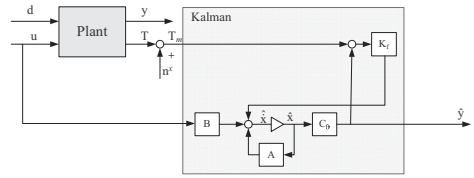

Figure 5: Block diagram of Kalman filter

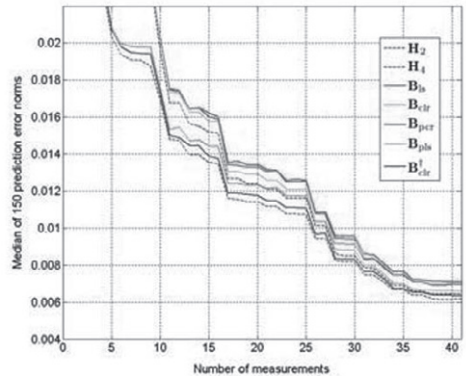

Figure 6: Median Prediction error

The algorithm of Kalman filter requires knowledge of the process noise variance W and the measurement noise variance V (Nakamura, 1982). If state-feedback control is used, the overall controller is optimal because of the separation principle. If an output-feedback controller ($u = \mathbf{K}y$) is used, then it is generally not optimal to use the $\hat{y} = \mathbf{C}\hat{x}$ estimated by Kalman filter. In loss method, the primary variable comes directly from combination of measurements ($c = \mathbf{H}y$). Since the measurements do not contribute similarly in the estimation of primary variable, it is expected that by putting weights on the state error terms, the estimation of primary variable will be improved. Another point is that we should think of what to use the estimation for. KF is said to be used for control,but if R approaches infinity, then it means that there is no control. Mejdell and Skogestad (1993) have shown that the kalman-filter might be better than a simple PCR in open-loop performance, which is because of the recursive nature of the filter, but PCR performs similarly if it is used for closed loop. We can model slowly-varying disturbances by adding states of the noise model. This gives the augmented kalman filter (Brown and C., 1997). Here, we use non-stationary noise. So zero steady-state is not reached.

5. Example

A binary distillation column model - Column A (Skogestad, 1997) - is used to demonstrate the performance of different estimators. There are two inputs, namely the reflux flow and the boilup, and two disturbances, which is the change in feed composition.

Table 2 shows the results of validation for estimators for different scenarios. Calibrating with one scenario and validating with another is mostly applicable to the last scenario. So, the shaded cells are actually showing the more interesting data. As it was expected,

the optimal estimator is obtained when it was calibrated and validated for its intended scenario. Note that all the scenarios are not comparable to each other because of different variances for different scenarios. Since there is no control in the first scenario, a small standard deviation in u was selected to give a small standard deviation in y.

Figure 6 shows the performance of estimators. Calibration data was generated by drawing random values for $\mathrm{u} \sim \mathcal{N}\left(0, 0.005^2\mathbf{I}_2\right)$, $\mathrm{d} \sim \mathcal{N}\left(0, 0.05^2\mathbf{I}_2\right)$, $\mathrm{y}_s \sim \mathcal{N}\left(0, 0.005^2\mathbf{I}_2\right)$ and $z_s \sim \mathcal{N}\left(0, \begin{bmatrix} 0.05^2 & 0.5^2 \end{bmatrix}\mathbf{I}_2\right)$, and calculating the corresponding output variables x_m and y for the respective scenarios (except scenario 4). The median of the prediction error for 150 runs are used to assess the estimators' performances because noise and variation in input variables resulted in a distorted picture of estimator performance by outliers. By increasing the number of regressors, the error decreases. All estimators are trained on calibration data from scenario 2 and validated on scenario 4.

Table 2: The mean prediction error of the model-based estimators applied to four operation scenarios

Caliberation Data \ Validation Data	S1	S2	S3	S4
S1	0.0085	0.2749	0.0215	0.0506
S2	0.0591	0.0093	0.0104	0.0104
S3	0.0599	0.0166	0.0098	0.0132
S4	0.0099	0.0099	0.0099	0.0099

6. Conclusions

In this paper, we introduced a new static estimator. Four scenarios have been used to get the calibration data and were validated for the closed-loop scenario. Our emphasis was on the fact that we should be aware of what we want to use the estimator for.

Validation of an absorber model of carbon dioxide capture in an aqueous amine solvent developed based on the SAFT-VR framework

C. V. Brand, J. Rodríguez, A. Galindo, G. Jackson and C. S. Adjiman

Department of Chemical Engineering, Centre for Process Systems Engineering, Imperial College London, London SW7 2AZ, U.K. c.adjiman@imperial.ac.uk

Abstract

The development of a model of an absorber for the removal of carbon dioxide (CO_2) from flue gas using aqueous solutions of monoethanolamine (MEA) is presented. This novel model incorporates state-of-the-art SAFT-VR thermodynamics into a rate-based process model. A characteristic of the proposed approach is that all the reactions are treated within a thermodynamic description, assuming chemical equilibrium throughout. This greatly reduces the amount of experimental data required to model the behaviour of CO_2 in the solvent. Furthermore, in contrast with traditional treatments of reactive systems of this type, no enhancement factor is used in the process model. The absorber process model is implemented in the gPROMS software platform and validated using published pilot plant experimental data. The predictive capabilities of the mass transfer correlations used in this model are assessed through a sensitivity analysis and a scaling of the diffusivity in the liquid phase is proposed. The scaling of the diffusivity is transferable to different operating conditions and good predictions are obtained for the composition profiles in the gas and liquid phases.

Keywords: CO_2 capture, reactive separation, SAFT-VR, monoethanolamine.

1. Introduction

Carbon dioxide (CO_2) emissions are largely considered to play a major role in climate change and particularly in global warming. Fossil fuel power plants are the major fixed point-source emitters of CO_2. In order to abate global warming, the UK Committee on Climate Change suggested reducing the emissions from 500 gCO_2/kWh to 100 gCO_2/kWh in the electricity sector by 2050. In this context, the development of carbon capture systems is a necessity that must be addressed in the short term, and amine-based post-combustion capture processes are seen as the most promising technology in terms of development and applicability. The major advantage of this technology is that it can be retrofitted to existing power plants.

There are, however, several concerns with amine capture processes, including large energy requirements, solvent degradation, and the environmental and health impact that may result from solvent leaks and solvent degradation products. Modelling studies can play an invaluable role in addressing some of these issues, including the choice of solvent and operating conditions that yield optimal performance.

A key challenge is to develop models that can accurately predict the behaviour of the process under different conditions. In our current study study, we address this challenge by developing a model of the CO_2 absorber that incorporates an advanced thermodynamic model of the physical properties *and* reactions into a rate-based process model. We use a version of the statistical associating fluid theory (SAFT) to model the

complex physico-chemical interactions between CO_2 and the solvent. Pilot plant data is used to validate the absorber model. The thermodynamic framework used is presented briefly in the next section and the process model is then described. In section 3, the model is validated against pilot plant data. A discussion of the results is presented in section 4.

2. Proposed model of a CO_2 absorber

The rate-based model of the absorber and the SAFT-VR [1, 2] formalism used to model the physico-chemical interactions within the absorber are presented here.

2.1. Thermodynamic treatment

In SAFT-VR, a molecule i is modelled as a chain of m_i segments. These segments are hard-cores of diameter σ_{ii} tangentially bonded to form the molecule. The attractive interaction between two segments is described by a square-well potential of range λ_{ii} and depth ε_{ii}. Off-centre and short range square-well association sites can be used to represent association interactions (hydrogen bonding and complex formation), also characterised by an energy and a range. The specificity of SAFT-VR is that the parameter λ_{ii} can be used to account for the variable range (VR) of intermolecular interactions.

In the SAFT framework, the Helmholtz free energy of a model mixture of associating chain molecules can be written as a sum of ideal, monomeric segment, chain and associative contributions. The thermodynamic properties needed to determine phase and chemical equilibrium, namely the pressure and chemical potential, are obtained as the corresponding derivatives of the Helmholtz free energy.

The reactions involved in aqueous amine solutions of CO_2 can be accounted for implicitly within the SAFT-VR thermodynamic model, with the products of the chemical reaction treated as associated aggregates of the reactant molecules [3]. This greatly reduces the number of parameters needed to describe the system as only the site-site interactions between the reactant molecules need to be specified. An accurate representation of the vapour-liquid phase equilibria of MEA + CO_2 + H_2O can be obtained in this manner. The principal reaction of interest between CO_2 and MEA is the formation of a carbamate [4]:

$$CO_2 + 2HOCH_2CH_2NH_2 \rightleftarrows [HOCH_2CH_2HCO_2^- + HOCH_2CH_2NH_3^+] \quad (1)$$

A schematic representation of how the carbamate formation is modelled in SAFT-VR is presented in figure 1.

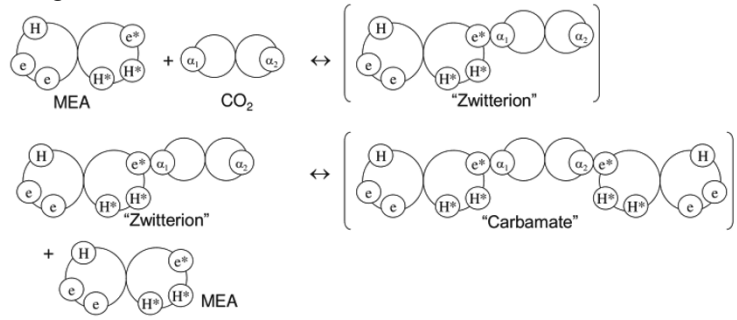

Figure 1. Schematic representation of the association scheme between MEA and CO_2 showing two reaction products. The bonding sites α_1 and α_2 on the molecular model of CO2 mediate the formation of the zwitterion and the carbamate by bonding to the e* site (of the NH_2 group) on MEA.

It can be shown that, under certain assumptions, treating the overall reaction as the generation of aggregates of the reactants is equivalent to assuming that chemical (reaction) equilibrium holds [5]. An important implication of using this approach is that the reaction products (and intermediates) do not need to be modelled explicitly. This reduces the number of components required in the overall model. We have recently shown that the concentration of carbamate is very well predicted with this method [6].
Every column stage is treated using a two-film model [7]. Each phase is split into two parts: a bulk phase and a film within which the chemical reaction and heat and mass transfer occur. In the bulk phase, the concentration, pressure and temperature are assumed to be uniform, while there may be a gradient in composition, temperature and pressure in the film. A schematic of the two-film model is shown in figure 2, with the profiles for compositions, temperature and pressure. The SAFT-VR thermodynamic model is used in the bulk phase to determine the chemical equilibrium state, and at the interface to determine the chemical equilibrium and phase equilibrium.

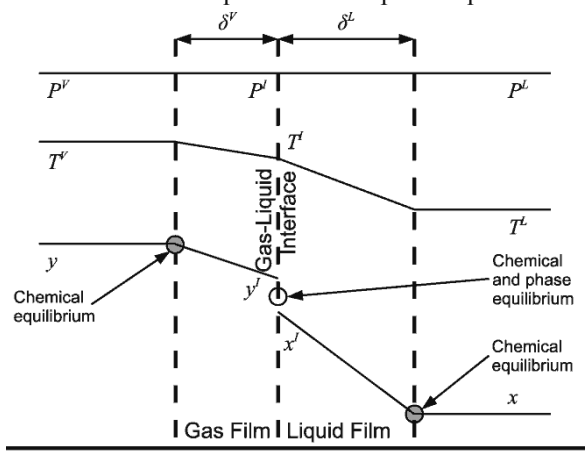

Figure 2. A schematic of the two-film model of a theoretical column stage. δ^V and δ^L represent the thickness of the gas and liquid films, respectively. P^V, P^I, and P^L are the pressures in the bulk vapour phase, at the gas-liquid interface, and in the bulk liquid, respectively. As can be seen, an isobaric profile is assumed in our current work. The temperatures of the bulk gas phase, of the gas-liquid interface, and of the bulk liquid are denoted by T^V, T^I, and T^L, respectively. Finally, y and x are the mole fractions in the bulk gas and liquid phases, respectively, and y^I and x^I are the corresponding mole fractions at the gas-liquid interface for the gas and the liquid phases.

2.2. Absorber model

The absorber column is divided into 50 stages, each representing a section of the packed column. Two widely used mass transfer correlations from Onda *et al.* [8] and Rocha *et al.* [9] are implemented in the model to compare their predictive capabilities.
The following assumptions are made in the steady-state model of the absorber:

- the bulk phases and film are at chemical equilibrium everywhere (i.e., the reaction rates are far faster than the mass transfer rates [4]).
- the interface is at phase and chemical equilibrium.
- the interfacial surface area is the same for both heat and mass transfer.
- the effective area is equal to the wetted area.
- the absorption column is considered to be adiabatic.
- there is no pressure drop along the column.

3. Model Validation

The absorber model developed in the current work is validated by comparing the model predictions with the pilot plant experimental data obtained by Tontiwachwuthikul *et al.* [10]. These include measurements at different points along the column, which have been successfully reproduced by other researchers. The validation is performed according to the operating conditions of Run T22 [10].

In preliminary calculations the model was found to over-predict the rate of absorption of CO_2 along the column. This is observed with the correlations of both Onda *et al.* [8] and Rocha *et al.* [9], which provide a very similar description. For the sake of clarity and conciseness, only results obtained with the Onda *et al.* [8] correlations are presented here. In order to investigate the nature of the over-prediction, a sensitivity analysis is performed. From this analysis, it transpires that the most influential parameter for the prediction of the composition profile is the diffusivity of the CO_2 in the liquid phase. In the reaction-implicit model, the CO_2 in the liquid phase represents CO_2, bicarbonate and carbamate. In effect, this is mostly carbamate, a much larger species than CO_2. A scaling of the CO_2 diffusivity in the liquid phase is therefore undertaken to account for the larger size of the carbamate; a good estimate of the rate of absorption of CO_2 is then obtained. The extent of rescaling is estimated from the experimental data obtained from Run T22 [10] for the gas and liquid composition profiles. On the basis of this estimation, the value that results in the least deviation between the pilot plant data and the model corresponds to a scaling of CO_2 diffusivity in the liquid phase to 4% of its original value. The liquid-phase temperature, gas-phase CO_2 concentration, and liquid-phase CO_2 concentration profiles for Run T22, with and without diffusivity scaling, are presented in Figure 3.

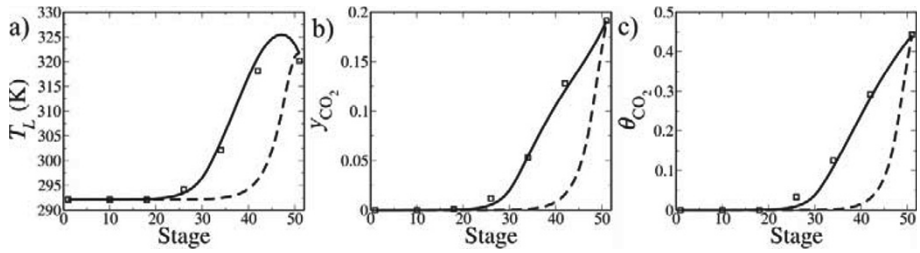

Figure 3. Comparison between pilot plant data (squares) and model results (curves) for Run T22 for the absorption of CO_2 in an 18%wt solution of MEA [10]. The dashed curves represent the results obtained without scaling of the diffusivity and the continuous curves the results obtained by scaling the CO_2 diffusivity in the liquid phase to 4% of its original value ($D' = 0.04D$) . a) Temperature profile for the liquid phase, b) gas-phase CO_2 concentration profile, and c) liquid-phase CO_2 concentration expressed in terms of loading $\theta_{CO2} = x_{CO2}/x_{MEA}$. Stage 50 corresponds to the bottom of the column.

4. Results

Other Runs from the same pilot plant absorber [10] are simulated using the same relative scaling of the diffusivity. The predictions for the temperature profile in the liquid phase, gas phase CO_2 concentration, and liquid phase CO_2 concentration for Run T20 are presented in figure 4. Runs T13, T14, T15, T16, T17, T19 and T21 have also been simulated and a similar description obtained. These runs represent a wide range of conditions in terms of amine concentration, inlet liquid phase CO_2 loading, inlet gas phase CO_2 concentration and gas-to-liquid flow-rate ratio.

Good agreement is found between the model predictions and the pilot plant data in relation to the liquid-phase temperature and the liquid- and gas-phase composition

profiles along the entire length of the column, which demonstrates that the scaling procedure can be applied in a transferable manner to different operating conditions. The temperature bulge at the bottom of the column is predicted well in terms of amplitude and location, despite the fact that no enhancement factor is used. To the best of our knowledge, no other published model predicts this bulge with such accuracy [11, 12].

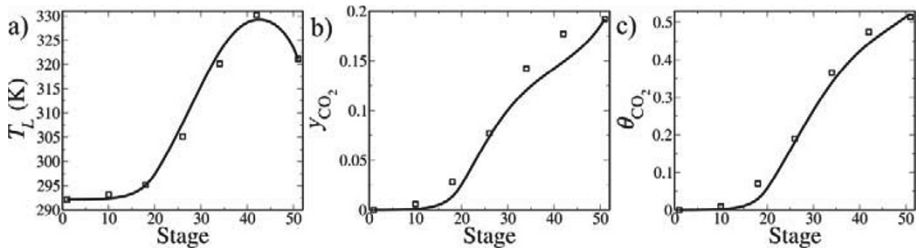

Figure 4. Comparison between pilot plant data (squares) and model results (curves) for Run T20 for the absorption of CO_2 in a 12%wt solution of MEA. Caption as in Figure 3.

5. Conclusions

A rate-based CO_2 absorber model incorporating a SAFT-VR thermodynamic treatment has been developed. The model combines physical and chemical interactions within a consistent thermodynamic framework, under the assumption that the chemical reactions are at equilibrium. The chemical reactions are treated implicitly in this formalism. Thus there is no need to incorporate an enhancement factor or to use experimental data on the rate of reaction. This greatly simplifies the description and provides a considerably more transferable model. A simple scaling of the CO_2 diffusivity in the liquid phase is proposed to account for the formation of carbamate. We show that, unlike an enhancement factor, the scaling is constant all along the entire length of the column and is transferable over a wide range of operating conditions. Our methodology allows for good predictions of the temperature and composition profiles in the gas and liquid phase along the absorber column.

EM Algorithm for Parameter Estimation in Batch Process

Zhonggai Zhao,a,b Biao Huang,b * Fei Liu,a

a Key Laboratory of Advanced Process Control for Light Industry (Ministry of Education), Jiangnan University, Wuxi, China, 214122.

b Department of Chemical and Materials Engineering, University of Alberta, Edmonton, AB, Canada, T6G 2G6

Abstract

This paper investigates the parameter estimation problem for batch processes through the maximum likelihood method. Unlike continuous processes, a batch process has short operating period and each batch repeats the same procedure but with different raw materials. Therefore, states and measurements in different batches are not same and should be considered individually. However, the feed of material is often adjusted according to the performance of previous batches, thus the initial states of the next batch are related to the states of the previous batch. The proposed algorithm takes individuality and commonality across different batches into account and develops likelihood functions accordingly. By treating the unmeasured states and the parameters as missing variables , the maximum likelihood estimation is accomplished by expectation-maximization (EM) algorithm. In the expectation step, due to the complexity of posterior density function (PDF), particle filtering methods are employed for the implementation of filtering and smoothing. Through iterative optimization, the unknown parameters along with the states are estimated. Simulation example illustrates feasibility of this method and demonstrates its effectiveness.

Keywords: Batch process, EM algorithm, parameter estimation, particle filter

1. Introduction

Batch process plays an important role in the production of food, medicine, and so on. In the last decade, 2-dimensional (2-D) models were often used for the simulation of the batch process dynamics, along the dimensions of both time and batches [Y. Yao et al., 2008]. Most of these models are data-driven ones. However, in some batch processes, first principle models are available for the accurate description of their behaviors [T. Liu et al., 2010], but the parameters are typically unknown or partially unknown. Consider a state space model with known structure given by,

$$\begin{cases} x_k = f(x_{k-1}, \theta) + \omega_{k-1} \\ y_k = h(x_k, \theta) + v_k \end{cases} \tag{1}$$

where x_k, y_k, θ, ω_{k-1}, v_k represent the state, measurement, parameter, state noise and measurement noise, respectively. Equation (1) provides a known model structure but the parameter θ needs to be estimated according to process data.

However, this model only reflects the dynamic behavior within one batch, and fails to capture the batch-to-batch dynamics. Most of the estimation methods have tried to solve

*bhuang@ualberta.ca.

parameter estimation problem of batch processes in the same way as continuous processes [J. T. Leppavuori et al., 2011], which cannot capture the relations between batches. Considering that the initial states of each batch have similarity but also with some slight variation in many batch processes, such as fed-batch fermentation processes, $x_{i,1} = x_{i-1,1} + \gamma_{i-1,1}$ is usually used for the assignment of the initial states and defines relationship between batches [Y. Yao et al., 2008], where i represents the batch number. However, in practice, the operator often adjusts the initial states of the current batch according to the terminal performance of the last batch. For instance, in batch fermentation process, substrate is added into the fermenter only once to ensure existence of sufficient but not too much nutrition during fermentation. If the substrate concentration remains large at the end of fermentation, the initial substrate concentration of next batch will be decreased [M. Boonmee et al., 2003]. Therefore, with consideration of relations between terminal states, a practical dynamic model to describe the batch process can be written as

$$\begin{cases} x_{i,k} = f(x_{i,k-1},\theta) + \omega_{i,k-1} \\ y_{i,k} = h(x_{i,k},\theta) + v_{i,k} \\ x_{i,1} = f(x_{i-1,T},x_{i-1,1}) + \gamma_{i-1,T} \end{cases} \tag{2}$$

where k denotes the sample number. Denote $\mathbb{X} = \{X_1, X_2, \cdots, X_I\}$ and $\mathbb{Y} = \{Y_1, Y_2, \cdots, Y_I\}$ as the states and the measurements for I batches, where X_i and Y_i are all the states and measurements of the i^{th} batch, respectively. Note that the third equation of (2) defined here is more general than $x_{i,1} = x_{i-1,1} + \gamma_{i-1,1}$ [M. Boonmee et al., 2003].

This paper investigates the parameter estimation given the model structure as (2), and maximum likelihood (ML) method is employed to solve the problem. Due to the distinct features of batch process, the individuality and commonality of batches are both considered, where likelihood function of each batch process is individually set up and batches are related through terminal states during implementation of the ML method. Moreover, since states are unmeasured, expectation-maximization (EM) algorithm is introduced to accomplish the ML estimation. In the expectation step of EM algorithm, particle filters are used for the smoothing and filtering of the nonlinear and non-Gaussian processes.

2. Maximum likelihood estimation

Given the measurements $\mathbb{Y}$, the log-likelihood is $logp(\mathbb{Y}|\theta)$ and θ can be derived by maximizing the log-likelihood: $\theta = argmax\ \ logp(\mathbb{Y}|\theta)$. However, it is difficult to calculate the log-likelihood according to (2) without knowing the state. Treating $\mathbb{X}$ as "observations", the parameter estimation using ML method can be written as below

$$\theta = argmax\ \ L_\theta(\mathbb{X},\mathbb{Y}) = argmax\ \ logp_\theta(\mathbb{X},\mathbb{Y}) \tag{3}$$

where $p_\theta(\mathbb{X},\mathbb{Y}) = p_\theta(\mathbb{X})p_\theta(\mathbb{Y}|\mathbb{X})$, $p_\theta(\mathbb{X}) = p_\theta(X_1)\prod_{i=2}^{I} p_\theta(X_i|X_{1:i-1})$ and $p_\theta(\mathbb{Y}|\mathbb{X}) = p_\theta(Y_1|\mathbb{X})\prod_{i=2}^{I} p_\theta(Y_i|Y_{1:i-1},\mathbb{X})$. In order to compute the log-likelihood shown in (3), several assumptions are made as follows.

Assumption 1: state within a batch or across batches follows a first-order Markov process, satisfying $p_\theta(X_i|X_{1:i-1}) = p_\theta(X_i|X_{i-1})$ and $p_\theta(x_{i,j}|x_{i,1:j-1},X_{1:i-1}) = p_\theta(x_{i,j}|x_{i,j-1})$.

Assumption 2: observations are conditionally independent given the states, satisfying $p_\theta(Y_i|Y_{1:i-1},\mathbb{X}) = p_\theta(Y_i|X_i)$ and $p_\theta(y_{i,j}|y_{i,1:j-1},x_{i,1:j}) = p_\theta(y_{i,j}|x_{i,j})$.

Therefore, $p_\theta(\mathbb{X}) = p_\theta(x_{1,1})(\prod_{j=2}^{T} p_\theta(x_{1,j}|x_{1,j-1}))\prod_{i=2}^{I}[(\prod_{j=2}^{T} p_\theta(x_{i,j}|x_{i,j-1})]p_\theta(x_{i,1}|x_{i-1,1},x_{i-1,T})$, $p_\theta(\mathbb{Y}|\mathbb{X}) = \prod_{i=1}^{I}\prod_{j=1}^{T} p_\theta(y_{i,j}|x_{i,j})$. For models with missing or hidden

data, EM algorithm is a valid method for parameter estimation through maximizing the likelihood. Since the state is actually unknown, EM algorithm is employed to maximize (3), and the expectation of log-likelihood according to [R. B. Gopaluni, 2008] is

$$\begin{aligned} Q(\theta_i,\theta) &= \int logp_\theta(x_{1,1})p(x_{1,1}|\mathbb{Y},\theta_i)dx_{1,1} + \sum_{i=2}^{I}\sum_{j=2}^{T}\int logp_\theta(x_{i,j}|x_{i,j-1}) \\ &\quad p(x_{i,j-1:j}|\mathbb{Y},\theta_i)dx_{i,j-1:j} + \sum_{i=2}^{I}\int logp_\theta(x_{i,1}|x_{i-1,1},x_{i-1,T}) \\ &\quad p(x_{i,1},x_{i-1,1},x_{i-1,T}|\mathbb{Y},\theta_i)dx_{i,1}dx_{i-1,T}dx_{i-1,1} + \sum_{j=2}^{T}\int logp_\theta(x_{1,j}|x_{1,j-1}) \\ &\quad p(x_{1,j-1:j}|\mathbb{Y},\theta_i)dx_{1,j-1:j} + \sum_{i=1}^{I}\sum_{j=1}^{T}\int logp_\theta(y_{i,j}|x_{i,j})p(x_{i,j}|\mathbb{Y},\theta_i)dx_{i,j} \end{aligned} \quad (4)$$

From (4), the likelihood function needs to be computed for each batch, and the third term of the right side reflects the interaction of batches. In the maximization step, the gradient of $Q(\theta_i,\theta)$ with respect to θ is calculated to estimate θ, where smoothing of $p(x_{i,j}|\mathbb{Y})$ and joint distribution $p(x_{i,t},x_{i,t+1}|\mathbb{Y})$, $p(x_{i,1},x_{i,T},x_{i+1,1}|\mathbb{Y})$ need to be resolved to obtain the Q function. Since nonlinearity and non-Gaussianity are usually involved in states and measurements, particle filters are employed to estimate the posterior density function of states following the approach of [N. Gordon et al., 1993, M. Klaas et al., 2006].

3. Implementation of EM algorithm for parameter estimation

3.1. Smoothing in batch process

Assume each batch has T samples. If $j < T$, the smoother is derived as [R. B. Gopaluni, 2008]

$$p(x_{i,j}|\mathbb{Y}) = p(x_{i,j}|Y_{1:i-1},y_{i,1:j})\int \frac{p(x_{i,j+1}|\mathbb{Y})p(x_{i,j+1}|x_{i,j},\theta)dx_{i,j+1}}{\int p(x_{i,j}|Y_{1:i-1},y_{i,1:j})p(x_{i,j+1}|x_{i,j})dx_{i,j}} \quad (5)$$

According to the Monte Carlo method, $p(x_{i,j}|\mathbb{Y}) = \sum_{n=1}^{N}\omega_{i,j|IT}^{(n)}\delta(x_{i,j}-x_{i,j}^n)$. Therefore, the smoother weights are $\omega_{i,t|IT}^{(n)} = \omega_{i,t}^{(n)}\sum_{j=1}^{N}\omega_{i,t+1|IT}^{(j)}\frac{p(x_{i,t+1}^j|x_{i,t}^n,\theta)}{\sum_{k=1}^{N}\omega_{i,t}^{(k)}p(x_{i,t+1}^j|x_{i,t}^k,\theta)}$.

If $j = T$, the smoother is transformed into

$$p(x_{i,T}|\mathbb{Y}) = \int p(x_{i+1,1}|\mathbb{Y})\frac{p(x_{i,T}|Y_{1:i})p(x_{i,1}|Y_{1:i})p(x_{i+1,1}|x_{i,T},x_{i,1})}{p(x_{i+1,1}|Y_{1:i})}dx_{i,1}dx_{i+1,1} \quad (6)$$

It should be noted that there is an assumption in (6): Owing to the fact that the effect of initial value of a stable filter fades out and has little effect on the final value, $p(x_{i,T}|x_{i,1},Y_{1:i}) = p(x_{i,T}|Y_{1:i})$. The smoother weights are $\omega_{i,T|IT}^{(n)} = \omega_{i,T}^{(n)}\sum_{j=1}^{N}\omega_{i+1,1|IT}^{(j)}\frac{p(x_{i+1,1}^j|x_{i,T}^n,x_{i,1}^j)\omega_{i,1|iT}^j}{\sum_{k=1}^{N}\omega_{i,T}^{(k)}p(x_{i+1,1}^j|x_{i,T}^k,x_{i,1}^k)\omega_{i,1|iT}^k}$, where $\omega_{i,1|iT}^j$ represents the smoother weights satisfying $p(x_{i,1}|Y_{1:i}) = \sum_{k=1}^{N}\omega_{i,t|iT}^k\delta(x_{i,1}-x_{i,1}^k)$. Similar to the calculation of $\omega_{i,t|IT}^{(n)}$, the smoother $p(x_{i,j}|Y_{1:i})$ is computed as

$$p(x_{i,j}|Y_{1:i}) = p(x_{i,j}|Y_{1:i-1},y_{i,1:j})\int \frac{p(x_{i,j+1}|Y_{1:i})p(x_{i,j+1}|x_{i,j})dx_{i,j+1}}{\int p(x_{i,j+1}|x_{i,j})p(x_{i,j}|Y_{1:i-1},y_{i,1:j})dx_{i,j}} \quad (7)$$

Therefore, the smoother weights are $\omega^n_{i,t|iT} = \omega^n_{i,t|iT} \sum_{j=1}^N \omega^j_{i,t+1|iT} \frac{p(x^j_{i,t+1}|x^n_{i,t})}{\sum_{k=1}^N \omega^k_{i,t} p(x^j_{i,t+1}|x^k_{i,t})}$.

3.2. Smoothing for joint distribution

If $t < T$, the joint distribution is [R. B. Gopaluni, 2008]

$$p(x_{i,t}, x_{i,t+1}|\mathbb{Y}) = p(x_{i,t+1}|\mathbb{Y}) \frac{p(x_{i,t+1}|x_{i,t}) p(x_{i,t}|y_{i,1:t}, Y_{1:i})}{\int p(x_{i,t+1}|x_{i,t}) p(x_{i,t}|y_{i,1:t}, Y_{1:i}) dx_{i,t}} \tag{8}$$

Then the smoother weights are $\omega^{(n)}_{i,t,t+1} = \frac{\eta^n_{i,t}}{\sum_{n=1}^N \eta^n_{i,t}}$, where $\eta^n_{i,t} = \omega^{(n)}_{i,t} \omega^{(n)}_{i,t+1|IT} \frac{p(x^n_{i,t+1}|x^n_{i,t})}{\sum_{k=1}^N \omega^{(k)}_{i,t} p(x^n_{i,t+1}|x^k_{i,t})}$.

If $t = T$, the joint distribution involves the initial states as

$$\begin{aligned} p(x_{i,1}, x_{i,T}, x_{i+1,1}|\mathbb{Y}) &= p(x_{i+1,1}|\mathbb{Y}) \frac{p(x_{i+1,1}|x_{i,1}, x_{i,T}) p(x_{i,T}|Y_{1:i}) p(x_{i,1}|Y_{1:i})}{\int p(x_{i+1,1}|x_{i,1}, x_{i,T}) p(x_{i,T}|Y_{1:i}) p(x_{i,1}|Y_{1:i}) dx_{i,1} dx_{i,T}} \\ &= \sum_{n=1}^N \omega^n_{i,T,1} \delta(x_{i+1,1} - x^n_{i+1,1}) \delta(x_{i,1} - x^n_{i,1}) \delta(x_{i,T} - x^n_{i,T}) \end{aligned} \tag{9}$$

The smoother weights are $\omega^{(n)}_{i,T,1} = \frac{\eta^n_{i,T}}{\sum_{n=1}^N \eta^n_{i,T}}$, where $\eta^n_{i,T} = \omega^{(n)}_{i,T} \omega^{(n)}_{i,1|iT} \omega^{(n)}_{i+1,1|IT} \frac{p(x^n_{i+1,1}|x^n_{i,T}, x^n_{i,1})}{\sum_{k=1}^N \omega^{(k)}_{i,1|iT} \omega^{(k)}_{i,T} p(x^n_{i+1,1}|x^k_{i,T}, x^k_{i,1})}$.

To summarize, the Q function can be expressed as

$$\begin{aligned} Q(\theta_i, \theta) &= \sum_{k=1}^N \omega^k_{1,1|IT} log p_\theta(x^k_{1,1}) + \sum_{i=2}^I \sum_{j=2}^T \sum_{k=1}^N \omega^k_{i,j-1,j} log p_\theta(x^k_{i,j}|x^k_{i,j-1}) + \\ &\quad \sum_{i=2}^I \sum_{k=1}^N \omega^k_{i-1,T,1} log p_\theta(x^k_{i,1}|x^k_{i-1,T}, x^k_{i-1,1}) + \\ &\quad \sum_{j=2}^T \sum_{k=1}^N \omega^k_{1,j-1,j} log p_\theta(x^k_{1,j}|x^k_{1,j-1}) + \sum_{i=1}^I \sum_{j=1}^T \sum_{k=1}^N \omega^k_{i,j|IT} log p_\theta(y_{i,j}|x^k_{i,j}) \end{aligned} \tag{10}$$

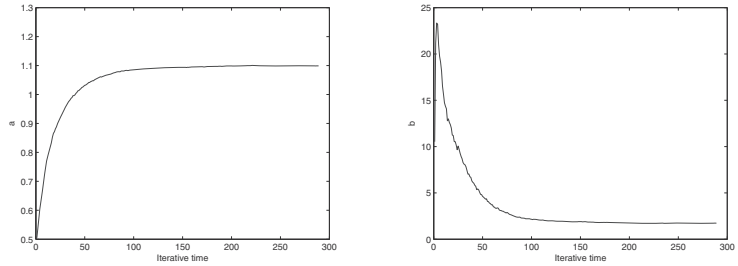
If an analytical solution of θ to maximize (10) is intractable, numerical methods can be employed to obtain the parameter estimation. Computations of (10) and θ are iterated until the convergence of θ.

4. Simulation

Consider a batch process given by the following model:

$$\begin{cases} x_k = a * x_{k-1} + \omega_{k-1} \\ y_k = a * b * x_k + \nu_k \end{cases} \tag{11}$$

and the initial state of each batch is dependent on the initial state and last state of the previous batch as $x_{i+1,1} = -0.01 * (x_{i,T} - 20) + x_{i,1} + \gamma_{i,T}$. The true values of a and b are 1.1 and 1.5, and the initial state of the initial batch is $x_{1,1} = 1.5$. Let the batch length equal to 20, and simulate data of 10 batches according to the model. The initial guesses of a, b and $x_{1,1}$ are 2.0, 1.0 and 1.0, and the number of particles for particle filtering is 20. All $\gamma_{i,T}$, ω_{k-1} and ν_k satisfy Gaussian distribution with mean values of 0 and the variances of 0.000001, 0.000001, 0.000001, respectively. Since the actual variances are unknown in the filtering process and their guessed variances are taken as 0.001, 0.03, 0.1 to simulate performance under the mismatch. The estimation results are shown in Fig 1. One can see that the estimations of both parameters asymptotically converge to the true ones.



(a) The estimation of a (b) The estimation of b

Figure 1: Estimation Results

5. Conclusion

The maximum likelihood method for parameter estimation is developed for batch process, which takes the individuality and commonality property of batch processes into account. Since the state is hidden, the expectation-maximization algorithm is employed to solve the maximum likelihood estimation problem. Due to the speciality of batch processes, smoothing algorithms for the terminal state of each batch and the joint posterior distributions are derived. In addition, in view of nonlinearity and non-Gaussian property of the process and noise, particle filtering methods are applied for filtering and smoothing.

Abstract

In this paper, we propose a filtering approach for state estimation of nonlinear continuous-discrete differential algebraic equations (DAE) systems. In such systems, while the process dynamics is a set of continuous time differential algebraic equations, the measurements are discrete time. We propose continuous-discrete unscented Kalman filter (UKF) for estimating states for such systems. The proposed approach is an extension of the work of Särkkä (2007), which considered nonlinear continuous-discrete ordinary differential equations (ODE) systems. The key idea in approach is that the mean and covariance of the differential states are integrated directly using continuous time differential equations. This is in contrast to the prevalent discrete time approach in literature, which involves propagating individual sigma points through noise free model and then computing the mean and covariance of the states. In our proposed approach, the algebraic states are computed from differential states by solving the algebraic equations separately. This idea of handling algebraic states is borrowed from Mandela et al. (2010). We demonstrate the applicability of the proposed continuous-discrete UKF approach by applying it for state estimation of a well known simulation case study.

Keywords: UKF, DAE, Continuous discrete system

1. Introduction

Nonlinear differential algebraic equations (DAE) systems are frequently obtained while modeling chemical processes. For example, while mass and energy balances typically result in differential equations, consideration of thermodynamics and equilibrium relationships result in algebraic equations. These dynamics are best modeled as continuous time DAE. However, measurements in such processes are usually available at discrete times due to sampling required for computer based data acquisition and control systems, thereby resulting in an overall nonlinear continuous-discrete DAE system. Hence, problem of state estimation for nonlinear continuous-discrete DAE systems is quite relevant for chemical industries.

In literature, the various extensions of Kalman filter such as extended Kalman filter (EKF) (Jazwinski, 1970) and UKF (Julier et al., 1995) have been mainly developed for state estimation of nonlinear ODE systems. Most of these techniques are widely used for discrete

*mbhushan@iitb.ac.in

time filtering problem. A few extensions of such approaches available for continuous-discrete filtering problem for nonlinear ODE systems are: continuous-discrete versions of EKF (Jazwinski, 1970), UKF (Särkkä, 2007) and cubature Kalman filter (Arasaratnam et al., 2010).

For DAE systems, extensions of EKF and UKF are available for state estimation of nonlinear but discrete time DAE systems. Becerra et al. (2001) extended EKF approach for estimating states of nonlinear DAE. However, their approach does not utilize the algebraic state measurements while computing algebraic states estimates. Recently, Mandela et al. (2010) proposed a modified EKF approach to overcome this problem. Further, they also proposed extension of UKF approach for state and parameters estimation of DAE systems. All these approaches are applicable for discrete time nonlinear DAE systems. However, most of the problems encountered in chemical processes are continuous-discrete DAE in nature. To the best of our knowledge, extensions of EKF and UKF for directly dealing with such continuous-discrete DAE systems are not available. In this article, we propose continuous-discrete UKF (CDUKF) approach for performing state estimation in nonlinear continuous-discrete DAE systems. The proposed approach is discussed in section 2 and is applied to a case study in section 3. The conclusions are presented in section 4.

2. Continuous Discrete Unscented Kalman Filter

In this section, the proposed CDUKF formulation for state estimation of nonlinear continuous discrete DAE systems is presented. Such systems have continuous time process model but the measurements are available at discrete time intervals. The proposed approach is an extension of the CDUKF formulation presented by Särkkä (2007) for handling nonlinear continuous-discrete ODE systems. In our approach, the differential states are handled in the same manner as in Särkkä (2007). During the prediction step, the mean and the covariance matrix of the differential states are integrated directly (with continuous noise contribution). This is in contrast to discrete UKF, where individual sigma points are propagated through the noise free model and noise contribution is considered only at the measurement sampling times while obtaining the covariance matrix. The method for handling algebraic states in our proposed approach is similar to that of Mandela et al. (2010), where algebraic states are computed separately by solving the algebraic equations using a nonlinear root finding solver. The issue of solving algebraic states separately from the differential states has been discussed in Mandela et al. (2010). The estimation step is similar to that of standard UKF (Julier et al., 1995) for computing estimated mean and covariance but only for the differential states. Algebraic equations are then solved separately to compute the mean of algebraic states. The exact procedure for the proposed CDUKF for nonlinear DAE is summarized next. More details are available in Kadu (2011). Consider the following continuous-discrete time DAE model:

$$\frac{dx(t)}{dt} = f(x(t),z(t),t) + L(t)e(t);\;\; g(x(t),z(t),t) = 0;\;\; y_k = h_d(x(t_k),z(t_k)) + v_k \qquad (1)$$

where t and k represent the continuous time and discrete sampling instant respectively, $x \in \mathbf{R}^{n_d \times 1}$, $z \in \mathbf{R}^{n_a \times 1}$ and $y_k \in \mathbf{R}^{r \times 1}$ are the differential states, algebraic states and the measurement vectors. n_d and n_a represent number of differential and algebraic states respectively. Process noise $e(t)$ represents the unmodelled process dynamics in Eq. (1) and is assumed to be white, Gaussian, continuous time stochastic process with mean zero and covariance $Q_c(t)$. The measurements are corrupted by noise v_k which is assumed to be

be white, Gaussian discrete time stochastic process with mean zero and covariance R_k. Further, v_k and $e(t)$ are assumed to be uncorrelated. Functions $f()$ and $g()$ represent the differential and algebraic equations in the DAE model and $h_d()$ represents the measurement model. $L(t)$ is the matrix associated with process noise. Further, without loss of generality inputs are not considered in the above model. $x(t_k)$ represents the value of $x(t)$ at k^{th} measurement instant. For given estimated states $(\hat{x}(t_k^+))$ and associated covariance $(P(t_k^+))$ at k^{th} measurement instant, the CDUKF formulation is summarized below. Here, $+$ and $-$ indicate the time instances just after and before the measurements.

Prediction or forecast step:
The predicted mean of differential states $(\hat{x}(t_{k+1}^-))$ and its covariance $(P(t_{k+1}^-))$ are computed by directly integrating following equations:

$$\frac{d\hat{x}(t)}{dt} = f(\hat{X}(t),\hat{Z}(t),t)w; \quad g(\hat{X}(t),\hat{Z}(t),t) = 0 \tag{2}$$

$$\frac{dP(t)}{dt} = \hat{X}(t)Wf^T(\hat{X}(t),\hat{Z}(t),t) + f(\hat{X}(t),\hat{Z}(t),t)W[\hat{X}(t)]^T + L(t)Q_c(t)L^T(t) \tag{3}$$

where $\hat{X}(t) \in \mathbf{R}^{n_d \times N_p}$ is the matrix of sigma points of differential states, which is given as (Särkkä, 2007):

$$\hat{X}(t) = [\hat{x}(t) \ \ ...\hat{x}(t)] + \sqrt{n_d + \kappa}\left[[0]_{n_d \times 1} \ \ \sqrt{P(t)} \ \ -\sqrt{P(t)}\right] \tag{4}$$

with κ as a tuning parameter and $w \in \mathbf{R}^{n_d \times 1}$ being the vector of sigma points weights specified as: $w_0 = \frac{\kappa}{(n_d+\kappa)}$ and $w_i = \frac{1}{2(n_d+\kappa)}, \ i = 1 \ to \ 2n_d$. Matrix $W \in \mathbf{R}^{N_p \times N_p}$ is defined as (Särkkä, 2007):

$$W = \left[I - [w \ \ ... \ \ w]_{N_p \times N_p}\right] w_{diag} \left[I - [w \ \ ... \ \ w]_{N_p \times N_p}\right]^T \tag{5}$$

where, $w_{diag} \in \mathbf{R}^{N_p \times N_p}$ is the diagonal matrix form of vector of sigma points weights and $N_p = 2n_d + 1$ is the number of sigma points. Corresponding to the vectors in matrix $\hat{X}$ (sigma points for differential states), the vectors for the algebraic states are obtained by solving the algebraic equations for the given differential states. These vectors make-up the matrix $Z \in \mathbf{R}^{n_a \times N_p}$ and are compactly represented by the algebraic equations: $g(\hat{X}(t),\hat{Z}(t),t) = 0$. Similarly, the notation $f(\hat{X}(t),\hat{Z}(t),t)$ indicates a matrix (size $n_d \times N_p$) of function evaluations, such that the j^{th} column is the function vector f (Eq. 1) evaluated for the j^{th} sigma point (i.e. j^{th} column of $\hat{X}(t)$ and $\hat{Z}(t)$ matrices). Eq. (2) is integrated from initial conditions $\hat{x}(t_k^+)$ and $P(t_k^+)$ to time t_{k+1}. The predicted differential state mean and state prediction error covariance matrix are then given as $\hat{x}(t_{k+1}^-) = \hat{x}(t_{k+1})$, and $P(t_{k+1}^-) = P(t_{k+1})$ respectively. The consistent predicted algebraic state mean $(\hat{z}(t_{k+1}^-) = \hat{z}(t_{k+1}))$ is obtained by solving algebraic equation $g(\hat{x}(t_{k+1}),\hat{z}(t_{k+1})) = 0$. The sigma points matrix $\hat{X}(t_{k+1}^-)$ is generated by using Eq. (4) in which the terms $\hat{x}(t)$ and $P(t)$ are replaced with $\hat{x}(t_{k+1}^-)$ and $P(t_{k+1}^-)$ respectively. The consistent matrix of algebraic states is computed by solving equation $g(\hat{X}(t_{k+1}^-),\hat{Z}(t_{k+1}^-),t) = 0$. These sigma points matrices are used in the next (estimation) step.

Estimation or data assimilation step:
The matrices of sigma points are propagated through measurement model to predict the matrix of measurement sigma points:

$$Y_{k+1}^- = h_d(\hat{X}(t_{k+1}^-),\hat{Z}(t_{k+1}^-)) \tag{6}$$

The predicted observation $(\hat{y}_{k+1}^-)$, the total covariance in innovation sequence $(P_{ee,k+1}^-)$ and the cross covariance between the state prediction error and innovation sequence $(P_{se,k+1}^-)$ are computed as:

$$\hat{y}_{k+1}^- = Y_{k+1}^- w; \quad P_{ee,k+1}^- = Y_{k+1}^- W [Y_{k+1}^-]^T + R_{k+1}; \quad P_{se,k+1}^- = \hat{X}(t_{k+1}^-) W [Y_{k+1}^-]^T \tag{7}$$

The Kalman gain (K_{k+1}), estimated mean $(\hat{x}(t_{k+1}^+))$ of differential state, associated state estimation error covariance matrix $(P(t_{k+1}^+))$ and estimated mean of algebraic state $(\hat{z}(t_{k+1}^+)$ are computed as:

$$K_{k+1} = P_{se,k+1}^- [P_{ee,k+1}^-]^{-1}; \quad \hat{x}(t_{k+1}^+) = \hat{x}(t_{k+1}^-) + K_{k+1}[y_{k+1} - \hat{y}_{k+1}^-] \tag{8}$$

$$P(t_{k+1}^+) = P(t_{k+1}^-) - K_{k+1} P_{ee,k+1}^- K_{k+1}^T; \quad g(\hat{x}(t_{k+1}^+), \hat{z}(t_{k+1}^+), t) = 0 \tag{9}$$

This completes one cycle: going from measurement instant k to $k+1$. This procedure is then repeated for the next measurement instance.

3. Results and Discussions

The applicability of the proposed CDUKF approach is demonstrated on a nonlinear DAE case study given by Becerra et al. (2001). The case study is based on a kinetic model of an isothermal batch reactor system represented using nonlinear DAE involving six differential (mass balances) equations and one algebraic electro-neutrality condition as:

$$\begin{aligned}
&\dot{x}_0 = -k_2 x_1 \frac{K_2 x_0}{K_2 + 10^{-z_0}}; \; \dot{x}_1 = -k_1 x_1 x_5 + k_{-1} \frac{K_1 x_4}{K_1 + 10^{-z_0}} - k_2 x_1 \frac{K_2 x_0}{K_2 + 10^{-z_0}} \\
&\dot{x}_2 = k_2 x_1 \frac{K_2 x_0}{K_2 + 10^{-z_0}} + k_3 x_3 x_5 - k_{-3} \frac{K_3 x_2}{K_3 + 10^{-z_0}}; \; \dot{x}_3 = -k_3 x_3 x_5 + k_{-3} \frac{K_3 x_2}{K_3 + 10^{-z_0}} \\
&\dot{x}_4 = k_1 x_1 x_5 - k_{-1} \frac{K_1 x_4}{K_1 + 10^{-z_0}} \\
&\dot{x}_5 = -k_1 x_1 x_5 + k_{-1} \frac{K_1 x_4}{K_1 + 10^{-z_0}} - k_3 x_3 x_5 + k_{-3} \frac{K_3 x_2}{K_3 + 10^{-z_0}} \\
&\left[Q^+\right] - x_5 + 10^{-z_0} - \frac{K_2 x_0}{K_2 + 10^{-z_0}} - \frac{K_3 x_2}{K_3 + 10^{-z_0}} - \frac{K_1 x_4}{K_1 + 10^{-z_0}} = 0
\end{aligned} \tag{10}$$

Hence, the model consists of six differential states $(x_0 - x_5)$ and one algebraic state (z_0). The measurement vector is $y_k = [x_0(t_k), x_1(t_k), x_2(t_k), x_3(t_k)]^T$. The values for the initial states and associated covariance matrix are taken from Becerra et al. (2001). Here, entire simulation is carried out at constant temperature of $98^o C$. The true differential states were generated using 500 steps of Euler-Maruyama scheme (Kloeden and Platen, 1999) between time interval of 0.01 h. The corresponding consistent algebraic state was obtained by solving the algebraic equation at each step of Euler scheme. The proposed CDUKF was implemented by integrating the mean and covariance of differential states using 300 steps of fourth order Runge-Kutta integration between measurement intervals. The consistent algebraic state at any stage is obtained by solving the algebraic equation. The following parameter values were used: Q_c is taken to be $1e-5$ times Identity matrix (of size 6×6), R_k is also taken to be a diagonal matrix with entries 4e-5,4e-5,1e-5,1e-5 on the diagonal, and $\kappa = 1$. The measurement sampling time was taken as 0.05 h. The true and CDUKF estimated values for five differential states $(x_0, x_1, x_2, x_4, x_5)$ and the algebraic state (z_0) are plotted in Figure (1) for illustration. It can be seen from the Figure that CDUKF tracks differential as well as algebraic states very well. All the computations were performed in MATLAB® version 7.4.

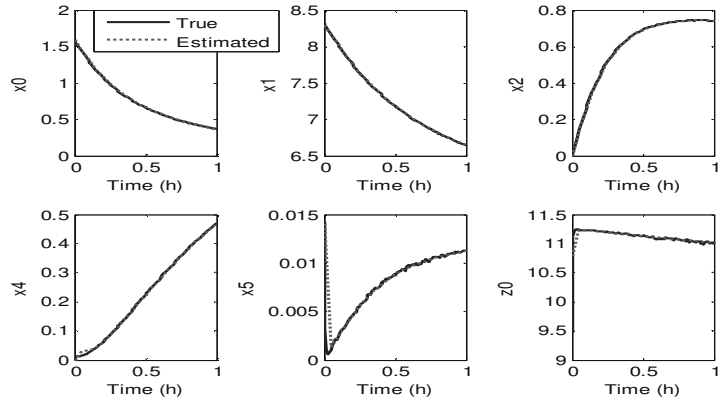

Figure 1. State estimation by CDUKF

4. Conclusion

A continuous-discrete extension of UKF (labeled CDUKF) for nonlinear continuous-discrete DAE systems has been proposed in this paper. This has the potential to provide more accuracy from modeling point of view compared to completely discrete time implementations and from estimation point of view compared to other types of continuous-discrete implementations, such as those based on EKF.

Abstract

A systematic development of constitutive models within a generic modelling framework has been developed for use in design, analysis and simulation of crystallization operations. The framework contains a tool for model identification connected with a generic crystallizer modelling tool-box, a tool for data handling and translation as well as model application features. Through this framework it is possible, for a wide range of crystallization processes, to generate the necessary problem-system specific models; to identify the parameters for constitutive models; and to handle or translate raw crystallization data. Application of the systematic framework is highlighted through a sucrose crystallization case study, for which the parameters for nucleation and crystal growth are first estimated from the available measured data and are then applied to study the crystallization operation.

Keywords: Crystallization, generic modelling, model identification, data handling.

1. Introduction

Crystallization is often applied in the production of salts and active pharmaceutical ingredients (API), and the crystallization step is an essential part of the manufacturing process for many chemicals-based products. Recently the monitoring and analysis of crystallization operations has received increased attention due to the growing need to control more sophisticated production lines as well as to measure/monitor the final product characteristics [1]. Usually crystallization operations involve a combination of several phenomena, and different kinetic models are required for their modelling. For example, growth of the crystals occurs in multiple dimensions and the relative rates of different growth and other kinetic phenomena control the shape and size distribution of the final product [2]. A full representation of the crystallizer operation therefore requires a combination of different constitutive (kinetic) models representing different aspects (nucleation, growth, agglomeration, breakage, etc.) of crystallization together with the population balance and other equations. The constitutive models, however, have parameters that need to be identified, for which measured data is necessary. The measured data can be in different form and dimension. For example, crystal size distribution (CSD) data could be available in the form of chord length distribution that is obtained through Focused Beam Reflectance Measurement (FBRM) equipment [3]. Use of this data for modelling purposes requires a translation procedure.

The objective of this paper is to present a framework for systematic development of constitutive models within a generic modelling framework for use in design, analysis and simulation of crystallization operations. The framework has three main options: a) crystallization model development and constitutive model identification, b) data

handling, and c) model application. For different crystallization operation scenarios, the measured data are translated to create an image of the crystallized product. Through the model identification option, the parameters of the constitutive models (embedded within the crystallizer model) are regressed to match the image of the translated data. With the models identified, they can be applied for model-based design and/or analysis of crystallization operations. The different features are highlighted through a sucrose crystallization case study involving crystallization model generation, model identification and the use of the model in analysis of crystallization operations.

2. Systematic identification of crystallization kinetics

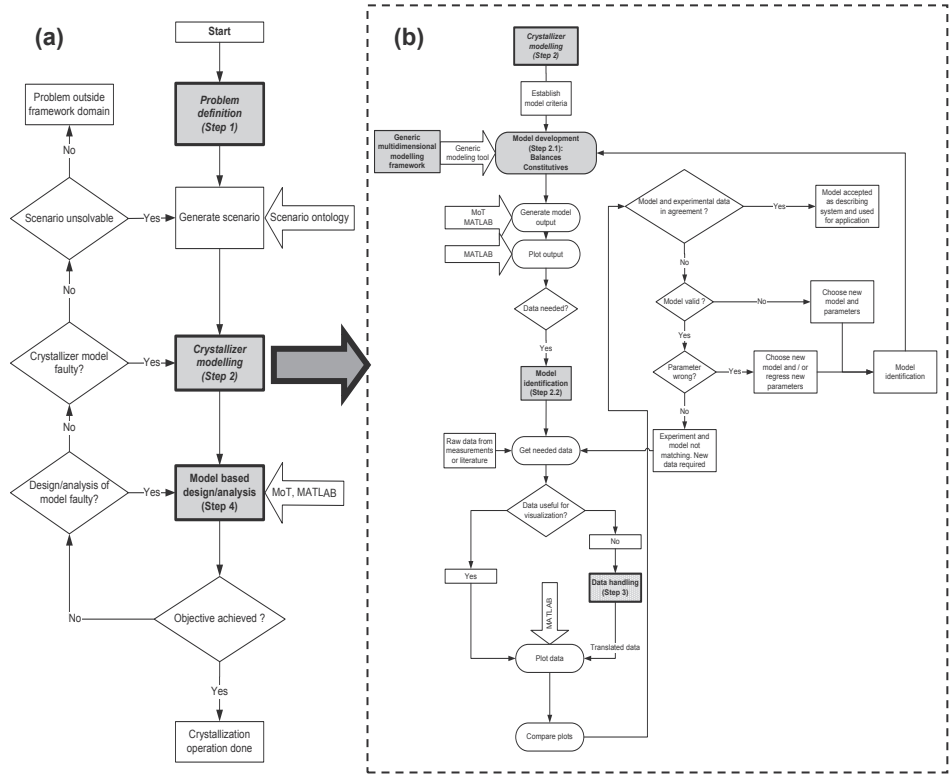

Figure 1. Systematic identification within a generic modelling framework

An overview of the different steps to be taken for systematic identification of crystallization kinetics within a generic modelling framework is shown in Fig. 1(a). The first step is the problem definition for the crystallization process under study where the overall objective is defined. Then the crystallization process scenario that needs to be investigated is generated from a scenario ontology tool-box. Step 2, crystallization model development, involves the model generation to represent the defined scenario. Here, the model identification and data handling frameworks have been integrated with the generic multi-dimensional modelling framework [4] as shown in Fig. 1(b). In step 2.1, the balance and constitutive equations are selected from the developed balances and kinetics model library in the generic multi-dimensional modelling framework [4] based on the specified assumptions and conditions. If the parameters are available, the generated problem-system specific model is then ready for use for the defined application. If not, data need to be supplied for model identification (step 2.2), for

example from experimental measurements. As such data may not come in the correct digital form for the corresponding model variable for example the CSD data shown in Fig. 2, a data handling step (step 3), which translates the data is employed. The model identification is completed by solving a parameter regression problem, including a consistency test for the data and a verification of the regressed parameters. After model identification, the complete model together with the estimated parameters is ready for use in model-based studies of crystallization operations (step 4).

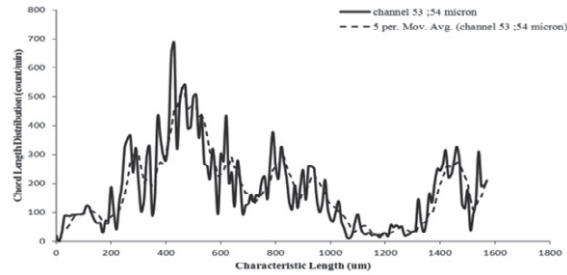

Figure 2. CSD data measured as chord length distribution

The data handling framework (step 3), as shown in Fig. 3, is used to translate the available/collected data to a form that can be employed for the parameter regression step. Here, different types of measured data are translated using an established data translation policy. Then the data are checked for consistency, after which, they are ready for parameter regression or model validation. New measured or collected data are needed if the available data fail the consistency test, while, the available model parameters are re-estimated if there is a mismatch between consistent data and model. Process-product knowledge is used for consistency check of data and evaluation of data-model mismatch.

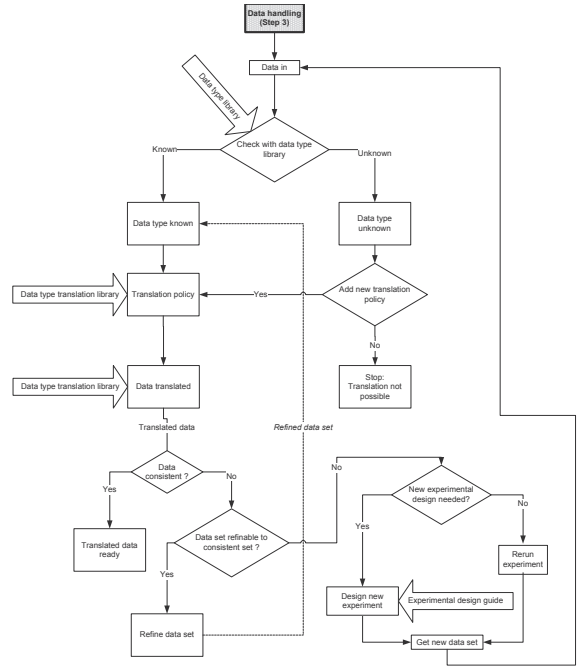

Figure 3. Data handling framework

3. Application of the systematic identification framework

The application of the frameworks for model identification and data handling is highlighted through a sucrose crystallization case study.

3.1. Problem definition (step 1)

The overall objective here is to develop a sucrose crystallization model for use in the design and analysis of crystallization operations. The operation scenario which consists of phase 1 (cooling operation), phase 2 (nucleation) and phase 3 (crystal growth) is then generated from the scenario ontology tool-box.

3.2. Crystallization model development and model identification (step 2)

The problem-system specific model for sucrose crystallization (see Table 1) is generated using the generic multi-dimensional modelling framework [4] by using similar conditions and assumptions as reported in the literature [5] (step 2.1). Before the generated model equations can be solved, the set of known variables (parameters and design variables) needs to be selected and specified. In this case study, values of the parameters k_{b0}, ΔE_b, b and m for nucleation (see Eq. (9) in Table 1) as well as k_{g0}, ΔE_g and g for crystal growth rate (see Eq. (10) in Table 1) are not available. Therefore, raw data need to be supplied. Measured data for temperature, concentration, supersaturation and total crystal mass were found in the literature [5]. Based on an analysis of the collected data, it is established that data handling and translation is not necessary as the data are found to be consistent and directly useable. The model identification step (step 2.2) is then performed in order to regress the parameters for the nucleation and crystal growth kinetic (constitutive) models.

Table 1. List of model equations for sucrose crystallization

No.	Equations	No.	Equations
1	$\frac{d\mu_0}{dt} = B_{nuc}$	6	$c^{sat} = a_{i1} + b_{i1}T + c_{i1}T^2 + d_{i1}T^3$
2	$\frac{d\mu_j}{dt} = jG\mu_{j-1}$ for $j = 1,2,3,4$	7	$S = \frac{c - c^{sat}}{c^{sat}}$
3	$\frac{dc}{dt} = -3\rho_c k_v G\mu_2$	8	$M_c = \rho_c k_v \mu_3$
4	$\rho V c_p \frac{dT}{dt} = -\Delta H_c \rho_c k_v V\ 3G\mu_2\ - U_1 A_1\ T - T_w$	9	$B_{nuc} = k_{b0} \exp\ -\ \Delta E_b / RT\ \ S^b M_c^{\ m}$
5	$\rho_w V_w c_{pw} \frac{dT_w}{dt} = \rho_w F_{win} c_{pw}\ T_{win} - T_w$ $+ U_1 A_1\ T - T_w\ + U_2 A_2\ T_{ex} - T_w$	10	$G = k_{g0} \exp\ -\ \Delta E_g / RT\ \ S^g$

The parameter estimation is performed based on the experimental data for temperature ($T_{i_{exp}}$), sucrose concentration ($c_{i_{exp}}$), supersaturation ($S_{i_{exp}}$) and total crystal mass ($M_{c,i_{exp}}$) as functions of time. The objective function for parameter regression takes the form:

$$F_{obj} = \min_{\theta} \left\{ w_T \sum_{i=1}^{n} \left\{ \frac{T_{i_{calculated}} - T_{i_{exp}}}{T_{i_{exp}}} \right\}^2 + w_c \sum_{i=1}^{n} \left\{ \frac{c_{i_{calculated}} - c_{i_{exp}}}{c_{i_{exp}}} \right\}^2 + w_S \sum_{i=1}^{n} \left\{ \frac{S_{i_{calculated}} - S_{i_{exp}}}{S_{i_{exp}}} \right\}^2 + w_{Mc} \sum_{i=1}^{n} \left\{ \frac{M_{c,i_{calculated}} - M_{c,i_{exp}}}{M_{c,i_{exp}}} \right\}^2 \right\} \quad (1)$$

Subject to: All model equations in Table 1 and $\theta_{\min} \le \theta \le \theta_{\max}$

Where $\theta = [k_{b0}, b, \Delta E_b, k_{g0}, g, \Delta E_g, m]$ is the set of parameters for the nucleation and crystal growth kinetics models, $\theta_{\min}$ and $\theta_{\max}$ are the specified lower and upper bounds for each parameter, respectively. The parameter regression problem is solved with the ICAS-MoT modelling tool and the resulting model parameters for the sucrose crystallization are given in Table 2 (F_{obj} =1.15x10^{-8}), where the values obtained are consistent with the estimated ones reported by Ouiazzane et al. [5].

Table 2. Optimum kinetic parameters for sucrose crystallization

Kinetic parameters	k_{b0}	b	ΔE_b	k_{g0}	g	ΔE_g	m
This work	3.2365x10^{13}	1.5	80.2765	2.4121x10^{6}	1	44.5618	0.4211
Ouiazzane's work	3.1512x10^{13}	1.5	78.752	2.2439x10^{6}	1	46.550	0.4136

Comparison of the simulation results with the identified sucrose model and the available experimental data shows a very good agreement (see Fig. 4). It is concluded that the sucrose crystallization model with the identified nucleation and crystal growth parameters is able to describe the temperature and sucrose concentration for the entire batch operation. Therefore the model is accepted to describe the system and is ready for use in the model-based studies.

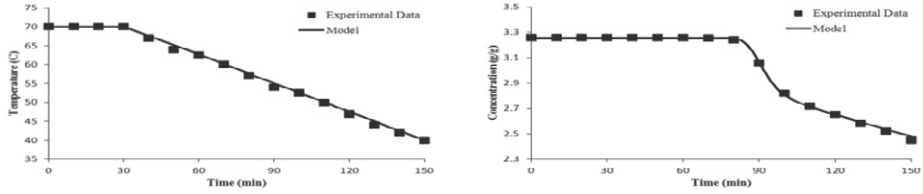

Figure 4. Model predictions and data (temperature and concentration) for sucrose crystallization

3.3. Application (step 4)

The model is now ready for design and analysis of crystallization operations. The open loop simulation results obtained are shown in Fig. 5, where the transient concentrations are plotted for 1-3 operational phases. Phase 1 indicates that the simulated sucrose concentration, initially at 3.26 g sucrose/g water is saturated from t = 30 min onwards. The sucrose (saturated) concentration is still maintained in phase 2 because most crystal nuclei are relatively small. The sucrose concentration only starts to decrease at t = 76 min during phase 3 (crystal growth): the crystal nuclei grow and a sucrose concentration of 2.46 g sucrose/g water is obtained by the end of the operation.

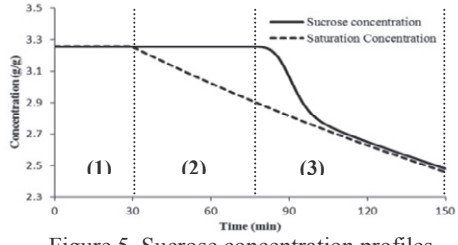

Figure 5. Sucrose concentration profiles

4. Conclusions

A systematic identification of crystallization kinetics within a generic modelling framework has been developed for operation and study of crystallization processes. The application of the newly developed framework for model identification has been highlighted through a sucrose case study. The sucrose crystallization model is generated through the generic crystallization modelling framework and the parameters for crystallization kinetics have been successfully estimated. Application of the data handling framework could not be highlighted because of the page limitation. Currently, this framework is able to handle and translate FBRM data into a one-dimensional CSD. Current and future work is focused on expanding the databases for operational scenarios, data measurement techniques and data translation policies that will allow a broader range of applications of the total modelling framework.

Generation of first and higher order derivative information out of the documentation level

Victor Alejandro Merchan, Robert Kraus, Tilman Barz,

Harvey Arellano-Garcia, Günter Wozny

Chair of Process Dynamics and Operation, Berlin Institute of Technology, Sekr KWT-9, Str. des 17.Juni 13, D-10623 Berlin,Germany

Abstract

The accurate and efficient evaluation of first and higher order derivative information of mathematical process models plays a major role in the field of Process Systems Engineering. Although it is well known that the chosen methods for derivative evaluation may have a major impact on solution efficiency, a detailed assessment of these methods is rarely made by the modeler. Since standard modeling tools and some solvers normally only support own default methods for derivative evaluation, the evaluation of further methods can be a tedious work, and thus requiring the connection of different tools.

In this contribution the implementation of a general method for generation of derivative information out of the documentation level is presented. Exploiting the possibility of code generation given by the web-based modeling environment MOSAIC (Kuntsche et al. 2011), derivative information of model equations is generated either by symbolic derivatives or by coupling the models with state of the art automatic differentiation (AD) tools. This offers the modeler different methods of getting exact derivative values and opens the possibility of integrating the assessment of derivative evaluations within the modeling and simulation workflow.

Keywords: Code generation, symbolic derivatives, automatic differentiation.

1. Introduction

The numerical evaluation of derivative information plays a major role in the solution of mathematical models in Process Systems Engineering. Typical problems like the solution of nonlinear equation systems (NLEs), the integration of dynamic systems described by stiff ordinary differential equations (ODEs) and differential algebraic equations (DAEs), or the solution of optimization problems do not only require derivative information of first and perhaps higher-order but also benefit from its efficient evaluation.

However, the evaluation of derivative values may not only be related to eventual higher robustness and rate of convergence but also to a big and not always justifiable, computational effort. The latter depends strongly on the suitability of the specific model to the employed method for derivative evaluation. The most popular methods for approximation or evaluation of derivatives are finite differences (FD), symbolic differentiation (SD), and algorithmic differentiation (AD). Good overviews about these and further techniques for derivative evaluation are given in (Tolsma and Barton 1998) and (Griewank 2009).

Following the literature of the last years, it is clear that AD has several significant advantages over FD and SD, since it offers the possibility of calculating exact tangents

and gradients of a procedure with a computational effort given by a small multiple of the effort required for the evaluation of the procedure itself (Griewank and Walther 2008). New algorithms for solution of ODEs (Schlenkrich et al. 2006) and optimization problems (Vekuturi et al. 2010) take advantage of this exact and efficient evaluation of tangents and gradients provided by AD, giving up the evaluation of full Jacobians and Hessians, but showing a high solution efficiency. However, many popular solvers for NLE, DAE and optimization still rely on full Jacobians and Hessians, which in some cases can be evaluated more efficiently with SD or FD. Furthermore, models are often coded in formats that can only be differentiated by specific methods.

Although the choice of the derivative evaluation method may have a major impact on solution efficiency, a detailed assessment of the different methods is rarely made by the modeler. Standard modeling tools and some solvers normally support only default or own methods and the implementation of further methods would result in a tedious work requiring the connection of different tools. In order to give the modeler the possibility of evaluating different derivative concepts on the solution of own models, a modeling environment should offer the modeler this possibilities automatically.

This work describes the implementation of flexible derivative generation based on modeling in the documentation level. Based on a documentation conform representation of model equations and the code generation capabilities of the web modeling environment MOSAIC (Kuntsche et al. 2011), solution code for NLEs and DAEs for different numerical solvers and modeling environment is generated along with derivative information provided either by FD, SD or standard AD tools. A direct assessment of different alternative methods for derivative evaluation is integrated into the modeling and simulation workflow.

2. Modeling in the documentation level with MOSAIC and derivatives

2.1. Documentation-level-modeling with MOSAIC

When modeling with the web-based modeling environment MOSAIC, the focus lies on the problem formulation and not on the implementation of a model to any specific programming or modeling language. Model equations coupled with an own notation are entered using LaTeX expressions allowing an equation representation conform to scientific papers or further types of model documentation. Internally the LaTeX expressions are transformed automatically to a well defined subset of presentation MathML that build the basis of model analysis and code generation: Out of the MathML expressions, program code can be generated for the solution with different numerical environments. Currently, models expressed by NLEs, ODEs, and DAEs are supported and thus solver code for these type of problems can be generated. To mention a few, code can be created for high level modeling languages like gPROMS and Aspen Custom Modeler, but also for MATLAB, and FORTRAN or C/C++ programs linked with standard numerical libraries.

A common fact concerning the different solvers supported by MOSAIC is that these may benefit from derivative information given by the user. This is especially interesting for the code generation for programming languages (Matlab, C/C++, FORTRAN), since high level modeling languages normally build own symbolic derivative objects. The implementation of derivative generation out of the documentation level as proposed by MOSAIC is shown in Fig. 1. Based on the MathML/XML representation of user defined models, not only code for symbolic derivatives can be created, so as to be provided or compiled along with solver code, but also derivative information can be obtained by adapting the solver code or code of symbolic derivatives to state of the art

AD tools. In the next section the implementation of symbolic derivatives and AD tools is discussed. Since FD is supported by all major solvers by default, when no further derivative information is given, it will not be treated in this work.

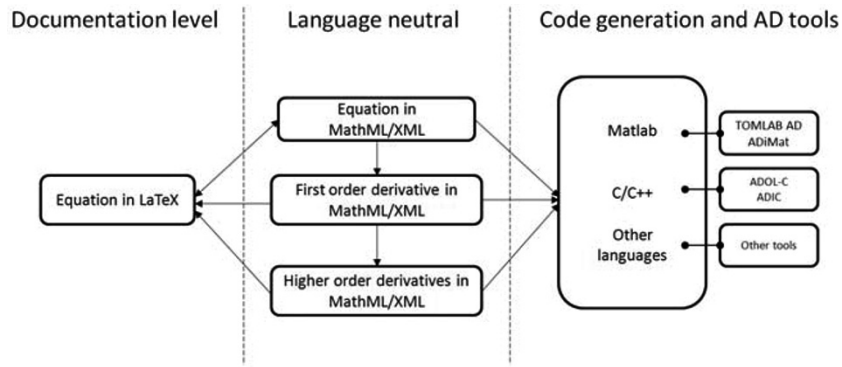

Fig. 1: Implementation of derivative generation out of the documentation level in MOSAIC

2.2. Symbolic derivatives in MOSAIC

The generation of symbolic derivatives implemented in MOSAIC is based on a recursive application of the differentiation rules on a tree representation of the respective equation object. Since the resulting derivatives are given by a further equation object, its respective MathML/XML representation can be used either to generate code for the evaluation of derivatives or it can be analyzed again in order to produce higher order derivatives.

Using the available MathML/XML expressions for equations and derivatives tailored Jacobians, Hessians or single derivative information can be generated that fulfill the format requirements of different solvers. Currently derivative code and sparsity patterns are generated for their use with Matlab and for C/C++ programs linked to the numerical libraries BzzMath (Buzzi-Ferraris) and CGSL.

2.3. Currently implemented AD-Tools

In addition to the symbolic derivatives, for some languages supported by MOSAIC, derivative information can be generated automatically by coupling the model equations with some standard AD tools. Compared to a MOSAIC specific, tool independent realization of AD, the generation of tailored code for different AD tools has the advantage of letting the user choose between different implementations, which provide the best of current AD tools. AD packages based on operator overloading and source transformation are supported. Further, depending on the chosen code generator and AD package further options are offered, e.g. forward or reverse mode.

Currently, the code generation has been adapted to generate BzzMath compatible derivatives with ADOL-C (Walther and Griewank 2008) and ADIC (Bischof et al. 1997), and derivative information for MATLAB either by the operator overloading package TOMLAB/MAD (Forth 2006) or the source transformation tool AdiMat (Bischof et al. 2002). By using the language specification tool, the user can adapt the structure of the solver code in order to use further AD tools. This is especially simple for tools based on operator overloading.

By looking at the generated code, the user may learn directly the specific needs and usage of the different AD tools. Solving the problem online, as it is offered when using the BzzMath library, the user has furthermore the possibility to compare different

standard tools or derivative evaluations methods (FD, SD and AD) without needing to install all libraries or tools in the own computer. The following results show a comparison of the influence of different derivative evaluation methods on the solution of a NLE as obtained by integration of derivative evaluation in MOSAIC's workflow.

3. Some numerical results

For the numerical test, we consider the distillation column test problem for a 20-stage column, also known as Hydrocarbon-20, a well known benchmark problem from the collection by (More 1991). In order to enhance the complexity of our case, all relations were entered in MOSAIC as single equations and thus resulting in a system with 280 equations while in the original formulation some of the equations are rearranged to form a reduced system with 99 equations.

For the tests the code generators for MATLAB and BzzMath are used, which create default implementations of the function fsolve and BzzMyNonLinearSystemObject respectively. The calculations with four different types of Jacobians are considered, the default implementation of finite differences, symbolic derivatives generated by MOSAIC, and derivatives gotten by coupling the model equations with AD operator overloading and source transformation tools. In MATLAB automatic differentiation was evaluated with TOMLAB/MAD using the sparse identity matrix as seed matrix, and ADiMat generating a compressed Jacobian in the forward mode. In case of the C++ code linked with BzzMath, standard methods for ADOL-C and ADIC are used.

Fig. 2 and 3 show the corresponding CPU-time required for the solution of the test problem with the different solvers and derivative evaluation methods. The MATLAB calculations were performed with MATLAB 2008b on a PC with Intel Core Duo CPU (3.00 GHz) and 2 GB RAM. The BzzMath results were calculated online by the MOSAIC server with an Intel Xeon CPU (2.67 GHz) and 504 MB RAM. Both solvers were executed with default settings, so that the resulting differences in CPU-time can be traced back to the influence of the derivative evaluation methods. The results should in no way be considered as comparison between different solvers, derivative evaluation methods of AD tools.

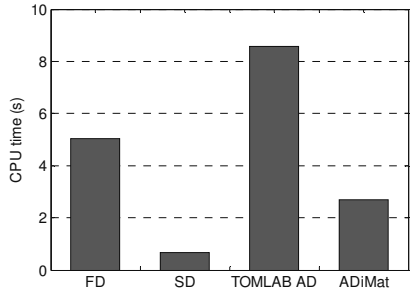

Fig. 2: CPU time for MATLAB solution

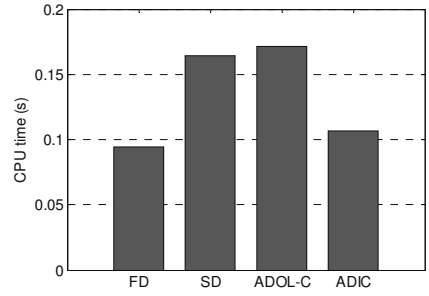

Fig. 3: CPU time for BzzMath solution

In both cases, an influence of the derivative evaluation method is well recognizable. However, while in the case of the BzzMath the influence of the derivative evaluation methods is almost no noticeable and FD results in the fastest execution, for MATLAB a stronger influence of the type of derivative evaluation can be noticed and the symbolic derivatives lead to a much faster execution. In spite of the fact that these results are only valid to the specific case above, they emphasize the central role of a proper choice of derivative evaluation methods and show in fact how a modeler can profit from having

the chance to test different methods of derivative evaluation on different environments. It is important to remark that following this strategy, the models need only to be defined once in the documentation level in order to enable the assessment of different solvers and derivative evaluation methods.

4. Conclusions and outlook

This contribution presents a general method for generation of derivative information out of the documentation level as implemented in the modeling environment MOSAIC. By this means an integration of the assessment of different derivative evaluations within the modeling and simulation workflow is achieved. So far the derivative generation has been used by the kind of problems supported by MOSAIC, currently NLEs and DAEs. With the extension of MOSAIC for the formulation and solution of optimization problems, a wide field for the application and assessment of derivative evaluation methods will be opened. The evaluation of higher order derivatives and the use of solution algorithms based on directional derivatives (tangents and adjoints) are of special interest.

Abstract

This paper presents a methodology for the identification of dynamic models using fuzzy logic that considers the inclusion of the measurement uncertainty in the process variables (described by the probability density function) directly in the model structure. The model comprises a type-2 fuzzy inference system, based on Takagi-Sugeno, together with the use of inputs and outputs in the non-singleton form (represented by membership functions) in both antecedent and consequent of each rule. Transformations of possibility measures into probability measures and conversely were also considered. A case study comprising a CSTR was analyzed and the results predicted by the fuzzy model were compared with Monte Carlo simulation. The proposed method presented good performance and provides a potential way to predict the dynamic propagation of measurement uncertainty through the process.
Keywords: Dynamic Identification, Dynamic Uncertainty, Fuzzy Model.

1. Introduction

Among the structures used in the identification of empirical models, particularly for the dynamic case, the fuzzy inference systems [1,2] represent a potential alternative, relatively simple, and provide the possibility of explicit inclusion of measurement uncertainty of process variables directly in the identification problem. The fuzzy inference systems (FIS) can be singleton fuzzification type (SFIS-Singleton Fuzzy Inference System) or non-singleton fuzzification type (NSFIS - Non-Singleton Fuzzy Inference System) [3]. The last case is suitable to cope with measurement uncertainties in the variables. In general, measurement uncertainties are evaluated in the form of probability density functions (pdf) instead of fuzzy sets (possibility distributions). In this case, the use of fuzzy sets represents an alternative to overcome the limits of probability theory and enables the modeling of the uncertainty of measurement [4]. Thus the transformation of probability into possibility, or conversely, provides an interchange between pdf and fuzzy sets. Mauris et al. and Dubois et al. [5,6] present an efficient method to transform the most common pdf's (Gaussian, Uniform, Triangular and Laplace) in a convex membership function called "truncated triangular possibility distribution" (tpd). Mauris et al. [5] also show the uncertainty propagation of input variables, represented by tpd, based on the extension principle [7]. The authors present algebraic equations which provide, in a simplified manner, the parameters of the output variable when it is represented by a linear combination of inputs represented by tpd Ferrero and Salicone [4] propose a new type-2 fuzzy set, RFV (Random Fuzzy Variables), to represent jointly the random and systematic effects on the process measurement. Also based on the type-2 fuzzy sets, a simplified analysis is performed using the law of propagation of uncertainty [8]. Algorithms for model identification have been proposed to incorporate measurement uncertainties in the formulation of the identification problem. Mouzouris and Mendel [3,9] present an application of NSFIS

and show a comparison with the SFIS, both based on the Mamdani structure [10]. Ferrero et al. [11–13] present a modified version of NSFIS capable to use variables in RVF form for use in dynamic identification. This structure does not consider the recurrence of uncertainty in the output variable. A recurring approach must be followed when the dynamic feature of the uncertainty is analyzed [14].This paper presents a methodology for identification of dynamic models based on a type-2 inference system fuzzy with Takagi-Sugeno structure capable to predict the uncertainty in the output variable at each time instant. The model structure comprises the use of non-singleton antecedents and the consequent of each rule is based on a NARX (Nonlinear Auto Regressive with eXogenous inputs) structure in which the input and output variables are represented by fuzzy sets. A continuous stirred tank reactor (CSTR) is adopted as case study. The fuzzy model results were compared with Monte Carlo simulation [14] in order to evaluate the capability of the proposed approach for the predict the dynamic uncertainty.

2. Fuzzy Inference System (FIS) and dynamic uncertainty

In general, the FIS comprise two types of structure (Mamdani and Takagi-Sugeno-TSK). Both structures are formed by rules of type IF-THEN, which represent, the connection of logical propositions by conjunction and implication operators. Unlike the structure of Mamdani, TSK considers a function that relates the output variable of the FIS with inputs [7] in the consequent of each rule.

In this paper we adopted the structure TSK, where the function in the consequent of each rule is a NARX (Nonlinear Auto Regressive with exogenous inputs) model (Eq. (1)), characterized more specifically by an ARX structure with nonlinearity generated by the feedback of the output predicted at previous time.

$$R^i\text{: IF } \tilde{\hat{y}}\left(k-n_y+1\right) \textit{ is } A_{n_y}^i \text{ AND } \tilde{x}_1\left(k-\theta_{x_1}-n_{x_1}+1\right) \textit{ is } B_{1,n_{x_1}}^i \text{ AND ... AND } \tilde{x}_j\left(k-\theta_{x_j}-n_{x_j}+1\right) \text{ é } B_{j,n_{x_j}}^i$$
$$\text{THEN } \tilde{\hat{y}}^i(k+1) = \sum_{m=1}^{n_y} a_{i,m}\cdot\tilde{\hat{y}}(k-m+1) + \sum_{l=1}^{n_{u_1}} b_{l,1}^i\cdot\tilde{x}_1\left(k-\theta_{x_1}-l+1\right) + \sum_{o=1}^{n_{u_j}} b_{o,j}^i\cdot\tilde{x}_j\left(k-\theta_{x_j}-o+1\right) + c_i \quad (1)$$

n_y and n_{x_j} are the number of past values of the output and each input x_j, respectively. θ_{x_j} is the delay from the input j. a_i, $b_{l,1}^i$ and c_i are the consequent parameters. k denotes discrete time samples. $A_{n_y}^i$ and $B_{j,n_{x_j}}^i$ are type-1 fuzzy sets corresponding to the output y and input x_j in the antecedent of rule i, respectively. $\tilde{x}_j$ is the non-singleton fuzzy set for each input j. $\tilde{\hat{y}}^i$ is the non-singleton fuzzy set predicted for each rule i. The final value predicted for to the output is given by equation (2):

$$\tilde{\hat{y}}(k+1) = \frac{\sum_{i=1}^{r}(\omega^i(\tilde{\mathbf{x}}(k))\cdot\tilde{\hat{y}}^i(k+1))}{\sum_{i=1}^{r}\omega^i(\tilde{\mathbf{x}}(k))} \quad (2)$$

where ω^i is the firing-level of rule i, $\tilde{\hat{y}}(k+1)$ is the predicted output (non-singleton) and the $\tilde{\mathbf{x}}(k)$ is the input vector. The data used for identification include measurement uncertainty that was inserted directly in the model. Each input variable was inserted in the antecedents in tpd form [5,6] allowing the direct insertion of the pdf of each input in the model. The truncated triangular possibility distribution (tpd) is a fuzzy set (possibility distribution) directly obtained through the pdf that represents the uncertainty model of the variable.

The law of propagation considers the pdf of each input $\left(g_{\mathbf{X}_1,\ldots,\mathbf{X}_N}(\xi_{1,1},\ldots,\xi_{N,m})\right)$ to obtain the pdf of the output $\left(g_{\mathbf{y}}(\boldsymbol{\eta})\right)$ using the Monte Carlo method (MCM) (Eq. (3)) in order to evaluate its uncertainty [15]. The advantage of this methodology compared to traditional approaches [8] is that it is not limited to linearity of the measurement function, symmetry of the pdf output and the Gaussian behaviour of the variables involved [14].

$$g_y(\boldsymbol{\eta}) = \int \ldots \int \delta\left(\boldsymbol{\eta} - f(\boldsymbol{\xi_1},\ldots,\boldsymbol{\xi_N})\right) \cdot g_{X_1,\ldots,X_N}(\xi_{1,1},\ldots,\xi_{N,m}) d\xi_{1,1},\ldots,\xi_{N,m} \tag{3}$$

$\boldsymbol{\eta}$ are possible values of the measurand $\boldsymbol{y}$, $\boldsymbol{\xi_i}$ are possible values of the input variable $\boldsymbol{X_i}$, f is the multivariate measurement model and $\delta(\cdot)$ denotes the Dirac delta function.
The propagation of dynamic uncertainty through MCM requires, at each time instant, the uncertainties of input variables and process parameters, based on their respective pdf. Thus, the pdf of output variables is obtained, from a measurement function, at each time instant [14].

3. Results

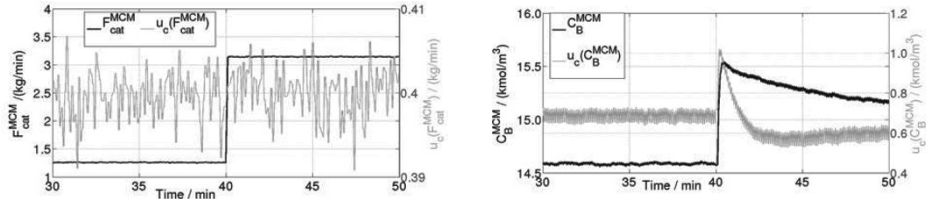
The case studied comprised a typical CSTR that transforms the reagent A into product B through a homogeneous catalysis (liquid phase). The reaction is endothermic and heating is required.
The model comprises a dynamic system with 4 ordinary differential equations (mass balance for reagent and product, energy balance in reactor and energy balance in the jacket) [14]. Uncertainty data for inputs, parameters and outputs are obtained applying MCM using the phenomenological model [14]. These data was used as reference for the identification of the NSFIS. A SISO (single input single output) case was considered. The concentration of the product (C_B) was the output and the flow of catalyst (F_{cat}) was the input. The consequent of each rule is represented by equation (4) ($\theta_{\text{F}_{\text{cat}}} = 0$, and the $n_{C_B} = n_{\text{F}_{\text{cat}}} = 1$).

$$\hat{\tilde{C}}_B^i(k+1) = c_i + b_{1,1}^i \cdot \tilde{F}_{cat}(k) + a_{i,1} \cdot \hat{\tilde{C}}_B(k) \tag{4}$$

$\tilde{F}_{\text{cat}}$ is the fuzzy set (tpd form) associated to the flow of catalyst, $\hat{\tilde{C}}_B$ is the fuzzy set (tpd form) associated to the concentration of the product B predicted by NSFIS.
Two trapezoidal fuzzy sets (high and low) were considered to represent both variables (C_B, F_{cat}) in the antecedents and the fuzzy model comprised 4 rules with 12 parameters.
Figures 1a and 1b present the estimate and the uncertainty of the input and output variables, both obtained through MCM. It was assumed Gaussian behavior over time and the transformation probability-possibility was applied.
According to equation (4), NSFIS identification comprises a nonlinear identification problem. The following objective function was adopted:

$$J = \sqrt{\frac{1}{N}\sum_{k=1}^{N}\left(\bar{y}(k) - \hat{\bar{y}}(k)\right)^2} + \sqrt{\frac{1}{N}\sum_{k=1}^{N}\left(\sigma(k) - \hat{\sigma}(k)\right)^2} \tag{5}$$

N is the number of measurements, $\bar{y}(k)$ and $\sigma(k)$ are the mean and uncertainty of the output at each instant, respectively (both estimated by MCM). $\hat{\bar{y}}(k)$ and $\hat{\sigma}(k)$ are the mean and uncertainty of output predicted by NSFIS at each instant, respectively.
It was applied a perturbation (+150%) in F_{cat}, at time 40 min. However, its uncertainty was not changed, as shown in Figure 1a. This perturbation was propagated to $u_c(C_B^{MCM})$ and the uncertainty of this measurand is changed during the transient (Figure 1b).



(a) (b)

Figure 1: (a) Flow of catalyst and uncertainty $\left(F_{cat}^{MCM}, u_c(F_{cat}^{MCM})\right)$. (b) Concentration of the product B with uncertainty $\left(C_B^{MCM}, u_c(C_B^{MCM})\right)$ MCM results.

Despite the identification procedure, an initial guess for the parameters was obtained through the linearization of NSFIS considering one-step ahead prediction and singleton variables [7,16].

The figure 2 shows the comparison between the NSFIS and MCM applied to evaluation the dynamic uncertainty. The coverage intervals were calculated considering the same coverage probability (95%) for the NSFIS and the MCM.

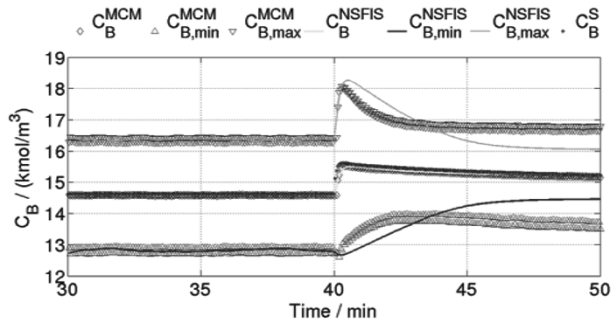


Figure 2: Simulated results (values and limits) predicted by the NSFIS $\left(C_B^{NFIS}, C_{B,min}^{NFIS}, C_{B,max}^{NFIS}\right)$ and the results (values and limits) obtained by MMC $\left(C_B^{MCM}, C_{B,min}^{MCM}, C_{B,max}^{MCM}\right)$ and the measured values for the concentration of the product B $\left(C_B^S\right)$.

The NSFIS has a good performance in the prediction of the concentration of the product B and the model described well the dynamic behavior. The NSFIS has an excellent prediction in the first stationary state ([30, 40[min). However, there was a difference between the NSFIS and MCM results during the transient period ([40 50] min) and also in the secondary stationary state. During the transient, the NSFIS found a longer interval than MCM probably due to the recurrence of predicted values in the NSFIS, i.e., recurrence of model uncertainty. However, in the second state stationary, the NSFIS found a shorter coverage interval than MCM. The causes of these differences are being analyzed.

4. Conclusion

This paper presented a method for predict dynamic systems using a Non-Singleton Fuzzy Inference System (NSFIS), capable to insert the measurement uncertainty of variables directly in the identification problem. A case study comprised a typical CSTR and the results were compared with the Monte Carlo Method (MCM), a well-known approach to predict the uncertainty propagation. The NSFIS represents a potential alternative to predict the dynamic uncertainty of output and can overcome the complex problem of dynamic measurement uncertainty, with a lower computational effort that

MCM. The time of processing of the NSFIS was 0.31×10^4 seconds, while the MCM took 1.09×10^4 seconds, both were processed in a computer with two CPU Intel Xeon E5620 2.4 GHz and 8 Gb of RAM.

Despite the restrictions associated to the transformation approaches of probability-possibility, and conversely, other general procedures can be applied considering any type of non-singleton inputs and the direct application of Extension Principle.

Abstract

The One Primary and One Secondary Particle Model (OPOSPM), which is a reduced population balance model, is used to estimate the optimum droplet coalescence parameters using steady state experimental data. The data is obtained from a pilot plant liquid extraction column of 80 mm diameter and 4.4 m height. The OPOSPM model is derived from the Sectional Quadrature Method Of Moments (SQMOM) with two identifiable parameters. These parameters are identified using a weighted nonlinear least square method with simple bounds. In this contribution, different coalescence models and correlations are studied for two different chemical test systems by solving a population balance inverse problem. The estimated droplet coalescence parameters are found to be dependent on the system physicochemical properties at a given rotor speed. After the droplet coalescence parameters had been optimized under specified column operating conditions, the OPOSPM is used effectively in full column simulation. The OPOSPM was found to predict accurately the mean dispersed phase holdup and mean droplet diameter along the extraction column height.

Keywords: Droplet coalescence, Population balance, OPOSPM, Simulation, RDC extraction column.

1. Introduction

Liquid-liquid extraction is considered one of the main important chemical industrial processes. Therefore, mathematical modeling and simulation of liquid extraction equipment is necessary for scale-up, model predictive control and optimization. However, because of their complex hydrodynamics, it is difficult to predict their performance using simple mathematical models owing to the discrete character of the dispersed phase. Hence, droplet population balance model (DPBM) has to be used. This takes into account droplet transport (rise and backmixing), and droplet interactions at macro-scale (droplet breakage and coalescence) and micro-scale (interphase mass transfer).

Due to the lack of experimental data at industrial scale, the only available data are inlet and outlet conditions and few intermediate data along column height. In contrast to previous work, where laboratory scale devices are used, an inverse population balance problem is solved to estimate the coalescence parameters using a pilot scale Rotating Disk Contactor (RDC). This optimization process is now possible from computational point of view by using the One Primary and One Secondary Particle Model (OPOSPM) as an alternative to the full DPBM [1]. The present liquid extraction model captures all the essential physical information contained in the detailed one and still tractable from

computational point of view. The model consists simply of two transport equations: namely, the number and volume concentration continuity equations. The model is derived from the Sectional Quadrature Method Of Moments (SQMOM), where only one primary and secondary particles are used. For reduction purposes, the model has two learning parameters for breakage and coalescence kernels respectively. These values can be easily determined using the full PBM model as an offline reference when the experimental data is not available. This model is considered suitable for online dynamic or steady state simulations, which can be viewed as the solution of an online inverse problem. Once the OPOSPM is learnt (two adjustable parameters are optimized) under specified column operating conditions, it can be used effectively to identify the unmeasured droplet coalescence parameters without significant loss of information.

2. Mathematical Model and Parameter Estimation

2.1. Population Balance Model

The general population balance equation (PBE), which describes hydrodynamics of liquid-liquid extraction columns (LLECs) in a one spatial domain can be written as [2]:

$$\frac{\partial f(\psi)}{\partial t}+\frac{\partial\left[u_y f(\psi)\right]}{\partial z}=\frac{\partial}{\partial z}\left[D_y\frac{f(\psi)}{\partial z}\right]+\frac{Q_y^{in}}{A_c}f_y^{in}(d;t)\delta(z-z_y)+S \tag{1}$$

In this equation f is number density function and (ψ) represents the droplet diameter (d) and the external coordinate at location (z) and time (t). The droplet velocity (u_y) is relative to the column walls. The first term on the right hand side is the droplet axial dispersion characterized by the dispersion coefficient (D_y). The second term is the droplet feed rate to LLEC with volumetric flow rate (Q_y^{in}) that is perpendicular to the column cross-sectional area (A_c) at a location (z_y) with an inlet number density (f_y^{in}). S represents the source term, which expresses the net number of droplets produced by breakage and coalescence per unit volume and unit time.

In practice, the size of equipment in process industries is large enough to prohibit the use of full DPBM given by Eq.(1). This is because the number of equations that have to be solved simultaneously is considerably large, which places a limit on the acceptable computational time. For this reason, the recently developed OPOSPM [1] presents a promising reduced version of Eq.(1):

$$\frac{\partial N}{\partial t}+\frac{\partial(u_y N)}{\partial z}=\frac{1}{A_c}\frac{Q_y^{in}}{\upsilon_{in}}\delta(z-z_y)+K_b(\vartheta(d_{30})-1)\Gamma(d_{30})N-\frac{1}{2}K_c\omega(d_{30},d_{30})N^2 \tag{2}$$

$$\frac{\partial\alpha}{\partial t}+\frac{\partial(u_y\alpha)}{\partial z}=\frac{Q_y^{in}}{A_c}\delta(z-z_y),\quad d_{30,i}=\sqrt[3]{\frac{6}{\pi}\frac{\alpha_i}{N_i}} \tag{3}$$

where υ_{in} is the feed mean droplet volume, the mean-mass droplet diameter (d_{30}) is an adaptive Gauss-Christoffel quadrature node. The breakage and coalescence frequencies are Γ and ω respectively, while ϑ is the mean number of daughter droplets produced by breakage. This model is able to capture the essential physical information contained in the full PBM and is still tractable from computational point of view. The model conserves the total number (N) and volume (α) concentrations of the population by solving directly two transport equations for N and α. For reduction purposes, the model has been expanded by introducing two learning parameters (K_b and K_c) for breakage and coalescence kernels respectively. These values can be easily determined using the full PBM model as an offline reference when the experimental data is not available.

Once the OPOSPM is learnt (K_b and K_c are optimized), it can be used efficiently to solve the inverse problem associated with droplet coalescence parameters without

significant loss of information. For this purpose, popular droplet coalescence models with adjustable parameters are carefully selected from the recent review on this topic by [3]. At this stage, a careful algorithm design is required in order to estimate these parameters with an accepted statistical error. This leads to apply the inverse problem approach to a full pilot plant RDC extraction column of 80 mm diameter and 4.4 m height. The measured dispersed phase holdup and mean droplet diameter at steady state for this column are taken from Garthe (2006) [4].

2.2. Coalescence Models

Despite the intensive work and published literature on population balance equation modeling, there are few studies on optimization packages, which can be used for coalescence parameter identification, when experimental data is available. Such an optimization package should be flexible to accommodate the chemical test system, column internal geometry and direction of mass transfer. In this regard, work is under way to develop such a package. In the present work, five different coalescence models are selected from the literature and are shown in Table 1.

Table 1. Summary of droplet coalescence models with adjustable parameters

(1)	$\omega(d,d',\phi_d)=\left[c_1\frac{\varepsilon^{1/3}}{1+\phi}(d+d')^2(d^{2/3}+d'^{2/3})^{1/2}\right]\times\left[\exp\left(-\frac{c_2\eta_x\rho_x\varepsilon}{\sigma^2(1+\phi)^3}\right)\left(\frac{(dd')}{(d+d')}\right)^4\right]$
(2)	$\omega(d,d',\phi_d)=\left[c_3\frac{\varepsilon^{1/3}}{1+\phi}(d+d')^2(d^{2/3}+d'^{2/3})^{1/2}\right]\times\left[\exp\left(-\frac{c_4\eta_x\rho_x\varepsilon}{\sigma^2(1+\phi)^3}\right)\left(\frac{(d^2+d'^2)\times(d^3+d'^3)}{(dd')\times(d^{2/3}+d'^{2/3})}\right)\right]$
(3)	$\omega(d,d',\phi_d)=\left[c_5\frac{\pi^2}{36}(d\times d')^3\right]+\left[c_6\frac{\pi^2}{6}\left(\frac{d+d'}{2}\right)^2\left\lvert d^3-d'^3\right\rvert\right]$
(4)	$\omega(d,d',\phi_d)=c_7\left(\frac{\pi d^3}{6D_R^3}\right)^{-0.49}We^{-0.51}\phi_d^{\,0.9}Oh^{-0.05}$
(5)	$\omega=c_8\varepsilon^{1/3}d^{7/3}n^2\exp\left(-\sqrt{\frac{We}{8}}\right)\exp\left(-c_9\frac{d^3}{\varepsilon}\right)$

In Table (1), model (1) is the Coulaloglou and Tavlarides (1977) model, which is developed for droplet coalescence in stirred vessel based on the kinetic theory of gases and drainage film theory [5]. Model (2) is due to Sovova, where in this model uses a different formula for the efficiency of collisions, where the coalescence of drops mechanism described by film drainage of Coulaloglou and Tavlarides model (second term) is replaced by a mechanism that is based on collision impact on coalescence efficiency [3]. Casamatta and Vogelpohl in (1985) proposed a semi-empirical model, in which the first term on the right hand side of Model (3) is the coalescence frequency caused by random motion, which is assumed to be proportional to the drop volumes. The second term represents the coalescence induced by difference in rise velocities [3]. A simplified coalescence model, with one adjustable parameter, is proposed by Laso (1986) as shown by model (4) in Table 1 [6]. The last model in Table 1 is due to Lane et al., where this model suggests that the droplet coalescence is related to the rate of binary collisions between droplets moving with a random velocity equal to the turbulent fluctuating velocity of eddies of the same size in the inertial subrange [7].

3. Results and Discussion

The mathematical model described above is programmed using MATLAB to simulate LLECs using the OPOSPM and the detailed DPBM for comparison. For optimization of

coalescence parameters the tolerance was set to 1.00E-6. The optimization algorithm is shown in Figure (1).

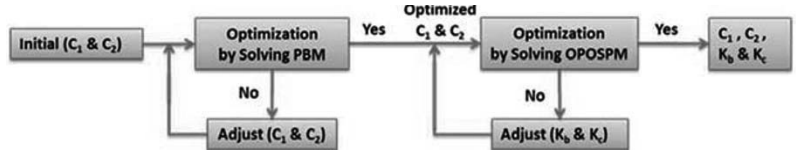

Figure 1: Optimization algorithm

The two EFCE test systems of a two-phase flow, butyl acetate-acetone-water (b-a-w) and toluene-acetone-water (t-a-w) are used. The pilot plant RDC extraction column internal and external geometry are shown in Table 2. The rotor speed is constant at 200 rpm, the volumetric flow rate for continuous and dispersed phase is 40 l/hr and 48 l/hr, respectively for both chemical tested systems.

Table 2. Geometries and specifications of the RDC extraction column

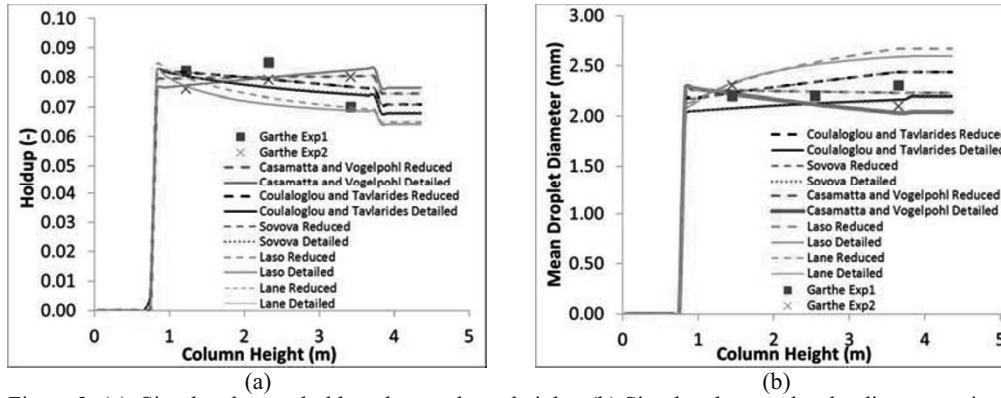
Internal geometry		External geometry	
Compartment height	50 mm	Column height	4.40 m
Internal stator diameter	50 mm	Column diameter	0.08 m
Rotator diameter	45 mm	Inlet of dispersed phase	0.85 m
Rotating shaft diameter	10 mm	Inlet of continuous phase	3.80 m
Relative free cross sectional stator	0.40 m²/m²		

The values of droplet coalescence parameters for different coalescence models (c_1-c_9) are estimated by solving the inverse problem for (b-a-w) and (t-a-w) as shown in Table 3. Using these optimized parameters, the simulated mean dispersed phase holdup and droplet diameter along column height as compared to the experimental data are shown in Figures (2) and (3) for (b-a-w) and (t-a-w) respectively.

Table 3. Optimized coalescence parameters ($c_1 - c_9$)

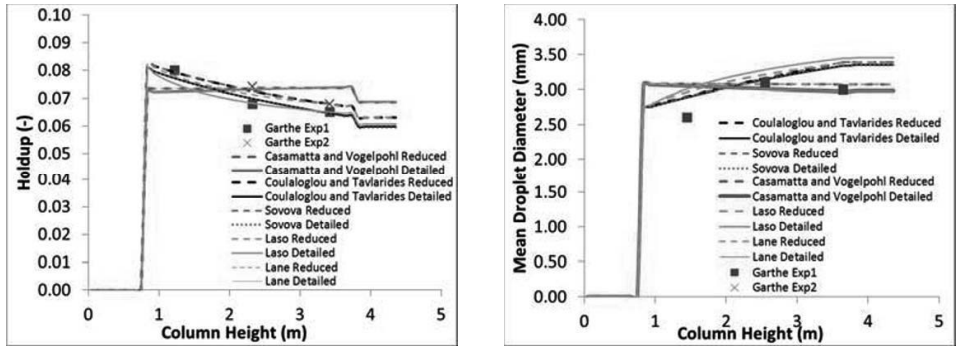
Liquid System	Coulaloglou & Tavlarides	Sovova	Casamatta & Vogelpohl	Laso	Lane
(b-a-w)	c_1=1.59E-02	c_3=9.15E-03	c_5=4.00E-01	c_7=2.50E-09	c_8=1.00E-09
	c_2=1.33E+10	c_4=8.84E+01	c_6=5.50E-01		c_9=5.49E+06
(t-a-w)	c_1=7.23E-03	c_3=4.02E-03	c_5=4.00E-01	c_7=1.45E-09	c_8=1.00E-09
	c_2=1.33E+10	c_4=1.12E+01	c_6=5.50E-01		c_9=5.49E+06

Note: The learning parameters values for both liquid test systems: K_b= 0.905 and K_c= 0.999.



(a) (b)

Figure 2: (a). Simulated mean holdup along column height. (b) Simulated mean droplet diameter using the OPOSPM and the full PBM compared to the experimental data for (b-a-w) system.



(a) (b)

Figure 3: (a). Simulated mean holdup along column height. (b) Simulated mean droplet diameter using the OPOSPM and the full PBM compared to the experimental data for (t-a-w) system.

By referring to Table 3, two main points are concluded: First, the values for the coalescence parameters are found dependent on the chemical test system. Second, the learning parameters in the reduced model are found insensitive to changes in the chemical test system and constant for this column geometry. Moreover, the reduced model reproduces accurately the information offered by detailed PBE at steady state [8] and dynamic behaviors [9] of Kühni extraction column. Further studies will be done to test the estimated parameters using different operating conditions.

4. Conclusions

In this work the OPOSPM is found to be a promising model for designing, simulating, controlling and optimizing an industrial pilot RDC extraction column when it is learnt using the detailed PBM. It gives a good prediction of the mean dispersed phase holdup and mean droplet diameter along the height of extraction column. The reduced OPOSPM can be used for online predictive control by solving an online inverse problem. From solving the inverse problem, Coulaloglou and Tavlarides model is found to be the best model to describe the coalescence of droplets using two different liquid systems.

Abstract

The selection of appropriate input harmonics in a multi-harmonic signal for the identification of nonlinear systems leads to a nonlinear, combinatorial optimization problem. Lack of efficient optimization tools for solving such problems had previously led to the development of an explicit Integer Linear Programming (ILP) based lexicographic optimization formulation. However, the dimensionality of such a formulation increases considerably with an increase in the number of frequencies and the problem has been reported to become intractable for higher frequencies. In this article, we demonstrate the ability of Constraint Programming (CP) to efficiently model and solve the original nonlinear problem to guaranteed global optimality. We successfully demonstrate the ability of CP to determine the optimal solutions much faster and also solve problems that have so far remained intractable. In addition, we also show the ability of CP to determine all the multiple optimal solutions and near best optimal solutions in a single optimization run.
Keywords: Input Signal Design, Combinatorial Optimization, Constraint Programming

1. Introduction

The design of input signals for the identification of nonlinear systems is a combinatorial optimization problem and has received considerable attention in literature (Boyd et al., 1983; Chua and Liao, 1989; Schoukens et al., 2002; Evans et al., 1996). For weakly nonlinear systems, it is beneficial to minimize the highest and lowest harmonics of the input signal for system identification. Moreover, the fact that no measurement of the linear kernel can be made below the first harmonic also necessitates the minimization of the first harmonic. The selection of such small yet evenly spaced input set for a higher number of harmonics is considered to be non trivial. Some of the previous research work addressing this problem includes the suggestion to use odd-odd sines or special odd sines (Schoukens et al., 2002). A solution procedure involving the use of several sets of frequencies such that the inter-harmonic distortion between these sets is distinct has also been proposed (Boyd et al., 1983; Chua and Liao, 1989). An intelligent search algorithm has also been proposed (Evans et al., 1996) but this algorithm was not guaranteed to determine the optimal solutions. Recently, an ILP formulation was proposed (Narasimhan and Rengaswamy, 2003) which could be used to solve problems of lower frequencies to global optimality. However, this procedure substantially increases the dimensionality of the problem and was found to be prohibitive for higher frequencies due to a very high computational cost.

From the above discussion, it can be seen that the selection of input harmonics for process friendly system identification is severely hampered by the non availability of a

robust solution technique which can solve the original nonlinear integer programming problem to global optimality. To overcome this drawback, the use of a robust optimization technique that can handle nonlinear constraints without compromising on its ability to reach the optimal solution is required. In this article, we show the ability of Constraint Programming (CP) to solve such nonlinear integer programming problems to global optimality without increasing the dimensionality of the optimization problem. The expressive modeling power of CP combined with strong constraint propagation techniques has helped us to solve the problems which have been previously reported to be intractable in literature. In addition to the determination of the globally optimal solutions, we also show the ability of CP to determine other valued added solutions. The benefits of using CP to solve these optimization problems are demonstrated for determining input harmonics of two different frequencies.

2. Constraint Programming

CP has been developed by the Artificial Intelligence and Computer Science community to solve Constraint Satisfaction Problems (CSPs). In an article (Biegler and Grossmann, 2004) on the future perspective of optimization, logic based methods such as disjunctive programming and CP have been identified as promising techniques for efficiently solving discrete optimization problems. CP has found applications in diverse areas and has enjoyed tremendous success in areas involving combinatorial optimization such as assignment and scheduling problems. For the sake of brevity, only brief descriptions of the various aspects of CP are discussed here. Additional details can be obtained from the literature (Kotecha et al., 2010).

The solution of an optimization problem by CP begins with the conversion of the optimization problem to an appropriate CSP which treats the objective function as a constraint and evaluates the objective function value at every feasible solution. This is followed by the elimination of the infeasible values from the domain of the variables by propagating the set of constraints. In case of problems with only one feasible solution, this initial propagation would lead to the optimal solution. However, if the constraint propagation does not reduce the domains of all variables to singleton, a decision variable is randomly selected and arbitrarily assigned a value from its updated domain. This non deterministic selection of the variable and a value from its domain is often referred to as choice point. After the selection of a choice point, the set of constraints are once again propagated for potentially reducing the domain of the other variables. Additional choice points are made on the other variables whenever necessary throughout the search procedure. This would eventually lead to a situation where either the domain of at least one of the decision variables becomes null or the domain of all the decision variables become singleton. The domain of a decision variable becoming null would indicate that the latest choice point leads to an infeasible solution and necessitates backtracking wherein the value of the latest choice point is revised. On the other hand, if the domain of all the variables becomes singleton it would indicate that a feasible solution has been reached and the bound on the objective function is updated. The choice points that lead to failures are removed from the domain of the decision variables thereby continuously reducing the domain of the variables. This procedure is continued till the complete search space is explored thereby guaranteeing the determination of the globally optimal solution without being trapped at suboptimal solutions.

Two of the most important features of CP are its expressive modeling power and the ability to guarantee the determination of globally optimal solutions even for non-convex

& nonlinear integer programming problems. The expressive modeling power enables the development of compact and "natural" models whereas the domain reduction by constraint propagation ensures the determination of the globally optimal solution without being trapped at local optimal solutions. Additional features like the efficient determination of the multiple solutions and near best solutions makes CP an attractive optimization technique (Kotecha et al., 2010). However, CP requires an explicit optimization framework for the propagation of constraints to reduce the domain of the variables; it may also occasionally require considerable amount of computational resources for the confirmation of the optimal solution as it does not rely on bounds/relaxations or derivative information.

3. Input signal Design – Problem Formulation:

Let the set of distinct harmonics that need to be selected be $S = \{x_1, x_2, ..., x_n\}, x_i \in \mathbb{N}$. The different objectives for the design of a plant friendly input signal are (i) minimization of the lowest harmonic (x_n), (ii) minimization of the highest harmonic (x_1), (iii) ensuring well-spaced grid; this is quantified by minimizing σ where $\sigma = \max_{\forall i=1,...,n-1}(x_{i+1} - x_i) - \min_{\forall i=1,...,n-1}(x_{i+1} - x_i)$. In the formulation next, the set of constraints represented in (2) ensure that the Type II contributions are distinct from the input frequencies whereas the set of constraints represented by (3) and (4) ensure that the Type II contributions are distinct from each other (frequency separation). The constraints in (5) define the bounds and domains of the harmonics. Additional details about the formulation can be obtained from literature (Narasimhan & Rengaswamy, 2006)

$$\min \quad \left\{\lambda_1 x_n + \lambda_2\left(\max_{\forall i=1,...,n-1}(x_{i+1} - x_i) - \min_{\forall i=1,...,n-1}(x_{i+1} - x_i)\right) + x_1,\right\} \tag{1}$$

$$s.t \quad x_k - (x_i + x_j) \neq 0,\ i = 1...,n; j = i,...,n; k = j+1,...,n \tag{2}$$

$$(x_l + x_i) - (x_j + x_k) \neq 0, \begin{cases} i = 1,...,n; j = i+1,...,n; \\ k = j,...,n; l = k+1,...,n \end{cases} \tag{3}$$

$$x_l - (x_i + x_j + x_k) \neq 0, \begin{cases} i = 1,...,n; j = i,...,n; \\ k = j,...,n; l = k+1,...,n \end{cases} \tag{4}$$

$$0 < x_i < x_{i+1} \leq N, \quad i = 1,...,n-1; \quad x_i \in \mathbb{N}, \quad i = 1,...,n \tag{5}$$

In the above equations, N is an upper bound for x_n and is given by $N=kn^2$ and λ_1, λ_2 are lexicographic constants. An optimization procedure based on standard optimization algorithms is not possible because the set of constraints represented in equation (2) to (4) are not in the conventional form. To overcome this issue, the problem was reformulated as an ILP formulation (Narasimhan & Rengaswamy, 2006). Results of this ILP formulation (not presented here) are compared with the results of CP. In addition to the objective function in (1), we will also be using the following objective function with a different precedence ordering

$$\min \quad \left\{\lambda_1\left(\max_{\forall i=1,...,n-1}(x_{i+1} - x_i) - \min_{\forall i=1,...,n-1}(x_{i+1} - x_i)\right) + \lambda_2 x_n + x_1,\right\} \tag{6}$$

The objective function in (1) and (2) will be referred as T1 and T2 respectively.

4. Results & Discussion

The results reported in this section have been generated on an Intel Core Duo CPU 2.00GHz with 3.00GB RAM machine running Windows Vista. ILOG OPL Studio 3.7.1 was used to model both the ILP and CP formulations. The ILP formulations were solved by ILOG CPLEX 9.1 whereas the CP formulations were solved by ILOG Solver 6.1. Additional discussion on the implementation procedures of the various algorithms can be obtained from literature (Kotecha et al., 2010).

Table 1 shows the dimensionality of the explicit ILP and CP optimization formulations. It can be seen that the number of binary variables increases drastically with an increase in the number of frequencies for the ILP formulation whereas the CP formulation does not have any binary variables irrespective of the number of frequencies to be selected. Also, due to the ability of CP to model the min-max constraints directly, the number of integer variables is reduced by 2 when compared with the ILP formulation. It can also be seen that an increase in the number of frequencies leads to a very large increase in the number of constraints for the ILP formulation as compared to the CP formulation.

Table 1: Dimensionality of the ILP & CP formulation

No. of frequencies	No. of binary variables		No. of integer variables		No. of constraints	
	ILP	CP	ILP	CP	ILP	CP
n = 7	252	0	9	7	522	258
n = 10	900	0	12	10	2007	996

The 100% reduction in binary variables and over 50% reduction in the number of constraints in the CP formulation are to be attributed to the highly expressive modeling power of CP.Table 2 shows the computational time required for the determination of a single global optimum solution.

Table 2: Computational performance of ILP & CP formulation

No. of frequencies	Obj. func.	Optimal solution		Computational time (secs)	
		ILP	CP	ILP	CP
n = 7	T1	{7 8 18 31 35 37 40}	{7 8 18 31 35 37 40}	134.6	2.29
	T2	{13 17 25 32 35 41 46}	{13 17 25 32 35 41 46}	31.18	1.12
n = 10	T1	-	{8 14 29 48 53 71 73 80 83 84}	> 24 hrs	6486
	T2	-	{34 36 40 51 60 67 79 89 92 97}	> 24 hrs	1204

For n = 7, it can be seen that CP is able to determine the globally optimal solution much faster than ILP for both the different objectives. For n = 10, it can be seen that ILP was not able to reach the global optimum solution whereas CP was able to determine the globally optimum solution in less than 2 hrs. Table 2 also shows that the time required for determining the optimal solution varies with the precedence ordering of various objectives. The optimal solution obtained in each case has also been shown in Table 2. As expected due to the lexicographic ordering, the solution in T1 (for both n = 7 & n = 10) has a lower highest input harmonic than T2. Similarly, the grid spacing for T2 is better than T1 as minimization of the grid spacing is given a higher precedence.

The objective function in T1 and T2 has only one globally optimum solution and hence CP was able to determine only this solution. To demonstrate that CP is indeed capable of determining all the globally optimal solutions, we solved the optimization problem to minimize the highest harmonic with 10 frequencies. This problem is characterized by

287 multiple solutions but only five of these solutions [{1 14 31 50 56 74 85 90 94 97}, {1 20 32 47 58 76 83 86 92 100}, {1 20 34 50 61 76 86 89 93 98}, {1 20 35 47 64 73 78 86 89 96}, {1 20 37 51 61 66 84 93 96 100}] are reported here for brevity. Table 3 shows the first five best solutions for the objective shown in T1 which prioritizes the minimization of the highest harmonic followed by grid spacing and the lowest harmonic respectively. For n = 7, it can be seen that the first solution has the lowest harmonic whereas the next four solutions have identical highest harmonic but the grid spacing increases. Between the last two solutions which have identical highest harmonic and grid spacing, the solution with objective function value 76240 is prioritized over 76253 as it has a smaller lowest harmonic. Thus it can be seen that CP can help in identifying value added solutions which can help the designer in making informed choices.

Table 3: Near best solutions:

No. of frequencies	Objective function value	Input harmonics	Grid spacing
n = 7	74483	{7 8 18 31 35 37 40}	12
	76121	{11 16 23 31 37 40 41}	7
	76211	{ 15 17 27 33 36 40 41}	9
	76240	{1 10 16 29 34 37 41}	10
	76253	{14 16 19 23 29 40 41}	10
n = 10	697250	{8 14 29 48 53 71 73 80 83 84}	18
	706531	{7 20 29 32 62 66 67 77 83 85}	29
	713456	{16 30 33 42 57 67 78 80 85 86}	14
	721725	{4 13 28 42 48 64 75 82 85 87}	14
	722005	{11 20 32 39 57 73 81 83 86 87}	17

In this article, we have shown that CP is suitable for solving combinatorial problems arising in system identification: in addition to determining globally optimal solutions, it can also be used to determine value added solutions and help in making informed decisions. Future work can potentially include exploring various multiple objectives without assigning any precedence ordering to the objectives.

Industry Embedded Training in (Bio)Process Systems

Elaine Martin,[a] Gary Montague,[b] Bryn Jones [c]

[a]EngD Director, [b]Professor of Bioprocess Control, [c]Dean of Postgraduate Studies, Newcastle Univesity, Newcastle-Upon-Tyne, NE1 7RU

Abstract

The traditional doctoral training approach for bioprocess systems engineers has been the conventional University based PhD. In some instances a degree of industrial interaction occurs but the predominant motivator has been academic lead rather than industrial demand. The traditional PhD programme has shortcomings in this context, both in terms of its support for multidisciplinary research and, with its focus on research rather than the researcher, its development of skills and attributes which align to the post-PhD industrial need. In response to industrial demand, a Doctoral Training Centre has been established to both foster multidisciplinary training and ensure the needs of industry are specifically addressed. This paper describes how a fundamentally different approach to doctoral training has been developed and how the academic / industrial collaboration is proving to be successfully changing the nature of the industrial interactive doctoral experience in bioprocess systems engineering.

Keywords: Industrial Training; Bioprocess Systems

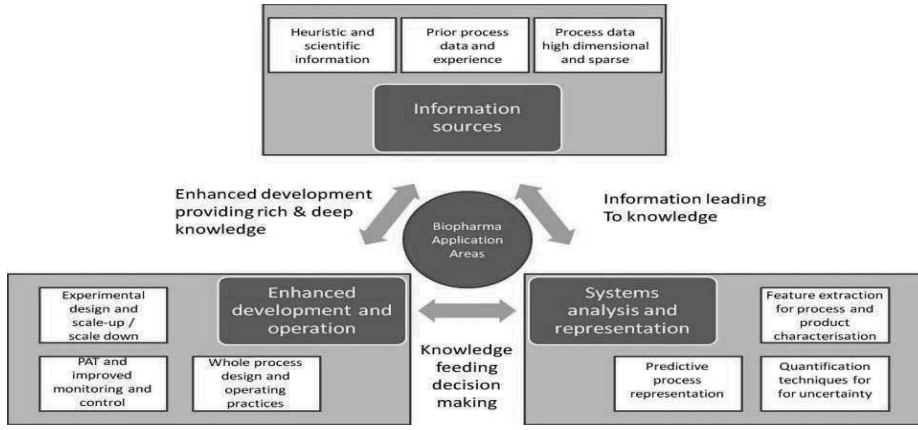
1. Introduction

Industry leaders have successfully relied on the implementation of advanced science and technical capability to remain ahead in fields such as drug development and manufacturing. However in the UK for instance, the Sector Skills Council for Science, Engineering and Manufacturing Technologies report stated that over a quarter of bioscience companies do not have sufficient science skills. 39% of bioscience/ pharmaceutical companies have long-term vacancies; with 22% having skill shortages in the science arena (five times that for other sectors). Given the international nature of the sector these shortages are a worldwide constraint. Our objective in terms of the submission and award of an Industry / Government funded Industrial Doctorate programme (EngD) in Biopharmaceutical Process Development was to directly address this shortfall through the training of graduates who have the necessary skills set to address this gap. The key motivation and technical focus of the EngD is the utilization of process systems techniques for process development and improvement. Equally important is the development, in EngD graduates, of the broader skill portfolio required by successful industrial leaders. In meeting these needs the EngD provides in-depth training in research and project management, coupled with business and commercial awareness and is supported by large multinational pharmaceutical companies through to equipment suppliers and SMEs.

Bioprocess development is an activity that can be categorised as data rich and information poor. Whilst fundamental science and engineering knowledge provides some capability in terms of interpretability of results, predicting performance is more difficult given the complex interactions between biological behaviour and bioprocess

engineering environments. Utilising heuristic knowledge from prior process developments goes some way to assisting in predicting likely outcomes, but supporting this with data from experiments throughout the development programme is essential. Data characteristics include high dimensionality arising for example from -omic and spectroscopic devices, varying sampling rates, end point only measurements or time course data. Whilst these data characteristics in themselves raise usage challenges, the predominant problem in bioprocessing is that typically data measurements are a significant, but small subset of all the influencing factors and states of the system. To date the development team has typically relied on their ability, i.e. human understanding, to extract from limited dimensional data and also focus on a snap-shots in time without taking account of previous history or unit-to-unit interactions.

The challenge is how to utilise the information spread across a number of data constructs by extracting pertinent information using appropriate tools in conjunction with heuristic knowledge and fundamental bioscience and engineering knowledge. Consequently the EngD research projects embrace to some degree each of the following elements: *Information Sources:* The forms of knowledge available regarding process behaviour is diverse and includes heuristic experience, fundamental science and engineering and process data encompassing that recoverable from devices now employed as a consequence of the acceptance and growth of measurement technologies through Process Analytical Technology (PAT). *Systems Analysis and Representation*: From the diversity of knowledge structures, process relationships can be captured in a form that can be used for process and product characterisation and subsequent process improvement. This philosophy is at the heart of Quality by Design (QbD). *Enhanced Development and Operation*: To gain benefit in bioprocess development, appropriate process representations need to be exploited within procedures that allow more informed decisions to be made for example in experimental design, scale-up and scale-down techniques, process monitoring approaches and process control methods.



2. Programme Objectives

The ultimate objective of the Centre is to respond to a critical industrial need in bioprocess development and produce Research Engineers who are skilled in research and project management, and who combine technical excellence with a high degree of business awareness. In fulfilling this overarching objective, three sets of sub-objectives

are being addressed, (i) those relating to the training programme, (ii) those relating to industry, (iii) those relating to academia.

With respect to the training programme, the prime objective is to provide EngD students with a unique, well-rounded, multi-disciplinary research training which promotes the development of skills in bioengineering, bioprocessing and biopharmaceuticals. Alongside this technical training, it is important to provide training in the complementary skills and attributes (presentation, project management, inter-personal, business awareness etc.) which will help EngD graduates fulfil their potential and succeed in their research careers.

With respect to industry the objective is to strengthen existing relationships and develop new collaborations between academia and industry and to realize the uptake and exploitation of the research undertaken by the EngD students. It is providing access to a pool of bioscience engineers who enable bio-manufacturing concerns to compete at international levels and importantly also it is ensuring that in the longer-term academic research addresses industrial need.

With respect to academia the objective is to establish the Centre as nationally leading and internationally recognized and for it to be the preferred location for the training of students who have competencies in commercial biopharmaceutical process development with respect to QbD and PAT. To do so it is necessary to further develop the existing collaborations between engineering, biology, computing science and to promote new collaborations that will realize major breakthroughs in the characterization and scale up of emergent technologies

3. Programme Design

To satisfy the programme objectives it has been necessary to adopt a very different approach to doctoral training. In contrast to a standard UK PhD, the three key differentiators are the cohort element, the modular component and the focus on working on industrially shaped research challenges, through which the EngD student develops at first hand the skills necessary to work in an industrial environment. The cohort element is core to the success of the programme as it is the medium through which the students learn how to work in inter-disciplinary teams and with colleagues whom they may not elect to work with. By requiring all students to take a number of compulsory modules, it has enabled a diverse group of engineers, biologists and chemists to address open-ended problems that require them to pool their skills to address the problem. This is a key feature of the taught component and one that industry has strongly advocated as they have clearly stated that PhD students do not have such opportunities.

The opportunity to work within an industrial environment for a significant proportion of the EngD provides students with all round training and exposes them to the constraints imposed by a company's business drivers. It is for this reason that the student has the opportunity to tackle a number of problems within the overarching theme of their research and hence the final output is a thesis by portfolio. This approach enables them to consider transferability of concepts to similar problems and exposes them to different technical areas, providing them with a breadth of experience. Industrial placement also brings management challenges as the placement of EngD's in a company to undertake their research projects necessitates a management structure that ensures the quality of

the research is of a standard commensurate with a PhD and also that students are not facing difficulties out with their control in terms of the execution of their project or on the pastoral side. Rigorous monitoring procedures have been implemented to ensure that any issues are captured early and can be managed appropriately.

The modular component is spread throughout the 4-year duration although there is an exponential drop in the number of modules attended by the students during this period. The taught component of the modular programme was developed through consultation with industry, external academics and other stakeholders including Research Institutes and the bioProcess Knowledge Transfer Network, a Government sponsored community of interested groups. It has thus been tailored to meet the technical challenges of industry alongside ensuring that the programme draws on areas of recognized expertise within Newcastle and satisfies academic quality processes. A degree of flexibility exists in the provision of modules with students able to select ones outside of the course that are specific to their needs but these form a small component of the overall delivery.

An additional feature of this programme is that the modular element is collaborative with other universities. The diversity of the industrially focussed projects necessitates the students studying a range of modules that enable them to tackle the multi-disciplinary nature of their research challenges. Economy of scale is thus an issue and recognising that not all the expertise necessary to deliver key topics resides in one university has resulted in the modular programme becoming collaborative. For example, formulation engineering is not a recognized area of expertise In Newcastle but for some projects the students require knowledge of specific aspects. This issue has been addressed through the setting up of Collaborative Provision with the EngD Formulation Engineering at Birmingham University.

4. Programme Recruitment

Twelve EngD researchers commence their studies annually to address the longer term training requirements of the UK and the industrially embedded nature of the programme serves to deliver research that satisfies industrial need. The EngD students typically spend approximately 75% of their time based in industry over the four years of their study and receive an enhanced stipend when compared to University based doctoral students. It has been essential to link the stipend level to engineering graduate starting salaries in the UK to recruit the required calibre of students.

Working with industry raises a number of challenges including company recruitment, ensuring that the research project is of a standard commensurate with the award of an EngD and intellectual property rights (IPR). The securing of 60 industrially supported projects over a 5-year period is fundamental to the programme. The current economic landscape could potentially impact on company recruitment but the shortfall in trained personnel in the area of the Centre has resulted in this not being an issue to date. Additionally the EngD model is seen by industry as a powerful tool as the student is typically based in the company full-time and thus are exposed to the challenges of working in industry and delivering against medium term goals. This aspect differentiates the students from their PhD counterparts. A further challenge with regard to placements is that they must align with the expectations of the EngD students themselves. This includes identifying whether an SME or large multi-national is more appropriate as the two groups provide contrasting experiences for the students. Student

recruitment is thus intrinsically linked to industrial placements. In summary, the student must satisfy three criteria (i) academic excellence, (ii) ability to work in an industrial environment and (iii) excellent communication skills. This has resulted in the most academically and outfacing students being recruited onto the programme.

The inter-disciplinary nature of the Centre has attracted applications from a range of backgrounds across science and engineering including chemical, process, biochemical and mechanical engineering, biotechnology, biochemistry, biomedical science, drug chemistry, applied biology, pharmaceutical science and mathematics and statistics. The female / male split re applications is 40% /60%. Recruitment statistics differ – cohort 1 comprised 5 females / 2 males whilst this trend was reversed in cohort 2 with the split being 4 females / 8 males. The most recent cohort is 7 males / 5 females. With respect to diversity, there is a significant difference between engineering and science subjects re male/female split, with science being dominated by females. One unique feature is the recruitment of EngD students who have worked in companies and have resigned from their jobs to do the EngD. This is not a feature observed often for PhDs.

The quality of serious applications is approximately a 50/50 split between 1st and 2.1 level degrees or distinction/merit for all 3 cohorts to date. In terms of recruitment, the split has remained consistent at approximately 50/50 re 1st/2.1. The rationale behind this 1st/2.1 split is that in terms of recruitment, we are seeking students who have the academic qualifications, excellent communication skills and who have undertaken additional activities over and above their degree. It is this latter feature that truly differentiates between the students. Unfortunately a significant number of projected 1st class honours students do not fulfil the additional criteria.

5. Concluding Comments

The establishment of the Industrial Doctoral Training Centre has required a fundamental re-appraisal of how industrially collaborative process systems engineering research is undertaken, particularly taking into account training needs and the benefits to the industrial partner. A number of challenges setting up and executing the EngD programme, combining a pedagogical element alongside the requirement to undertake research within an industrial environment arose. Challenges facing such a programme include (i) University procedures and alignment with current quality assurance policies, (ii) industrial participation, and (iii) student recruitment / monitoring. Establishing a set of procedures to ensure the appropriate progression of the individual projects results and making sure that all are adhered to is essential. Indeed, one of the most difficult challenges that was not appreciated at the outset was how only a limited number of academics found the industrial collaborative nature of research to their liking. While the challenges from an academic perspective merit careful attention, the rewards of the EngD programme have proved significant for the University, the company and particularly the student.

Chemical Engineering Education and Industry Megatrends

Victor Heinänen, Timo Seuranen, Markku Hurme

Aalto University, Department of Biotechnology and Chemical Technology, P.O.Box 16100, FIN-00076 Aalto, Finland

Abstract

The traditional chemical engineering paradigms have been the unit operations approach and later transport phenomena. Most of the education of chemical engineering has been based on these two basic approaches. The question raised is what is the next paradigm and further, how it should be taken into account in the education on chemical engineering? There have been several proposals for the next paradigm, such as process systems engineering, integrated multidisciplinary and multi-scale process engineering, chemical product design and sustainable chemical engineering.

Keywords: Education of chemical engineering, megatrends, paradigms, curriculum

1. Introduction to Paradigms and Megatrends in Chemical Engineering

Paradigm is a constellation that defines a profession and an intellectual discipline (a pattern or model). Commonly recognized paradigms are: *Pre-paradigm* - engineers with no formal education; *0^{th} paradigm* - formal engineering education, end of 1800 (beginning of chemical engineering education, MIT 1888); *1^{st} paradigm* - unit operations, 1908 concept proposed by Arthur D. Little, 1923 first textbook; *2^{nd} paradigm* - transport phenomena, 1960; and *3^{rd} paradigm* - innovative/creative product design/engineering, starting at 21^{st} century. [1], [2]

In the previous century, the generic concepts of "unit operations" and "transport phenomena", often referred to as the first and second paradigm in chemical engineering, were developed. In the 1980's, there were some main innovations e.g. process and heat integration and mass integrations in the plant value chain, also referred as industrial ecology. Now global scales are sought out, greenhouse gases as a topical example.

In the last decade, the design and development of chemicals-based products has been discussed by several authors as the "emerging third paradigm in chemical engineering" [2], [3], [4]. On the contrary, Siirola has made a proposal that an electrically dominated chemical processing could be a new chemical processing paradigm. He also points out that sustainability attributes when selecting and optimizing among alternatives during design are considered but very rarely these same objectives are controlled during operations [5].

Megatrends which have had the largest impact to the field of chemical engineering are the Industrial Revolution (18th Century to the present), WW I and WW II, the post war period (1945-1965), the greatest economic growth, massive inflation during the late sixties and the energy crisis, economic recession of the early seventies, Internet, globalization, green chemistry, LCA and sustainability. In addition, social and political megatrends, e.g. environmental regulations and governance, have also significant impact on the process industry and chemical engineering education. Some of the aforementioned paradigms and megatrends are presented in Figure 1 with US inflation rate, unemployment rate and change of GDP relative to previous year.

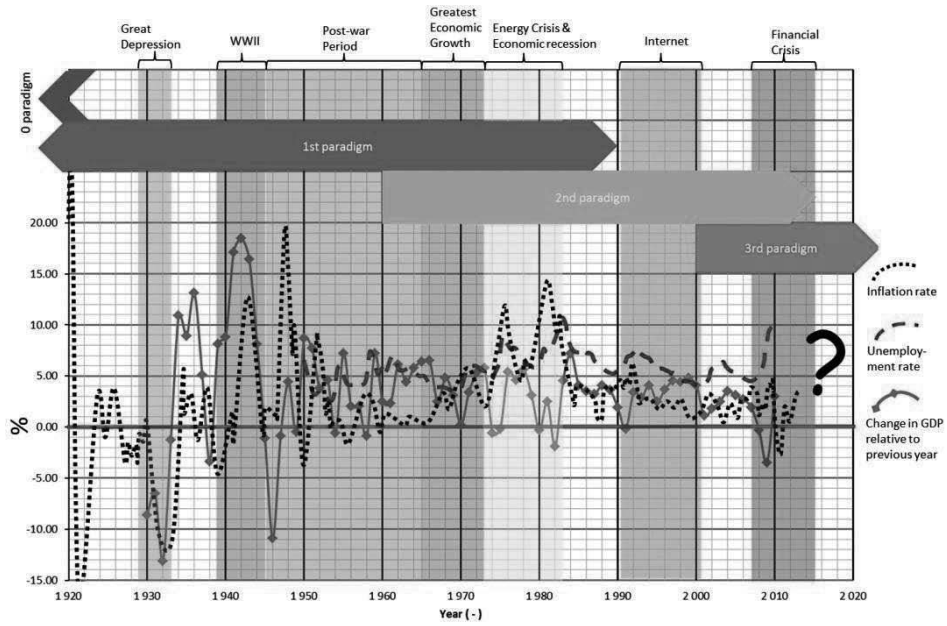

Figure 1. Graph of some paradigms and megatrends. In addition the inflation rate, unemployment rate and change in GDP relative to previous year in USA. [6], [7], [8]

2. Predicting the Future Megatrends and Paradigms

There are many predicting methods which have broad purpose of creating and/or strengthening awareness about the future by offering alternative future images and choices of action based on those images. They are used to generate, present, manipulate, and evaluate information about the future. Qualitative trend-analysis methods such as environmental scanning and monitoring involve keeping track of developments. Naisbitt's Megatrends [9], [10], for example, are based on a form of environmental scanning called content analysis. The approach is based on the premise that a small number of innovators start trends becoming popular with more and more people. Trend analyses share also the assumption that the future will in some way be an extension of the past [11]. Delphi analysis is perhaps the best known qualitative, structured futures method in use today [12]. Scenario development as an aid to planning is focused on developing alternative visions of the future. Visioning exercises typically look farther into the future (i.e., 10 years or more) than other futures methods. Scenario planning (or scenario learning) has proven to be a disciplined method for imagining possible futures in which decisions may be played out, and a powerful tool for asking "what if" questions to explore the consequences of uncertainty [13]. Cross-impact analysis is often thought of as an extension of the Delphi method. It involves identifying and evaluating the impact of trends or events upon each other [14].

The megatrends already playing a role or emerging are in our opinion: the era of (financial) uncertainty, urbanization and demand for municipal water technologies, innovative product development, new energy sources and energy efficiency, and finally generation Y, which is classified as people born between years 1980-2000.

The last few years the economic situation has globally been challenging and stigmatized by miss-trust and uncertainty accompanied with fear of a double-dip. Recent develop-

ment indicates a prolonged era of slow growth and uncertainty. As the population of Earth grows, demand for fresh water and energy increases. This results in to development of innovative new solutions to processes and products. This is suitable for generation Y. This generation has grown up during the ICT revolution and thus is quite familiar with new technologies and media. The generation Y is driven by an urge to change the world.

3. Profile of the Future Chemical Engineering Professional

Factors driving the education of chemical engineering are the changing needs of industry and society. Generally, they are linked to megatrends which have major effects on industry and employment. Much of the manufacturing industry of bulk products has already moved from the traditional industrial countries to developing countries, where the rising markets are. In addition, manufacturing industry has moved to the countries where the raw materials, like the oil, gas, minerals, forest resources and inexpensive labor, exist abundantly. This means the closures of old industrial production sites, such as steel industry in Europe. As a result, a market differentiation has taken place, e.g. Asia has a growing basic chemical industry, America is focusing on biofuels, fertilizer industry and shale gas, Middle East on oil and petrochemical industry and Europe on conglomerates industry.

These issues mentioned above have not been much discussed in the designing of the chemical engineering curriculum. The changes and shifts in megatrends and globalized economics have also been reflected on the labor force. In several industrial countries it has been estimated that an average person changes jobs 5-8 times during the work career. This may involve also changing the profession in some cases. Many of the existing job titles did not exist 30 years ago. Since a career lasts about 40 years or more, it is clear that the life-long learning is essential for chemical engineers, as well as, for chemical engineering curriculum. This has been recognized by many organizations that have developed several forms of part-time education and in-house courses.

The traits of the ideal 2020 worker according to Finnish journalist Petri Korhonen are: entrepreneurial working style (ownership of their work, as if working for themselves, also independence and responsibility), communication and presentation skills (articulates mutual interests and listens to counterparts), self-awareness (recognizing ones strengths and weaknesses, knowing own motivators), extended language portfolio (one or two main languages, such as English and German, and one or two languages of developing economies, such as Polish, Turkish or Spanish), international or ex-pat experience (flexibility, ability to tolerate uncertainty), IT-skills (incl. finding information and social media), general education and awareness (what is in the world news and causalities of global and local events, literature and culture), good overall fitness (coping with stress, better cognitive abilities) and finally, the courage to change ones field of work. [15]

Taking into consideration these traits and demands, the skill profile of the future process engineers can be compiled as in Figure 2. It consists of technical competences, personal characteristics, interactive traits and ability to work as a part of society. Each of these sections can be broken down to more detailed lists of concepts, such as natural sciences, applied engineering sciences and engineering applications. These in turn can also be broken down in individual pieces, such as mathematics, physics and chemistry in natural sciences.

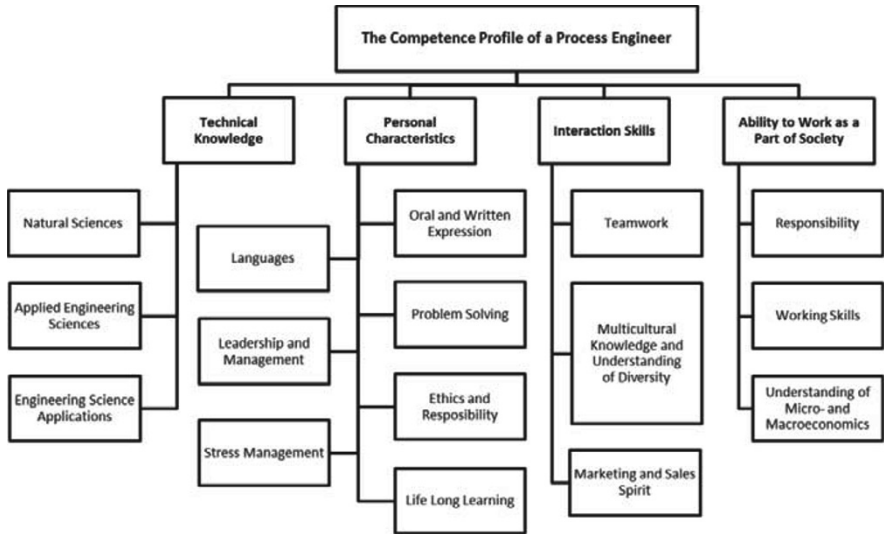

Figure 2. The competence profile of a process engineer.

4. Teaching Chemical Engineers to Face the Challenges of the Future

In recent past, it was adequate to prepare the graduate to a single task or a series of predefined assignments needed in the industry. The industry is now evolving from manufacturing to an information society i.e. an experience society or an adventure society, where the value earning logic of companies depends on innovations and developing new ways of working. The key factor is the ability to evolve and disrupt the daily work routines. In the future, working by the book is a subsiding resource. Strict rules and precise instructions are replaced by vague guidelines. Goals are becoming more abstract. The content and rules of work must be defined in an individual level. [16], [17]

These changing needs of the occidental innovation industry affect the higher education sector dramatically. Combining this with the Y generation, the educational system is forced to change. The best ways of teaching this generation is probably not strict class room discipline and thousand-page books. The video-gaming generations or virtual-life generations are highly skilled in IT, intuitive optimization and learning-by-playing.

Higher education should evolve as the world around it has evolved and embrace new technologies rather than see them as threats. Teaching should consist of design projects, which at best are real life problems from the industry. The design projects (i.e. problem based learning) are the best form of inspiring entrepreneurial attitudes and attributes of participants. Simulators are used too rarely even though they are the everyday tools in the chemical engineer graduates life. In fact, simulators can be associated with an interactive video gaming experience reinforcing the learning experience of theory and enhancing the future engineers' intuitive knowledge. This is especially true to dynamic simulators. Social media and other e-learning possibilities are also used quite rarely. With these the students can learn where ever and whenever they want (this translates to: when they are at their best performance level). At best, e-learning and social media enable mass-customization of courses to the client, namely to the student.

The basic toolbox of an engineer is something, which does not change dramatically in time and is always needed. The tools include technical principles and unit operations, natural sciences (mathematics, thermodynamics, chemistry, physics, etc.) and qualitative and quantitative evaluation. Regulations and laws are always changing and thus

there is no sense in teaching these in more detail than in a nice-to-know basis and the new developments and niche data can be adopted at work and thru life-long learning. Though, the tools are general and must be adopted to each situation. These problem solving skills require sometimes little or even dramatic creativity and innovations.

5. Conclusion and discussions

As the World, with new global connections and dependencies, is changing, the industry is evolving and perceptions of these changing, the knowledge and information needed in succeeding should meet new ways of segmenting education. The skills sought after can be identified as basic engineering skills, ability to life-long learning and skills to adapt and create.

Our claim is that not only the industry is differentiated but also the education should differentiate to comply with the changes of industry and society taking place. For example, the chemical engineering curriculum should be different in industrializing countries than in the traditional industrial countries, since also the industries and work tasks are different. The chemical engineer curriculum in Europe should be focusing on science skills, new product development and creativity whereas Asian chemical engineering education should focus to high-quality engineering and design.

Use of Podcasts for Teaching Process Control

Srinivas Palanki,*
Department of Chemical & Biomolecular Engineering; University of South Alabama; Mobile, AL, USA

Abstract

In the past decade there has been interest in quantifying teaching effectiveness in technology-mediated lectures in the science, technology, engineering and mathematics (STEM) fields. We developed podcasts for an undergraduate process control course and used two different mechanisms for delivering these lectures. Student performance was assessed via the department's student outcomes assessment procedure for ABET accreditation. It was found that podcasts were an effective tool to prepare students, especially when combined with active learning techniques.

Keywords: podcasts, process control, active learning

1. Introduction

In the past decade there has been interest in quantifying teaching effectiveness in technology-mediated lectures in the science, technology, engineering and mathematics (STEM) fields. The major motivation for these studies is the fact that STEM fields have high attrition rates compared to other fields such as humanities and business. One major reason for high attrition is the fact that most of STEM education is currently delivered via traditional lectures to classes with a large number of students, which affords a very limited amount of exchange of ideas and students have a difficult time grasping the relevance of what they should be learning [Tobias, 1990]. It has been shown that after roughly ten minutes of a typical lecture, about fifty percent of the class is inattentive [Horowitz, 1988]. Many recent studies show that students learn better when they are engaged in an instructor-guided problem-solving environment [Lewis and Lewis, 2005; Moog and Spencer, 2008]. Student performance represents a key aspect of teaching effectiveness and reviews of research comparing the effectiveness of interactive video versus face-toface instruction have found that student achievement in video-enriched courses is the same or better than courses involving face-to-face interaction [Wetzel et al., 1994; Storck and Sproull, 1995]. Webster and Hackley [1997] studied the influence of technology mediated distance learning in a variety of fields and demonstrated both qualitatively as well as quantitatively the benefits of using a media-rich, technologically savvy instruction medium over a conventional chalkboard. Toto and Booth [2008] studied the effects and implications of mini-lectures on learning in a first-semester general chemistry course. In this study, mini-lecture videos on general chemistry topics were prepared and delivered to students in a Web-based format instead of traditional 50 minute lectures three times a week. In each video, one core concept was described. Students with access to these videos scored 11.2% higher than students who attended traditional lectures. In addition, when concepts that were traditionally perceived to be difficult were tested, students who viewed mini-lecture videos scored 21.8% higher than traditional students. This marked improvement clearly shows the potential advantages of web-based videos in teaching STEM concepts. Falconer et

*spalanki@usouthal.edu

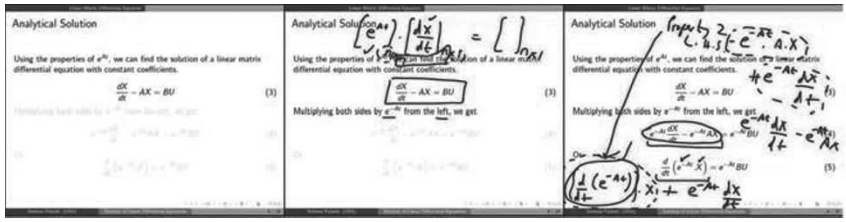

Figure 1. Screenshots of Lecture Video Annotated with Instructor's Comments

al. [2009] implemented this concept of using screencasts in five chemical engineering courses in the University of Colorado. It was observed that a significant majority of the students were in favor of this mode of instruction [e.g. 91% of the graduate reaction engineering class and 83% of the undergraduate material and energy balances class said that screenshots are useful for learning].

2. Development of Podcasts

Pen-tablet technology to annotate slides has been available for the past two decades. The availability of inexpensive desktop-based screen-capture software that is easy to use in the past five years makes it possible to make podcasts. These podcasts provide the look-and-feel of a traditional in-class lecture and when coupled with synchronized audio, allows the instructor to (a) emphasize key points in the lecture and (b) do calculations and derivations on the side using the pen-tablet technology just as he would in a chalkboard. This also makes the lecture more lively and avoids the problem of "death by PowerPoint".

We developed a series of podcasts for a traditional undergraduate process control class. The slides were made using the "beamer" style of LaTeX. Annotations on the slides were made using a Wacom Bamboo tablet and electronic pen as shown in Figure 1. The podcasts were made on a Pentium PC in the instructor's office. The software Camtasia was used to capture the audio and video part of the lecture.

3. Classroom Implementation

Two different approaches were used to test the efficacy of the podcasts in learning: (a) passive learning and (b) active learning. These approaches are described below:

Passive Learning: In Spring 2010, students taking the process control class were given a choice between attending traditional lectures along with access to podcasts or viewing the podcasts on their own without coming to class. In the traditional lecture setting, we used the same slides that were used in the podcasts; however the students had an opportunity to interrupt the lecture and ask questions. They also had access to the podcasts that they could view at their leisure. Students who chose to not attend the traditional lectures had to view the podcasts (which could be rewound and heard multiple times) and then make an appointment to see the instructor if they had questions. Half the class opted to attend the traditional lectures while the other half chose to only view the podcasts. There were very few questions asked on a regular basis during the traditional lecture by students attending the lectures or during office hours by students viewing the podcasts.

Active Learning: In Spring 2011, we used a different approach to encourage students to view the podcasts and ask questions in the process control class. Students were *required* to attend every lecture. However, they were required to view the podcast associated with each lecture, *prior* to attending the class. We divided the class into teams of two students each and we randomly picked the name of a student team out of a cup at the beginning of each class. The team whose name was picked was required to give a 30 minute presentation on that day's lecture material. The team was allowed to use the instructor's slides or could use the chalk board. The instructor (as well as the rest of the class) would assist the student team if they were stuck at any point in the lecture.

4. Assessment

In both semesters the following fixed grading scale was used to assign overall grades in the process control class: F = below 40%, D = 40% to 49%, C = 50% to 69%, B = 70% to 84% and A = 85% to 100%. Student performance was assessed via the department's student outcomes assessment procedure for ABET accreditation. The student outcomes are listed below:
Graduates of the Department of Chemical Engineering at the University of South Alabama will:

1. Have demonstrated knowledge of the mathematical, science, and engineering principles fundamental to the practice of chemical engineering. (a)
2. Be able to design and conduct experiments and analyze and interpret data related to chemical engineering. (b)
3. Demonstrate the ability to accomplish design problems to meet desired needs. (c)
4. Demonstrate an ability to function successfully in a team environment accommodating the contributions of team members having a variety of skills and perspectives. (d)
5. An ability to identify, formulate, and solve chemical engineering problems. (e)
6. Have been encouraged to develop high personal standards of integrity and ethical responsibility. (f)
7. Have demonstrated proficiency in written, graphical, and oral communications. (g)
8. Have a broad enough education to understand the impact of engineering solutions in a global and societal context. (h)
9. Indicate a motivation to continue developing knowledge and skills after graduation. (i)
10. Have knowledge of contemporary issues related to chemical engineering. (j)
11. Demonstrate an ability to use techniques, skills, and modern computational and analytical tools necessary for engineering practice. (k)

Table 1 lists the instruments where each outcome was assessed. It should be noted that some outcomes (e.g. Outcome 1) were assessed in almost all the instruments used in the course (e.g. home assignments, quizzes, tests, final project) while some outcomes (e.g. Outcome 3) were assessed only in a few instruments. For each outcome, a numerical score from 1 to 5 was assigned based on the average performance of the class for that particular outcome. The numerical scores indicated the following assessment: 1 = performance far below expectation, 2 = performance below expectation, 3 = performance meets expectations, 4 = performance exceeds expectations, and 5 = performance far exceeds expectations. The average performance of the class was computed for each outcome and compared with the overall grading scale used in the course and used for assigning the numerical score. For example, the class average for Outcome 1 was 66% in Spring 2010 and this is a C grade in the fixed grading scale described above. Thus Outcome 1 was assigned a numerical score of 3. The departmental objective for accreditation purposes is to get a score of 3 or better for each outcome; otherwise action has to be taken to make changes to the way the course is taught.

Table 1. Assessment Instruments for Student Outcomes

Outcome	Asssessment Tool
1	Home Assignments 2-7, Quizzes 1-2, Tests 1-3, Final Project
2	Laboratory Assignments 1-2
3	Home Assignment 3, Final Project
4	Laboratory Assignments 1-2
5	Home Assignments 2, 3, 6, 7, Quizzes 1-2, Tests 2-3, Final Project
6	Design Project
7	Design Project
8	Home Assignment 1
9	Design Project
10	Home Assignment 1
11	Home Assignments 2, 3, 6, 7, Quizzes 1-2, Tests 2-3, Laboratory 1, Final Project

It was observed that in both 2010 as well as 2011, each outcome received an average score of 3 or higher thereby indicating that the minimum requirement for each outcome in this course was met. Table 2 shows the outcomes assessment results (the maximum score for each outcome is 100%) for Spring 2010 and Spring 2011. It is observed that in each outcome assessed, the Spring 2011 class did much better than the Spring 2010 class. The results of Table 2 are very encouraging as these results clearly show that when students are involved in teaching the lecture, their performance is better. The podcasts were, in general, effective in preparing students to give class lectures. Furthermore, since student teams did not know *in advance* if they would be selected to present in class, all student teams came prepared for every class and this helped ensure that students reviewed the course material at frequent intervals and not just before a test. We are now utilizing this methodology to develop podcasts for teaching nanotechnology concepts in several core engineering courses in Chemical, Mechanical and Electrical Engineering via a project funded by the National Science Foundation.

Table 2. Outcomes Assessment Results

Outcome	Spring 2010	Spring 2011
Outcome 1	66%	80%
Outcome 2	66%	94%
Outcome 3	71%	81%
Outcome 4	59%	94%
Outcome 5	70%	82%
Outcome 6	70%	77%
Outcome 7	70%	82%
Outcome 8	77%	92%
Outcome 9	70%	77%
Outcome 10	77%	92%
Outcome 11	70%	83%

5. Conclusions

Podcasts can be an effective means to enhance the student learning experience. However, the mere availability of podcasts does not necessarily improve student learning. In this paper, it was observed that when podcasts were utilized with active learning techniques, there was a significant improvement in student learning outcomes.

Abstract

The current drive towards environmental sustainability, the rising costs of energy, fresh resources as well as waste treatments have forced process industries to pay much attention on the improvement of their processes. Consequently, significant efforts have been devoted to develop systematic techniques for heat conservation and waste reduction. In the past, the synthesis of optimal resource conservation network (RCN) has been dealt independently for single resource. To date, very little has been accomplished on the use of heuristic techniques for simultaneous heat and resource conservation. In this work, a novel methodology is developed for the synthesis of RCN, focusing on simultaneous heat and mass integration. With the newly developed methods, the minimum resources consumption and waste generation can be identified. A case study is utilised to demonstrate the applicability of the methodology.

Keywords: Energy minimisation, resource conservation, waste reduction, simultaneous.

1. Introduction

Process integration has been commonly used as an effective tool for resource conservation and waste reduction. El-Halwagi (2006) defines process integration as *a holistic approach to process design, retrofitting and operation which emphasis the unity of the process*. Process integration can be categorized as *heat integration* and *mass integration*. *Heat integration* is a systematic methodology that provides a global understanding of heat utilization within the process and employs this understanding in identifying the utility targets and optimising heat recovery as well as energy-utility systems (El-Halwagi, 2006). On the other hand, *mass integration* is a systematic approach that provides a fundamental understanding of the global flow of mass within the process and employs the understanding in identifying performance targets and optimizing the generation and routine of species throughout the process (El-Halwagi, 2006). Extensive reviews on energy and mass integration can be found in Furman and Sarhinidis (2002) and Dunn & El-Halwagi (2003).

Most of the studies in the area of process integration have been mainly focused on either heat or mass integration separately. However, in many cases, simultaneous consideration of heat and mass integration is needed. For example, when solvent is utilised in the industry for extraction purpose, heating or cooling is needed to meet the process operating conditions. In such cases, mass and heat management need to be

considered simultaneously as both the quality and temperature of solvent are equally important. In this work, the main objective is to develop a novel methodology to optimize heat-integrated resource conservation network (RCN) using a simultaneous approach of heat and mass integration.

2. Problem Statement

The problem to be addressed is given as follow: Given a process with a set of process sinks j with a given flowrate (G_j), contaminant compositions (C_j) and temperature (T_j), and a set of process sources i which can be consider for in-plant reuse/recycle. Each source is given flowrate (W_i), contaminant composition (C_i) and temperature (T_i). In addition, fresh resources r are readily available to supply to the process sink. Streams mixed from fresh resources and process sources are categorised as hot or cold streams for heat integration. Heat exchangers are used to recover heat from hot streams to cold streams. Heaters and coolers may be used to provide external hot (Q_h) and cold (Q_c) utilities. The objective of the work is to develop a systematic procedure for the synthesis of heat-integrated RCN with minimum total annualized cost (TAC).

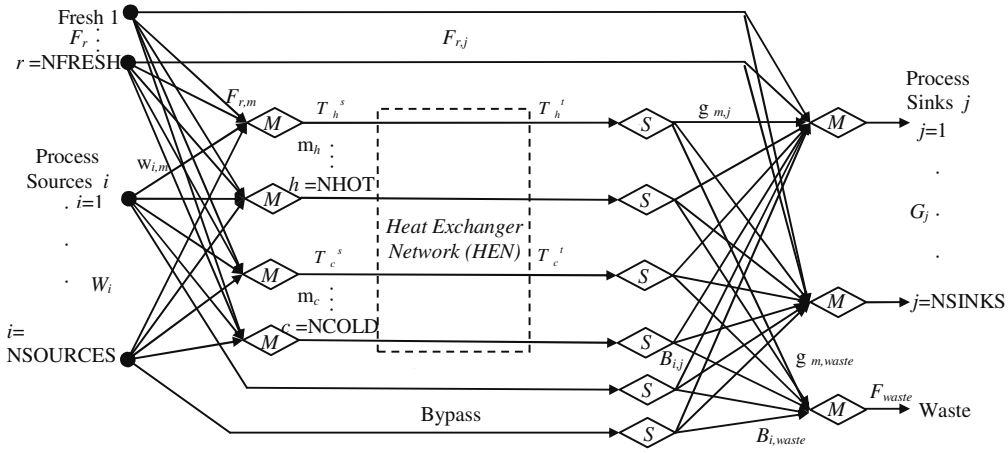

Figure 1: Superstructure of heat-integrated RCN

3. Model Formulation

Based on the problem statement, the optimization problem can be formulated as below:

$$\min_{F_r, Q_h, Q_c} TAC = k * \left\{ \sum_{r=1}^{NFRESH} Cost_r F_r + Cost_h Q_h + Cost_c Q_c \right\} \quad (1)$$

$$s.t.$$

$$HIRCN$$

$$CONSTR$$

where $Cost_r$, $Cost_h$ and $Cost_c$ are the costs of fresh resources, hot and cold utilities. HIRCN is the heat-integrated RCN model and CONSTR is the process constrained imposed in the network optimization. Meanwhile, k is referred to the operating hour per year. In the following section, HIRCN and CONSTR are presented in detail. Based on mass and energy balances of each node in the heat-integrated RCN (Figure 1), HIRCN model can be obtained as follows:

Splitting of fresh sources:

$$F_r = \sum_{j \in NSINKS} F_{r,j} + \sum_{n \in NHOT,NCOLD} F_{r,n} \quad r \in NFRESH \tag{2}$$

where $F_{r,j}$ and $F_{r,n}$ are the flowrate of fresh sources to sink *j* and HEN respectively.

Splitting of process sources:

$$W_i = \sum_{n \in NHOT,NCOLD} w_{i,n} + \sum_{j \in NSINKS} B_{i,j} + B_{i,waste} \quad i \in NSOURCE \tag{3}$$

where $w_{i,n}$, $B_{i,j}$ and $B_{i,waste}$ are the flowrates of source *i* supply to HEN, by-pass of HEN and waste respectively.

Mass balance at the inlet of HEN for hot and cold streams*:*

$$m_n = \sum_{i \in NSOURCES} w_{i,n} + \sum_{n \in NHOT,NCOLD} F_{r,n} \quad n \in NHOT, NCOLD \tag{4}$$

Composition tracking at the inlet of HEN:

$$m_n C_n = \sum_{i \in NSOURCES} w_{i,n} C_i + \sum_{r \in NFRESH} F_{r,n} C_r \quad n \in NHOT, NCOLD \tag{5}$$

where C_n is the contaminant concentration for mixture of source *i* and fresh *r* while C_r is the contaminant concentration if fresh *r*.

Energy balances at the inlet of HEN:

$$m_n Cp_n T_n^s = \sum_{i \in NSOURCES} w_{i,n} Cp_i T_i + \sum_{r \in NFRESH} F_{r,n} Cp_r T_r \quad n \in NHOT, NCOLD \tag{6}$$

where Cp_n, Cp_i and Cp_r are the heat capacities of mixture of source *i* and fresh *r*, source *i* and fresh *r* while T_n^s and T_r are the temperatures of hot and cold stream, and fresh resources, respectively.

Mass balances in the splitting point at the exit of the HEN:

$$m_n = \sum_{j \in NSINKS} g_{n,j} + g_{n,waste} \quad n \in NHOT, NCOLD \tag{7}$$

where $g_{n,j}$ and $g_{n,waste}$ are the flowrate from HEN to sink *j* and waste.

Mass balances at the mixing point before the sinks:

$$G_j = \sum_{n \in NHOT,NCOLD} g_{n,j} + \sum_{i \in NSOURCES} B_{i,j} + \sum_{r \in NFRESH} F_{r,j} \quad j \in NSINKS \tag{8}$$

Composition tracking at the mixing point before the sinks:

$$G_j C_j = \sum_{n \in NHOT,NCOLD} g_{n,j} C_n + \sum_{i \in NSOURCES} B_{i,j} C_i + \sum_{r \in NFRESH} F_{r,j} C_r \quad j \in NSINKS \tag{9}$$

Energy balances at the mixing point before the sinks:

$$G_j Cp_j T_j = \sum_{n \in NHOT,NCOLD} g_{n,j} Cp_n T_n^t + \sum_{i \in NSOURCES} B_{i,j} Cp_i T_i + \sum_{r \in NFRESH} F_{r,j} Cp_r T_r \quad j \in NSINKS \tag{10}$$

where Cp_j and T_n^s are the specific heat capacity for sink and target temperature for hot and cold streams in HEN respectively.

Mass balance of the waste:

$$F_{waste} = \sum_{i \in NSOURCES} B_{i,waste} + \sum_{n \in NHOT,NCOLD} g_{n,waste} \tag{11}$$

CONSTR for the optimization problem is listed as below:

Process Constraints for contaminant concentration (Eq. 12) and temperature (Eq. 13) of process sink *j*:

$$C_j^{\min} \le C_j \le C_j^{\max} \quad j \in NSINKS \tag{12}$$

$$T_j^{\min} \le T_j \le T_j^{\max} \quad j \in NSINKS \tag{13}$$

where $C_j^{\min}, C_j^{\max}, T_j^{\min}, T_j^{\max}$ are the minimum and maximum concentration and temperature of process sink *j*.

Based on the concept of *floating pinch* (El-Halwagi and Manousiothakis, 1990) for mass integration, the following binary integer constraints ($\lambda_{h,p}^t, \lambda_{h,p}^s, \eta_{c,p}^t$ and $\eta_{c,p}^s$) are included in the model.

$$\lambda_{h,p}^t = \begin{cases} 1 \ if \ T_h^t < T_p & h \in NHOT \\ 0 \ if \ T_h^t \ge T_p & p \in NPINCH \end{cases} \tag{14}$$

$$\lambda_{h,p}^s = \begin{cases} 1 \ if \ T_h^s < T_p & h \in NHOT \\ 0 \ if \ T_h^s \ge T_p & p \in NPINCH \end{cases} \tag{15}$$

$$\eta_{c,p}^t = \begin{cases} 1 \ if \ T_c^t < T_p & c \in NCOLD \\ 0 \ if \ T_c^t \ge T_p & p \in NPINCH \end{cases} \tag{16}$$

$$\eta_{c,p}^s = \begin{cases} 1 \ if \ T_c^s < T_p & c \in NCOLD \\ 0 \ if \ T_c^s \ge T_p & p \in NPINCH \end{cases} \tag{17}$$

where, T_p is the potential pinch candidates and is calculated using minimum temperature difference (ΔT_{min}) as follow:

$$T_p = \begin{cases} & h \in NHOT \\ T_h^s - \Delta T_{\min} & c \in NCOLD \\ T_c^s + \Delta T_{\min} & p \in NPINCH \end{cases} \tag{18}$$

where T_h^s and T_c^s are the supply temperature of the hot and cold streams in HEN.

Meanwhile, Q_c can be calculated via Equation 19.

$$\begin{aligned} Q_c \ge & \sum_{h \in NHOT} m_h Cp_h \left\{ \lambda_{h,p}^t (T_p - T_h^t) - \lambda_{h,p}^s (T_p - T_h^s) \right\} - \\ & \sum_{c \in NCOLD} m_c Cp_c \left\{ \eta_{c,p}^s (T_p - T_c^s) - \eta_{c,p}^t (T_p - T_c^t) \right\} \ p \in NPINCH \end{aligned} \tag{19}$$

where m_h, m_c, Cp_c, Cp_h, T_h^t and T_c^t are the flowrate, specific heat capacities and the target temperature for the hot and cold streams in HEN respectively.

The overall energy balance to calculate Q_h is expressed as below:

$$\sum_{h \in NHOT} m_h Cp_h (T_h^s - T_h^t) - \sum_{c \in NCOLD} m_c Cp_c (T_s^t - T_s^s) + Q_h - Q_c = 0 \tag{20}$$

Note that the optimization problem presented above is an MINLP problem. In this work, Extended Lingo v.11 with Global Solver is used to solve the optimization problem.

4. Case Study

A case study of vinyl acetate monomer plant taken from El-Halwagi (2006) is modified and adapted to illustrate the proposed approach. In this case study, $Cost_r$ (fresh acetic acid cost), $Cost_h$ and $Cost_c$ are given as \$0.625/kg, \$3.758/kW.h and 0.005\$/kW.h respectively. In addition, k, ΔT_{min} and all Cp values (Cp_n, Cp_i, Cp_r and Cp_j) are taken as 8000 h/yr, 10°C and 2.5kJ/kg.K respectively. Besides, two hot streams (T_h^s of 360K and 470K with T_h^t of 300K and 370K) and one cold stream (T_c^s of 360K with T_c^t of 460K) are also given. The proposed model is solved in 10s on a PC machine (2.66 GHz, 1GB RAM) and leads to the global optimal solution as presented in Figure 2. The minimum TAC is determined as \$62.7 million/year with the optimal F_r, Q_h and Q_c values of 9633 kg/h, 0 MW and 364.12 MW respectively. For comparison, solving the model with sequential approach (reuse/recycle network followed by HEN) leads to a TAC of \$1,355 million/ year (F_r, Q_h and Q_c values are 9584 kg/h, 43 MW and 372.4 MW respectively) which is much higher than the optimal solution of the proposed model.

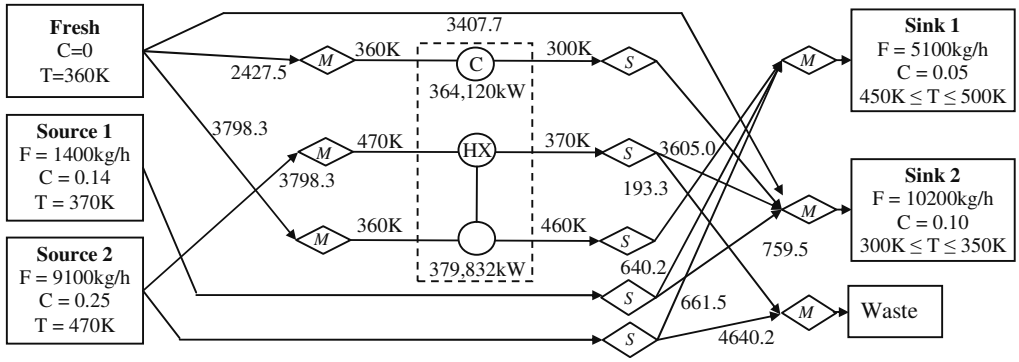

Figure 2: Optimal solution for vinyl acetate monomer plant.

5. Conclusion

In this work, a novel systematic methodology for synthesis of heat-integrated RCN is presented. An MINLP formulation has been developed to identify the minimum TAC of a heat-integrated RCN while satisfy the process constraints. A case study of vinyl acetate plant is solved to illustrate the applicability of the proposed approach.

Abstract

The design and operation of combined cooling, heating and power (CCHP) systems are complicated due to the fluctuating demands that the system faces. Many mathematical models for the design and/or operation of CCHP systems have been developed to obtain better performances of such systems. Most of these models adopt a constant efficiency assumption, while others take equipment off-design characteristics into account. In this paper, we present two mathematical models for the optimal design and operation of CCHP systems with the target of minimizing the total annual cost. For comparison purposes, one model is formulated to represent the performance of a CCHP system running at design conditions, *i.e.*, with constant energy efficiency. In the other model, both the design and off-design characteristics of all key equipments in a CCHP system are considered. These two models were applied to different CCHP systems. Comparative studies of overall costs and operation schedules of different CCHP systems were performed to examine the impacts of equipment off-design characteristics on the optimal design and operation of CCHP systems. Results show that introduction of thermal storage facilities, connection to power grid and a well designed operation strategy can diminish the negative impacts of adopting the constant efficiency assumption.

Keywords: CCHP; off-design; internal combustion engine; absorption chiller

1. Introduction

Combined cooling, heating and power (CCHP) system is broadly regarded as an efficient and economic approach for simultaneous provision of cooling, heating and electricity. CCHP can increase the overall energy efficiency of an energy system by recovering a large proportion of waste heat produced in power generation. However, the expected performance of CCHP cannot be achieved without appropriate combination and operation of machinery, due to the fluctuating heating, cooling and electricity demands that the system faces. Many mathematical models for the design and/or operation of CCHP systems have been developed to obtain a better performance of such systems. A key difference amongst these models lies in their different methods in dealing with the off-design characteristics of equipment. Most models assume that the

efficiency or coefficient of performance (COP) of equipment do not change while operating at off-design levels (Arcuri, Florio et al. 2007; Cho, Mago et al. 2009; Ren and Gao 2010). This assumption can greatly simplify modelling work, but it also leads to less accurate results based on which systems design or operation strategies are made. In some other studies, more complex models are developed considering off-design characteristics of equipment (Li, Nalim et al. 2006). However, these models usually pose significant or even formidable computational challenges due to their nonlinear nature.

In this work, we illustrate the extent of negative impacts of the constant efficiency assumption on the accuracy of CCHP modelling. We present two mathematical models for the optimal design and operation of CCHP systems with the target of minimizing the total annual cost. For comparison purposes, one model is formulated to represent the performance of a CCHP system running at design conditions, *i.e.,* with constant energy efficiency. The other model considers both the design and off-design characteristics of all key equipment in a CCHP system. These two optimization models are applied to configure an optimal CCHP system for a hotel in Beijing. The impacts of equipment off-design characteristics on the optimal design and operation of CCHP systems are discussed based on the modelling results.

2. System configuration of a CCHP system

A typical configuration of CCHP systems is shown in Fig. 1. In the system, internal combustion engines (ICE) are used in the power generation unit (PGU) for simultaneous production of electricity and heat. Recovered heat in the PGU is used to meet the heating and cooling demands together with gas boilers (GB). Cooling demand is met via absorption chillers (AC). When the amount of electricity generated by the PGU is not enough, extra electricity can be drawn from a power grid. A thermal storage unit (TSU) is employed to achieve a proper utilization of energy.

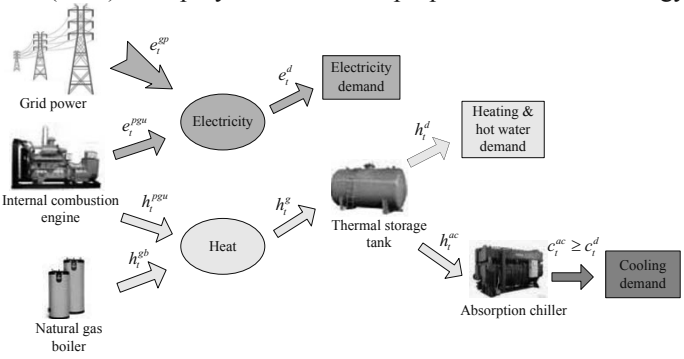

Fig. 1. Energy flow diagram of CCHP system

3. Mathematical formulation of the optimization models

Two mathematical models are developed with the target of minimizing the total annual cost of a CCHP system, covering capital cost, operation and maintenance (O&M) cost and fuel cost. One model adopts the constant efficiency assumption, whilst the other one considers the off-design characteristics of equipment. Equipment performance curves adopted in this study are obtained from (Li, Nalim et al. 2006). Sizes of equipment are standardized thus cannot be changed, but installation of multiple pieces of equipment is allowed.

The model with the constant efficiency assumption is a mixed integer linear programming (MILP) problem, whilst the other is a mixed integer nonlinear programming (MINLP) problem due to nonlinear terms introduced by equipment performance curves. However, this MINLP problem can be converted to a MILP problem through certain linearization techniques. The proposed problems are solved on the platform of GAMS with CPLEX as the MIP solver (GAMS Development Corporation 2008).

4. Case study

The baseline case is a typical hotel in Beijing with an area of 60 thousand square meters. We also include a 30 thousand square meters case and a 90 thousand square meters case for sensitivity analysis. The hourly electricity, heating, cooling and hot water demands of three representative days in winter, summer, and transitional seasons of the baseline case are shown in Fig. 2 (Jin, Zheng et al. 2008).

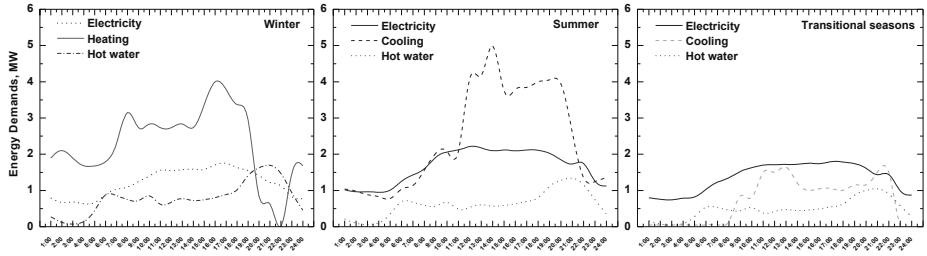

Fig. 2. The energy demands profile of a typical hotel in Beijing

Besides the demands information, both models also require technological and economic information of different technologies, as shown in Table 1, as well as energy prices information as exogenous inputs (Lu 2007; Ren, Zhou et al. 2010). Natural gas price and average time-of-use electricity price are published by Beijing government, 2.05 RMB/m^3 and 0.746 RMB/kWh, respectively (Beijing Municipal Commission of Development & Reform 2011).

Table 1. Technological and economic information of different technologies

Technology	Capacity	Unit capital cost	O&M cost	Lifetime	Rated efficiency
ICE	1.46 MW	5.2 million RMB	72 RMB/MWh	20 yr	41.4%
GB	0.96 MW	0.82 million RMB	2.16 RMB/MWh	20 yr	89.6%
AC	1.3 MW	1.6 million RMB	8 RMB/MWh	20 yr	1.26 (COP)
TSU	-	90.06 RMB/kWh	-	20 yr	90%

5. Results and discussions

The optimal total annual costs generated by both models are presented in Fig. 3. It shows that the constant effiency assumption has a rather small impact on the optimal results, and the relative differences between these two types of models in the three cases are all less than 5 percent. Moreover, the relative difference gets smaller as the building area increases. The reasons for this small difference and the dimishing relative difference are explained next.

5.1. Effect of multiple pieces of equipment

Fig. 4 shows the the joint efficiency curve of a PGU installed with multiple internal combustion engines. If the PGU faces a low electricity demand, only one engine will be employed, therefore it is easy to fall into an inefficiency zone. However, when the electricity demand is large and multiple engines work together to satisfy the large demand, the overall efficiency of the PGU can remain close to its rated efficiency.

The number of equipment pieces adopted in the three cases are listed in Table 2. As a larger building area needs more energy, more equipments are installed, allowing them operating in the efficient zone. The relative gap of the total annual costs provided by two models with different assumptions becomes smaller as the building area increases, because flexibility in opreating multiple equipments can improve the overall efficiency.

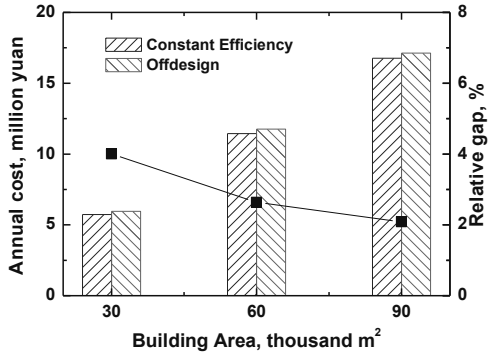

Fig. 3. The total annual costs and relative gaps of the costs generated by two different optimization models

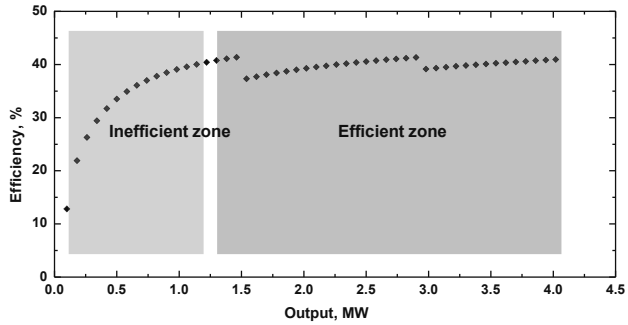

Fig. 4. The joint efficiency curve of a PGU with multiple internal combustion engines

Table 2. The number of equipment pieces employed in three different cases

Building Area, thousand m^2	30	60	90
Gas engine	1	2	2
Gas boiler	1	2	3
Absorption chiller	2	4	6

5.2. Effect of thermal storage and grid connection

The introduction of thermal storage technologies and grid connection can prevent energy generation technologies from operating in the inefficient zone. Thermal storage

technologies can shift extra heat generated during low demand periods for consumption during peak hours. Therefore, energy generation technologies can choose to produce more energy when demand is high and stop working when demand is low. The power grid plays a similar role as an effective electricity storage technology.

5.3. Implications

The aforementioned effects can guarantee that the efficiency of energy generation technologies won't significantly diverge from their rated efficiency. Therefore, the results generated by an optimization model with the constant efficiency assumption are credible. This also indicates that in the planning of a CCHP system, it is desired to employ several small scale equipments instead of only equipment with a large capacity. The introduction of thermal storage and grid connection can also contribute to the improvement of the overall efficiency.

6. Conclusions

The constant efficiency assumption of the optimization model for the design and operation of CCHP systems has a small impact on the optimization results. Multiple pieces of equipment operate together and thermal storage and grid connection can prevent energy generation technologies from working in inefficient zone in a CCHP system. This proves that the results generated by an optimization model with the constant efficiency assumption are credible.

Abstract

Production of fuels from carbon dioxide as carbon source may contribute positively to the global carbon balance. However, technologically, alternative fuels can be produced from CO_2 and, thus, a systematic appoach is needed in order to select the optimal energy carrier in terms of energetical efficiency. The evaluation of the production routes is an excellent task to apply the methods from process systems engineering, e. g. superstructure-based process design (Liu et al., 2011). In this contribution, we present an approach that takes the topology of the process as independent variable. This methodology is applied to the methanation of CO_2 and a comparison of methane and methanol as chemical storage of renewable energy is presented.

Keywords: Process Design, Energy Systems Engineering, Methane, Renewable Energy

1. Introduction

The sequestration of carbon dioxide (CO_2) has been seen as a way to reduce the CO_2 emissions to atmosphere but unfortunately this approach handles the concentrated CO_2 stream only as a waste to dispose. The highly complex CO_2 removal causes significant additional costs and remarkable efficiency deficit for the power plant (Haszeldine, 2009).

Recently, an energetical analysis of the processes, where CO_2 is used as a carbon source for the production of fuels, such as methanol or methane, has been published (Rihko-Struckmann et al., 2010). The reuse of exhaust CO_2 could contribute positively to the global carbon balance.

The renewable wind and solar energy sources suffer from intermittent and fluctuating character, and therefore it is necessary to find an efficient chemical storage for electricity produced from these energy sources. In this contribution we want to assess the potential of competitive production routes to store the electrical energy chemically by applying CO_2 as carbon source in terms of methane (CH_4) or methanol (MeOH). The discussed alternative processes utilise CO_2 from fossil power plants and hydrogen (H_2) produced by electrolysis from renewable energy sources.

The considered overall energy conversion-storage routes are shown in Fig. 1 (left). Fluctuating energy sources are used to produce hydrogen via electrolysis. In the next step, CO_2 is utilised to convert the hydrogen to methane or methanol, which can be stored much easier than hydrogen. In this contribution, we will focus on the conversion of H_2 into methane (1).

$$CO_2 + 4\,H_2 \leftrightarrow CH_4 + 2\,H_2O \qquad \Delta_R H^\circ = -164.7\,\mathrm{kJ/mol} \tag{1}$$

*zinser@mpi-magdeburg.mpg.de

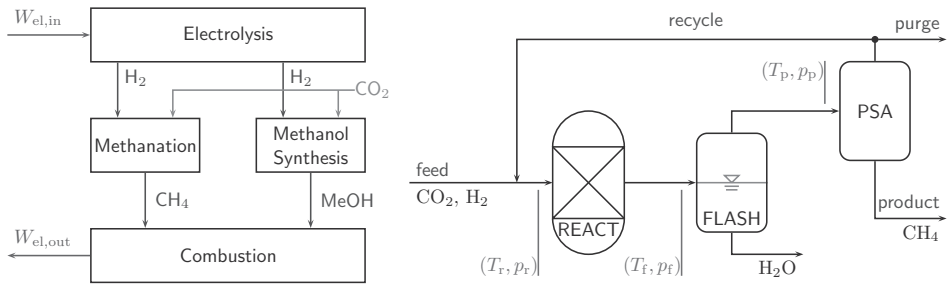

Figure 1. Competitive routes: methane and methanol as chemical storage of renewable energy (left). Basic scheme of the methanation process (right).

2. Methanation Process

A scheme of the overall methanation process is given in Fig. 1 (right). The methanation reaction (1) – originally discovered by Sabatier and Senderens (1902) – is performed in the methanation reactor REACT. Besides methanation, the reverse water-gas-shift reaction (RWGS)

$$CO_2 + H_2 \leftrightarrow CO + H_2O \qquad \Delta_R H^\circ = 41.2\,\mathrm{kJ/mol} \tag{2}$$

is considered. The reaction equilibria assumed to be established at the reactor outlet depend on the operating temperature and pressure.

The resulting mixture of CO_2, H_2, CH_4, H_2O and CO in the outlet stream of the reactor has to be splitted into the product CH_4, the side product water, and a recycle stream. This can be done by a flash evaporation (FLASH) and a downstream pressure swing adsoption unit (PSA).

3. Modeling

The reactor outlet composition is determined at given (T, p) by the Gibbs energy minimization method (Lwin, 2000)

$$\min_{n_i} nG = \min_{n_i} \sum_{i=1}^{N_c} n_i \Delta_f G(T) + RT \sum_{i=1}^{N_c} n_i \ln x_i + RTn \ln \frac{p}{p^\circ} + RT \sum_{i=1}^{N_c} n_i \ln \phi_i \tag{3}$$

subject to $\mathbf{An} = \mathbf{An}^0$ and $n_i > 0 \forall i$ where $\mathbf{A}$ is the atomic matrix that describes the elemental balances of the participating atoms, $\mathbf{n} = [n_1, \ldots, n_{N_c}]^T$ is the vector of moles at equilibrium conditions, and $\mathbf{n}^0$ represents the initial composition of the reactor feed stream.

Fig. 2 (left) shows the temperature-dependent chemical equilibria at $p = 1\,\mathrm{MPa}$ assuming ideal gas behaviour ($\phi_i = 1$) for an initial composition of $n_{CO_2} = 1\,\mathrm{mol}$ and $n_{H_2} = 4\,\mathrm{mol}$,

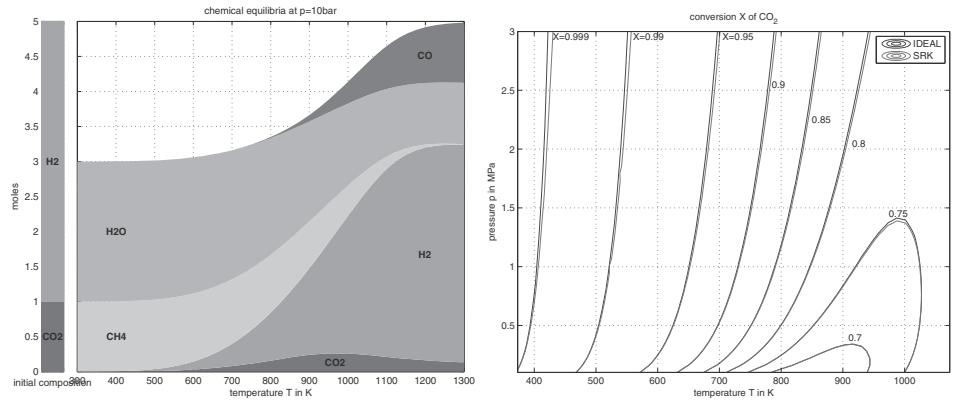

Figure 2. Temperature-dependent chemical equilibria at $p = 1\,\mathrm{MPa}$ (left). Conversion of CO_2 at different temperatures and pressures for the ideal gas law and the Soave-Redlich-Kwong equation of state (right).

respectively. Furthermore, the non-ideality of the system was assessed by use of fugacities calculated from the Soave-Redlich-Kwong (SRK) equation of state (Soave, 1972). The obtained results for ideal as well as non-ideal gas phase behaviour are depicted on the right hand side of Fig. 2. In our study, we fixed the reaction conditions to $T_\mathrm{r} = 450\,\mathrm{K}$ and $p_\mathrm{r} = 1\,\mathrm{MPa}$ and used the ideal gas law for further computations.

The vapor-liquid separation in the flash evaporator is computed by solving the vapor-liquid equilibrium (VLE) condition $x_i\phi_i^\mathrm{L} = y_i\phi_i^\mathrm{V}$ directly using the SRK equation of state. The inlet conditions of the flash were fixed to $p_\mathrm{f} = 0.5\,\mathrm{MPa}$ and $T_\mathrm{f} = 310\,\mathrm{K}$.

The PSA separation was modeled as a simple split fraction unit, where the product stream consists of 99% of the CH_4 at the inlet and 5% of the feed of the other components. The rest of the feed stream is conducted to the recycle stream. The inlet condition of the PSA unit was fixed to be at $T_\mathrm{p} = 310\,\mathrm{K}$ and $p_\mathrm{p} = 0.5\,\mathrm{MPa}$. The outlet streams of the PSA unit were fixed to have a pressure of $p_\mathrm{p}^\mathrm{out} = 0.15\,\mathrm{MPa}$.

The purge gas stream is set to 0.2% of the recycle stream.

4. Optimization

The superstructure of the methanation process is given in Fig. 3. For the inlet streams of the reactor, flash and PSA well defined states (T, p) have to be attained. This can be achieved by a general "state changer" (SC). Three different types of state changer units were defined (Fig. 3, bottom): Type 1 units realize only a pressure change of the system, type 2 and type 3 units realize a change in pressure and temperature. Compared to type 2, the type 3 state changer introduces an additional free continuous variable, the temperature prior to the compression step, which is freely optimizable.

In the case of the methanation process, the state changers SC_1 and SC_5 can be any of the available types (1, 2 or 3), as the outlet temperature is not necessarily fixed. For the

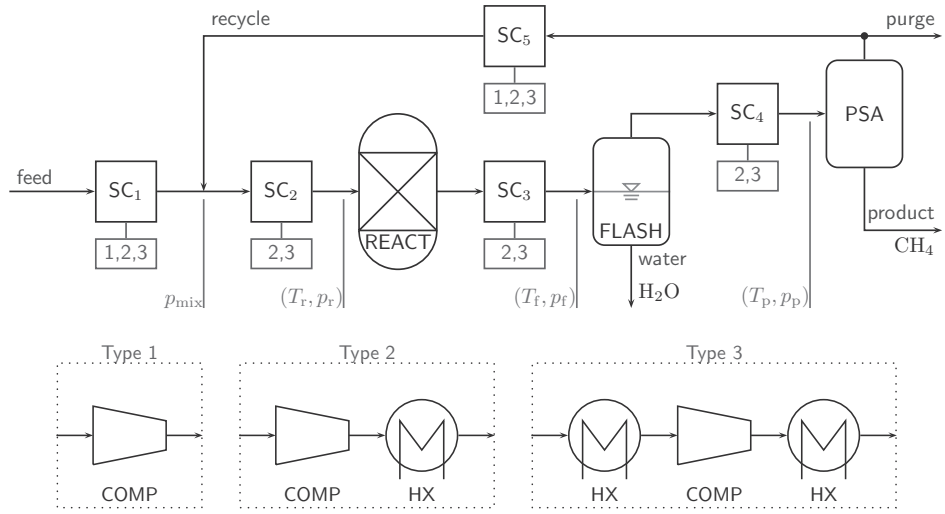

Figure 3. Superstructure of the methanation process and possible types of state changers (top). Different types of the state changers (bottom).

other state changers, the outlet temperature is fixed, because the units REACT, FLASH and PSA are defined to work in a certain state (T, p) as described above.

Each state changer SC_X has to be one of the given types $t_X \in \mathbb{T}_X$ where t_X is the type of state changer SC_X and the sets of possible state changers $\mathbb{T}_X$ are given in Fig. 3 (blue boxes). This leads to $\prod_X |\mathbb{T}_X|$ different process topologies where $|\mathbb{T}_X|$ is the cardinality of $\mathbb{T}_X$.

In general, the optimization task can be formulated as a mixed-integer nonlinear programming (MINLP) problem:

$$\min_{\{c_i\},\{t_X\}} \quad f(W, Q, \{Y_j\}) \qquad \text{s.t.} \quad c_i \in \left[c_i^{\min}, c_i^{\max}\right] \qquad t_X \in \mathbb{T}_X \tag{4}$$

where the objective function f depends on the required electrical work W of the overall process, the required heat duty Q of the process and some additional properties of interest $\{Y_j\}$, e. g. the purity of the product.

Continuous variables c_i are process conditions like temperatures and pressures.

5. Results

In the first study, the objective function includes only the required electrical energy, i. e. $f(W) = W$. The free variables for optimization were the pressure p_{mix} at the point where the feed stream and the recycle stream are mixed, the outlet temperatures $T_{\text{SC}X}$ of the state changers SC_1 and SC_5 and the intermediate temperature $T^{\star}_{\text{SC}X}$ of type 3 state changers.

Table 1. Some selected optimization results for different process topologies. The valid values of the temperatures were limited to the range $T \in [300\,\mathrm{K}, 500\,\mathrm{K}]$.

process topology (t_1,t_2,t_3,t_4,t_5)	continuous variables at optimum p_{mix} [MPa]	$T^{\star}_{\mathrm{SC1}}$ [K]	T_{SC1} [K]	$T^{\star}_{\mathrm{SC2}}$ [K]	T_{SC5} [K]	el. work / heat W [kW]	Q [kW]
(1,2,2,2,1)	0.2513	—	—	—	—	30.7	–169.7
(2,2,2,2,1)	0.3195	—	300	—	—	24.7	–164.6
(2,3,2,2,2)	0.3199	—	316	300	377	24.7	–164.5
(3,3,2,2,2)	0.3165	300	309	300	395	24.8	–164.5

The feed stream of the process was set to a CO_2:H_2 ratio of 1:4 and $9.5\,\mathrm{mol\,H_2\,h^{-1}}$ which corresponds to 1 MW power input into a electrolyzer.

Some selected results of the process optimization are given in Table 1. For a process with a minimum demand of electrical energy, the topology $(t_1,t_2,t_3,t_4,t_5) = (2,2,2,2,1)$ is a good choice.

6. Outlook

In this contribution, we initiated a superstructure based approach for process optimization with regard to the process topology. Next, this methodology will be applied to the methanol synthesis and a systematical comparison of both routes as options for chemical storage of renewable energy will be done.

A previous study already indicated that the efficiency of the overall route (electrical energy $\rightarrow$ chemical storage $\rightarrow$ electrical energy) is around 29% for methane and 18% for methanol (Zinser et al., 2011).

Integrated Biomass Power Plant and Storage for Peak Load Management

Wai Shin Ho, Haslenda Hashim*, Zarina A. Muis
Process System Engineering Centre(PROSPECT), Faculty of Chemical Engineering, Universiti Teknologi Malaysia, 81310, UTM JB, Johor, Malaysia

Abstract

This paper presents a simulation based linear programming model of a biomass power plant integrated with energy storage (ES) system for peak load demand management. The integrated biomass power plant using biomass bubbling fluidized bed technology (BBFB) with ES is then compared to a biomass power plant without ES. The results revealed that the integrated BBFB with ES can significantly increase the economics of the system from a total deficit of $195528 (without ES) to a total profit of $227072.70 (with ES) over a 20 years period. The optimum size of BBFB power plant is 140 kW, while the capacity of NaS battery is 257 kWh with a maximum discharge rate (power) of 107.0 kW.

Keywords: *Distributed Generation; Renewable Energy; Biomass; Peak Load Management; Energy Storage*

1. Introduction

Interest in distributed generation (DG) had been proliferating over the decades and Distributed generation (DG) is not new and in fact, the first grid was DG based. This scenario then changes when centralized electricity generation of fossil fuel was found to be more economical. Since then, the development of electricity grids shifted to centralized system. Due to environmental issue, consideration for DG has reemerged with renewable energy (RE) as its generation source. Nevertheless, the economics of the grid is still a major concern. Many researches had been developed to design DG systems especially for rural areas where grid connectivity is not viable. DG system is also one of the most promising ways to transform a specific community to an eco- community. For grid-connected communities, the electricity should be drawn from local power plant to minimize the loss of energy through the transmission line. Most of the researches focused on a hybrid system of RE such as solar, and wind integrated with a back-up generator [1][2]. However, in countries where biomass is found abundant, biomass alone is able to meet the energy demands. Biomass is advantageous to solar and wind due to its constant availability. Nevertheless, similar to any thermal power plant, biomass faces issues on load variation (off peak and peak period) resulting in low capacity factor which leads to higher cost of electricity. As a solution to the mentioned issue, the economics of energy storage (ES) as a tool for peak load management of a biomass power plant is studied for an existing residential community. This study is carried out by developing a simulation base linear programming model which applies the cut and branch algorithm.

2. Distributed Energy System

The amount and type of biomass resources is different at different location and therefore, in order to obtain consistent results, Malaysia is selected as the case study due to abundant biomass resource such as palm oil, rice husk and wood residue. Moreover, the Malaysian Government has been promoting RE utilization through the establishment of feed-in tariff (FIT) policy where a fixed remuneration is provided per kWh of electricity injected to the grid. In this study it is assumed that the government would consider utilizing locally generated electricity without relying on the national grid except during time of maintenances and breakdowns. Biomass bubbling fluidized bed (BBFB) technology with palm kernel shell (PKS) as the biomass fuel source is applied in this study. The main criteria for selecting this setting is due to its low cost compare to other available technology and biomass fuel [3]. For the ES device, sodium sulfur (NaS) is chosen due to its suitability as a bulk storage device and its cheap price compare to other type of batteries.

2.1. Biomass System Design

The system is designed in such that BBFB power plant is the only power generator to meet the system's energy demand while generating excess energy during off-peak period for storage. The accumulated energy in the storage will be regenerated during peak hours depending on economic constraints. The current generated from BBFB power plant is an alternating current (AC) and thus, required to be converted to direct current (DC) for storage, while the energy from storage would be reconverted to AC before delivered to the load. The configuration of the system is as shown in Fig 1.

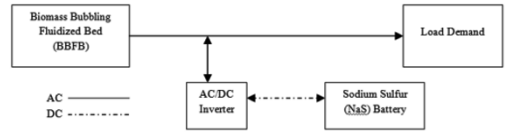

Fig. 1 Configuration of Isolated Biomass System

2.2. Data Collection

Table 1 and Table 2 shows BBFB and NaS battery specification and its cost respectively.and shows.

Table 1. BBFB power plant parameter [3].

Capital cost ($/kW)	Fixed operating and maintenance (O&M) cost ($/kW)	Variable O&M Cost ($/MWh)	Heat rate (GJ/MWh)	PKS fuel price ($/GJ)	Feed-in tariff ($/kWh)
3860.00	100.50	5.00	14.24	1.35	0.11

Table 2. NaS battery parameter [4]

Energy capacity related cost ($/kWh)	Power related cost ($/kW)	Fixed O&M cost ($/kW)	Charging and discharging efficiency (%)	Inverter efficiency (%)	Depth of discharge (%)	Battery life (yr)
346.00	173.00	23	88.3	90	80	10

The simulation based LP model is formulated based on an eco-community of 200 energy consumers with load demand as shown in Fig 2.

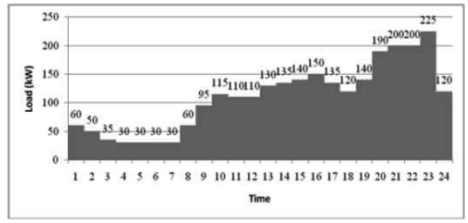

Fig 2 shows the load profile of 200 customers. [5]

3. Mathematical Model

In Malaysia, most of the RE projects are targeted for investors and as such, the objective function built in this model is to maximize the net profit of the system. The variables in this model are as shown in Table 3.

Table 3. List of Variables

Variables	Description
L^B_t	BBFB generation to meet the load at time, *t*
$L^S t$	Power from NaS battery at time, *t*
T^B_t	Total power generated at time, *t*
S^B (integer)	BBFB capacity
S^E (integer)	NaS battery energy capacity
P^E (integer)	NaS battery power
B^E_t	Power generated from BBFB for storage at time, *t*
D^B_t	Excess electricity injected to the grid
E^B_t	Accumulated energy from BBFB in NaS battery

The objective function of the integrated system is given in Eq. 1.

$$Max\ P = P_B - C_{NaS} \tag{1}$$

P_B is net profit from BBFB given by Eq. (2) and C_{NaS} is the cost of NaS battery given by Eq. (3):

$$P_B = \sum_t ((L^B_t + (L^S_t \times n^D \times n^I)) \times d \times f \times FIT) - \sum_t (T^B_t \times d \times f \times (V^B + (U^B \times H^B))) - S^B(C^B + (F^B \times f)) \tag{2}$$

t is the set of time from 1 to 24 hour, including a made-up time, 25 hour; L^B_t, BBFB generation to meet the load at time, *t*; $L^S t$, power from NaS battery at time, *t*; n^D, NaS battery discharging efficiency; n^I, AC/DC converter efficiency (90 %); *d*, amount of day in a year; *FIT*, FIT for biomass electricity generation; T^B_t, total power generated at time, *t*; V^B, BBFB variable O&M cost; U^B, PKS fuel cost; H^B, heat rate of BBFB; S^B, BBFB capacity; C^B, BBFB capital cost; F^B, BBFB fixed O&M cost; *f*, project life (20 yr). From Eq. (2), only utilized biomass energy in meeting the load is considered for remuneration, therefore, instead of the total biomass generation, the amount of direct generation to load plus the discharge of earlier stored energy from NaS battery to load is

equated in Eq. (2). Excess generated energy which is dumped or injected to the national grid in this case is not included for remuneration. This is to illustrate the condition of this case study of not relying on the national grid.

$$C_{NaS} = (S^E \times C^E \times f^{fac}) + (P^E \times PC^E \times f^{fac}) + (P^E \times F^E \times f) \quad (3)$$

S^E is the NaS battery energy capacity; C^E, NaS energy capacity related cost and BoP; P^E, NaS battery power; PC^E, NaS battery power related cost; F^E, NaS battery fixed O&M cost; f^{fac}, life factor of NaS battery life to project life given by Eq. (4**), where** f^E is the NaS battery life. The energy balance model for BBFB, NaS battery, and meeting the load on the other hand is shown in Eq. (5), Eq. (6), and Eq. (7) respectively.

$$f^{fac} = f / f^E \quad (4)$$

$$T^B_t = L^B_t + B^E_t + D^B_t \quad (5)$$

$$E^B_{t+1} = E^B_t + (B^E_t \times n^C \times n^I) - L^S_t \quad (6)$$

$$L^D_t = L^B_t + (L^S_t \times n^D \times n^I) \quad (7)$$

B^E_t is the power generated from BBFB for storage at time, t; D^B_t is excess electricity injected to the grid; E^B_t is the accumulated energy from BBFB in NaS battery; n^C, NaS battery charging efficiency; L^D_t is the load demand of the 200 customers. Several constraints are also developed for the model. To ensure the stability of the battery in a daily cycle basis, the accumulated energy is the storage at time, t = 25 (made-up) must be equal to time, t = 1 as shown in Eq. (8):

$$E^B_{t=25} = E^B_{t=1} \quad (8)$$

Constraint to prevent the accumulated energy in the battery to be more than its capacity (after considering the battery's depth of discharge, D^E) and the discharge rate of the battery to be more than its maximum discharge limit is given in Eq. (9), Eq. (10), and Eq. (12) respectively. In addition, as BBFB technologies in this study uses the steam turbine which require long response time if fluctuation were allowed during power generation. An additional constraint to force the system to generate a constant amount of power is as given in Eq. (11).

$$E^B_t \leq D^E \times S^E \quad (9)$$

$$L^S_t \leq PC^E \quad (10)$$

$$T^B_t = S^B \quad (11)$$

4. Results and Discussions

In this study, mathematical models for integrated biomass with and without energy storage are developed and coded into GAMS. To achieve optimal solution, CPLEX 12 solver which applies the cut and branch algorithm was employed. It was found that the optimum configuration of the BBFB-NaS battery system would generate a total profit of

$227072.70 over 20 years with payback period of 12.38 years. Under this configuration, the required size of BBFB power plant is 140 kW, while the capacity of NaS battery is 257 kWh with a maximum discharge rate (power) of 107.0 kW. For the system without ES, instead of profit, the total deficit calculated is $195528 while the required size of BBFB power plant is 225 kW. This indicates ES can play a significantly role to increase the economics of the system. The energy utilization profile for a) biomass system and b) integrated BBFB and NaS battery system is shown in Fig. 3. It can be seen from this figure that the excess energy generated from the system with ES is less than the system without ES. It is noted that the stored energy as shown in Fig. 3b from time 5:00 to 15:00 and from 16:00 to 19:00 will be utilized to meet the peak demand at night. This study however does not consider energy shortage during maintenances and breakdowns period. Nevertheless, it is recommended that during maintenances and breakdowns period, the electricity supply should be drawn from the national grid.

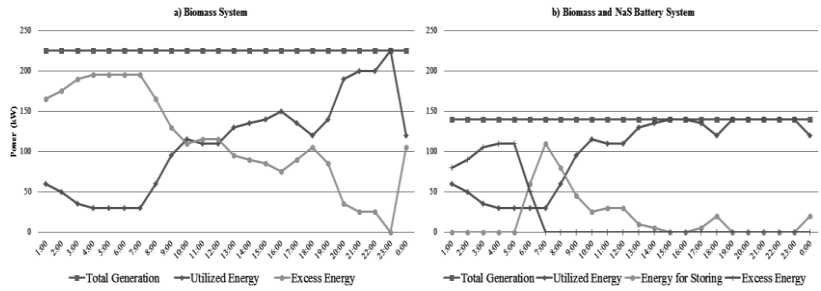

Fig. 3. Power Utilization Trend a) Biomass System b) Biomass and Sodium Sulphur Battery System

5. Conclusion

The simulation based LP model is able to determine the optimal size of integrated biomass power plant with and without ES. The optimization results convinced that ES device can indeed function as a tool for peak load demand management as well as increasing the profit gain from thermal power plant project while improving the stability and reliability of the electricity network.

An optimization procedure for retrofitting process energy systems in refineries

Bingjian Zhang, Shengyuan Wu, Qinglin Chen*

chool of Chemistry and Chemical Engineering, Key Lab of Low-carbon Chemistry & Energy Conservation of Guangdong Province, Sun Yat-Sen University, No. 135, Xingang West Road, Guangzhou, 510275, China

Abstract

An optimization procedure is proposed in this paper for total site energy systems and is applied to industrial refinery complexes based on the insight of process production and energy utilization. Firstly, all process plants in the total site are optimized to target the minimum individual utilities, where processes and HENs are improved for better energy utilization and recovery. As a result, the efficiency of energy utilization is guaranteed for a single plant. Secondly, heat integration between plants is employed to recover surplus heat, which can transfer some heat below the pinch points of supplier plants into other receiver plants to decrease utility requirements. This may not change the first step, but can reduce the cold utilities of the supplier plants and the hot utilities of the receiver plants. Thirdly, low-temperature heat recovery and utilization systems are established with considering the layout and distribution of energy sources and sinks. The recovered low-temperature heat can be used to heat storage tanks and pipelines, preheat boiler feed water, and even to be low-temperature electricity generation. Finally, steam power systems are optimized in the new condition of steam and firedamp balance in the total site. A real industrial example for total site energy optimization is taken to demonstrate the performance of the presented method, and the energy requirement decreases more than 16%.

Keywords: energy system, optimization, heat integration, energy conservation

1. Introduction

Petrochemical industries intend to transform a large amount of crude oils into gasoline, diesel and other chemical pieces to meet the need of people's life while consuming a lot of energy that includes fuels, steam, electricity, etc. China government pays attention to the energy efficiency in such energy-intensive industries. Heat exchanger networks (HENs), heat integration between plants and utility systems are deployed in the total site in order to distribute the energy resources for process operations and to get better energy utilization. Therefore, it is exposed to us how to optimize such a complex energy system for realistic application?

Process synthesis and systematical optimization are effective ways that can be applied in optimizing process energy systems for better energy efficiency and economic benefits. These methodologies and technologies are based on thermodynamics or mathematical programming, and involve heat integration (Zhao, et al. 2006; Verheyen, 2006; Ponce-Ortega, et al. 2008), utility system optimization (Kim, et al. 2001; Luo, et al. 2011), total site integration (Bagajewicz, et al. 2003; Zhang, et al. 2006), and even integration of an industrial area (Matsuda, et al. 2009).

An optimization procedure is proposed in this paper for total site energy systems and is applied to industrial refinery complexes based on the insight of production process and

energy utilization. The optimization procedure is divided into four steps from process optimization to total site integration. A real industrial example for total site energy optimization is taken to demonstrate the performance of the presented method, and the energy requirement decreases more than 16%.

2. The procedure of total site optimization

A refinery is, in general, made up of many process plants, auxiliary plants, storage tanks and utility systems to separate crude oil into specified fuel oils and chemical products. Meanwhile, there are many chemical reactions and separations in refining processes. Therefore, it is very difficult to optimize such a complex process system simultaneously for better energy efficiency. Three link model presented by Hua (2000) decomposes the complex process system into three subsystems: Energy use link, energy recovery link and energy conversion link. The three subsystems are optimized independently, and then coordinated to get a globally optimal result. The optimization procedure is shown as Fig. 1.

An optimization procedure for the energy system in a total site indicated as Fig. 2 is proposed here to extend the three link model. The optimization procedure divides the optimization procedure into four steps. Firstly, chemical reactions and separations are optimized and flowsheets are restructured to decrease the total process energy requirement E_N. Secondly, heat exchanger networks (HENs) and heat integration between processes or plants are deployed to decrease the hot or cold utility demands, in other words, increasing recycled energy E_R. Thirdly, the surplus heat below the pinch points of process plants are collected by medium streams, and then used to keep the fluids in storage tanks at predetermined temperatures or to preheat boiler feed waters in utility systems. As a result, recovered energy export E_E increases. Fourthly, steam power system is optimized to satisfy the new utility requirements of process plants, reducing energy import E_P and decreasing the requirements of primary energy sources, such as fuel oils, firedamp gas, etc. Furthermore, the energy streams saved can be transformed into high value added chemical products.

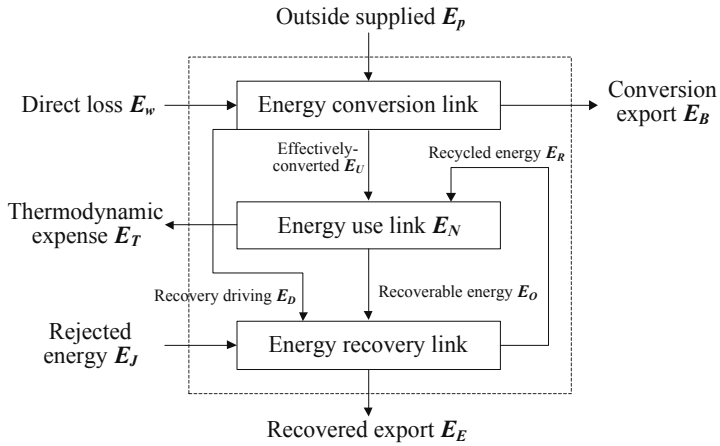

Fig. 1. A diagram of the three link model

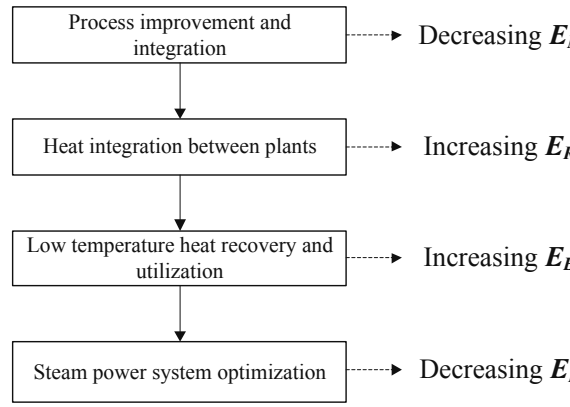

Fig. 2. An optimization procedure for process energy system

2.1. Process improvement and integration

Chemical reactions and separations are the cores of process systems indicated as Union model (Linnhoff, et al. 1982). Therefore, chemical reaction and separation improvements and process flowsheet restructure can essentially reduce the energy requirements of process system. The objective of chemical process optimization is to minimize the total process energy requirement E_N under the condition of satisfying product specifications.

$$\min E_N \tag{1}$$

$$E_N = f(d,z,x) \tag{2}$$

$$h(d,z,x) = 0 \tag{3}$$

$$g(d,z,x) \le 0 \tag{4}$$

Where d is the vector of design variables, z is the vector indicating the structure, and x is the vector of state variables. For example, over-vaporized oil in a vacuum distillation unit (VDU) can be recycled to the vacuum heater to decrease the outlet temperature of the vacuum heater when the distillate rate is kept constant, and then the heat load of the vacuum heater is decreased.

2.2. HEN optimization and heat integration between plants

The optimal chemical processes fix the boundary conditions of all hot and cold streams in plants, and then the maximum recoverable energy E_O is determined. Therefore, HEN optimization can be done in a process plant to reduce the utility requirements, and heat integration between plants can be employed to decrease the cold utility of supply plant and the hot utility of receive plant. More detailed heat integration between plants can be found in the open literatures (Morar, et al. 2010; Zhang, et al. 2011).

2.3. Low-temperature heat recovery and utilization

On the one hand, there is often some surplus heat at a relative low temperature after heat integration between or in process plants. On the other hand, boiler feed water in steam power system and temperature keeping for storage tanks are low-temperature heat sinks in a refinery. Additionally, there is a long distance between utility facilities and process plants. Therefore, a low-temperature heat recovery and utilization system can be introduced after process improvements and heat integration for process plants. A medium stream is employed in the system to collect the surplus heat in process plants

and then to transfer it into storage tank areas or into steam power system. The low-temperature heat recovery and utilization system can be simplified as Fig. 3.

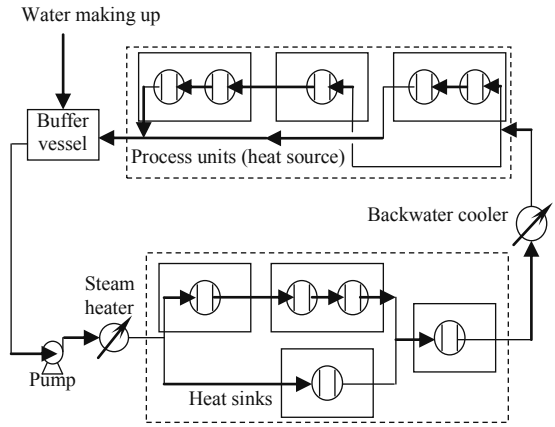

Fig. 3. The simplified flowsheet of low-temperature heat recovery and utilization system

2.4. Utility balance and optimization

Energy savings in three former steps should be finally reflected in decreasing the energy input from outside the system. Outside supplied energy E_P feeds into energy conversion link, so steam power system is the final agent of energy savings for total site energy optimization.

There are new balances of energy streams in a total site when process improvements and heat integration have been done for process plants, and steam power system should be optimized to adapt the new utility requirements. Steam power system has been widely investigated in last several decades, and these open technologies can be used to optimize steam power systems.

3. Example

A 5 Mt/a refinery is taken out as an example to demonstrate the proposed procedure for optimizing the energy system in the total site. The refinery includes a crude distillation unit (CDU), a fluid catalytic cracking unit (FCCU), a hydrotreating unit (HU) and a steam power system.

According to the proposed optimization procedure, in the first step, process improvements and flowsheet reconstruction are motivated to decrease E_N, The options involve optimizing the pumparound heat removals in atmospheric and vacuum towers, selecting high efficiency packing to reduce the pressure drop and decreasing the over-vaporizing rate in the vacuum tower, transferring the cold high-pressure segregator into hot high-pressure segregator in HU. In the second step, heat integration is investigated. The retrofit measures involve hot discharge/feed between CDU and FCCU and transferring the recycle slurry oil in FCCU into CDU to preheat the crude oil. In the third step, a recycle medium water system is set up to collect waste heat in CDU and FCCU and to use it preheating the boiler feed water for the steam power system. In the forth step, the steam power system is optimized to meet the new requirements of steam and fuel gas in the total site. The retrofit results are shown in Table 1. The dynamic

capital pay-off time is less than four years, and the specific refining energy requirement decreases from 81.0 to 68.3 kgEO/t.

Table 1 The economic evaluation for the retrofit program of energy system.

Item		Value
Energy requirement before retrofit / (kgEO/t)		81.0
Energy requirement after retrofit / (kgEO/t)		68.3
Gross investment / (10^6 RMB)		134.7
Annual profit / (10^6 RMB)	Before-tax	94.3
	After-tax	65.4
Internal rate of return / %	Before-tax	82.5
	After-tax	55.3
Capital pay-off time / year	Static	2.9
	Dynamic	3.4

4. Conclusions

Energy system in a refinery can be divided into energy conversion, utilization and recovery subsystems. In order to get a profitable retrofit program for the total energy system, an optimization procedure is presented and motivated for industrial applications. The optimization procedure involves four steps those are outlined based on the insight of energy utilization in refining processes. The application in the example indicates that the proposed optimization procedure is engineering-practical and can be carried out to retrofit the energy system to get better economic benefits.

Abstract

A hierarchical optimization structure is proposed for PAFC Stack. The performance of a PAFC stack is mapped with an easy to implement, low CPU usage consuming reduced order model, used as constraint equation block for the optimizer. The model is validated using different sets of experimental polarization data. Effect of variation of operating variables like hydrogen flow rate, humidifier and cell temperature on the load current versus voltage and power profiles are simulated. Finally, an economic optimization of a PAFC stack is carried out to get the optimum set of operating variables.
Keywords: PAFC, Optimization, Reduced order Model, Electrolyte Concentration

1. INTRODUCTION

In the wake of increasing energy demands and environmental concerns, fuel cells offer an innovative alternative to current power sources since they are highly efficient with renewable fuels and environment friendly. A fuel cell is an electrochemical device that converts chemical energy of a fuel directly into electricity. Of the several classes of hydrogen fuel cells, Phosphoric Acid Fuel Cells (PAFCs) represent one of the most mature technologies. Mathematical modeling and simulations are essential tools for the performance mapping of fuel cells and stacks over varying ranges of operating conditions like temperatures, partial pressures, humidity, flow rates etc. The major application of a mathematical model is online optimization for maximum utilization of the available resources for maximum profitability. Though hierarchical optimization has been used for industrial applications (Ganguly et. al, 1992; Basak et al, 2002 etc), hierarchical scheme for PAFC optimization is hardly available in international literature. A novel hierarchical scheme with Successive Quadratic programming based optimization is proposed for PAFC stack operation in the present work.

2. PAFC – WORKING PRINCIPLE

A phosphoric acid fuel cell (PAFC) is composed of two porous gas diffusion electrodes, namely cathode and anode

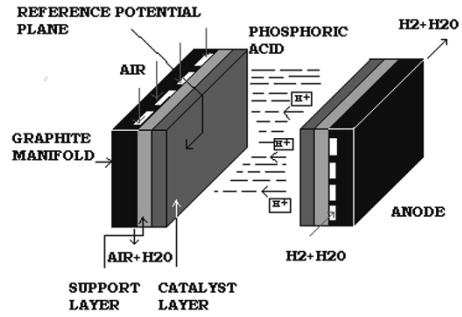

Fig 1. Schematic of a PAFC

juxtaposed against a porous electrolyte matrix. The gas diffusion electrodes are composed of a porous substrate (carbon or cloth) facing the gas feed and a reactive catalyst layer consisting of platinized fine carbon powder, facing the electrolyte. At the anode, hydrogen ionizes to H^+ and migrates towards the cathode to combine with oxygen, forming water. The free energy of reaction is converted to electrical energy, which is available in the form of a potential difference developed between the two electrodes. The reactions at anode and cathode are as follows:

Anode: $H_2 = 2H^+ + 2e^-$ Cathode: $½O_2 + 2H^+ + 2e^- = H_2O$

3. HIERARCHICAL OPTIMIZER FOR PAFC STACK

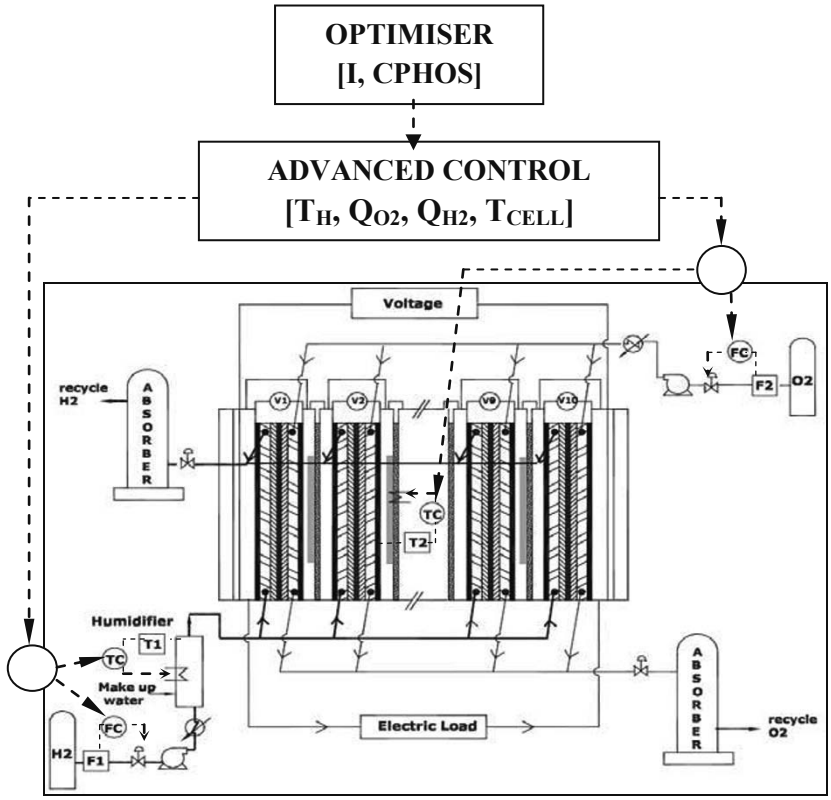

Fig 2. Hierarchical Optimization Structure for PAFC Stack

A stack consists of a number of fuel cells connected in parallel across which a given electrical load is applied. Hydrogen supplied is humidified in order to prevent drying of electrolyte by evaporation of water. In place of oxygen, air can also be used for oxidation.

4. STRUCTURAL BLOCKS FOR OPTIMIZATION

4.1 CONSTRAINT EQUATION BLOCK FOR OPTIMIZATION

The constraint equation block for optimization comprises of variable bounds, computed variable blocks, single cell simulation block and inferential prediction block. Computed variable block computes and maps the input variables to simulation block from the experimental raw data. Single cell simulation block computes the current versus individual cathode, anode overpotential, moisture transport rates from cathode and anode sides and more importantly the electrolyte concentration for each cell of the stack. Finally the inferential block computes the output variables from PAFC stack using the simulation output data from all the individual cells.

The simulation block consists of a cathode model and an anode model. For a particular overpotential, the cathode model calculates the current density and water flux. For this calculated current density, the anode model calculates the anode overpotential and anode side water flux. From a moisture balance of anode and cathode water flux, the concentration of phosphoric acid electrolyte are calculated and updated. Using this new value of electrolyte concentration, the computation is repeated until concentration of two successive steps are equal.

This steady-state model uses a one dimensional integrated cathode-electrolyte-anode model as the base model. Gas diffusion resistance and Tafel kinetics using flooded agglomerate approach for catalyst layer is considered for cathode modeling. Gas diffusion through support layer and through liquid electrolyte encapsulation along with Nernst equation for anode overpotential is used for anode modeling. Overall moisture balance over the cathode-electrolyte-anode assembly is used to obtain steady state electrolyte concentration. Finally, space marching is carried out along the direction of gas flow to take into account the variation of partial pressure and flow rate of inlet gases. Space marching of a 1-D base model instead of solving a full-fledged 2-D model considerably reduces the computational load. Current versus total over potential, rate of moisture transport and steady state electrolyte (phosphoric acid) concentration are obtained as model output. The detailed model equation development for single cell PAFC is presented in Kargupta et al (2012).

4.2 OBJECTIVE FUNCTION

The power generated by the fuel cell stack is a function of load current (I), hydrogen and oxygen flowrates (Q_{H2}, Q_{O2}), cell temperature (T_{cell}), humidity of inlet hydrogen stream and electrolyte concentration ($Cphos$), Humidity of inlet hydrogen is a function of humidifier temperature (Th), hydrogen flow rate. In phosphoric acid fuel cell the electrolyte, (phosphoric acid) concentration determines the proton conductivity and thus the power generation. For normal operation of fuel cell the electrolyte concentration must be controlled at optimal value. Drying of electrolyte due to moisture evaporation and excess dilution of electrolyte (due to low cell temperature/high humidifier temperature) drastically decreases the power generation. In the present work, a steady state optimization scheme for PAFC stack has been proposed which can be utilized in the hierarchical structure (Fig. 2). At the top most level, the process optimization variables considered, are the load current and electrolyte concentration. The set points of variables $Qh2$,$Qo2$,Th and TFC in the advanced control level are determined by the I and $Cphos$. The disturbance variables are considered in the lower most frontend control level. The present paper deals with the steady state optimization layer only.

The objective function is to maximise the profit which can be expressed mathematically as follows:

Maximize $\varphi = P_1 - P_2 - P_3 - P_4$

with respect to the operating variables where φ is the profit based objective function. P_1 is the selling price of power generated by stack

P_1 = (power x price x wt x flag) = function of (I, cphos)

where, electricity generated is in terms of kW-min, price is the selling price of power per kW-min, wt is the weighting of this term in the objective function and flag is a parameter whose value depends on the zone of operation of fuel cell. The purpose of flag is to prevent the optimum solution from being in the undesirable operation zones, namely acid drying and flooding. In some cases penalty is introduced in terms of flag. Acid drying may be caused by low humidity of inlet hydrogen stream, very low hydrogen flow rate whereas flooding is caused by high hydrogen flow rates, 1ow fuel cell temperature etc.

P_2 is the cost price of raw materials consumed defined as follows

$P_2 = Q_{hyd}$-consumed *C_{hyd}*wt_i + Qoxygen-reacted*C_{ox}*wt_j = function of (I)

where, C_{hyd} and C_{ox} are cost of hydrogen and oxygen respectively per litre, *wti* and *wtj* are the weight functions. For the unutilized fuel and oxygen a loss function is defined:

$P_3 = Q_{hyd}$-excess *C_{lh2}*wt_i + Qoxygen-reacted*C_{lo2}*wt_j = function of (Qh2,Qo2,I)= function of (I,Cphos)

P_4 is the operating cost which includes the fuel cell heater cost, compressor cost and humidifier heat load.

P_4 = price * [(H*wt_1) + ($H_{humidifier}$*wt_2) + ($W_{compressor}$*wt_3)]

where H is the heater plate input, $H_{humidifier}$ is the heat input to humidifier and $W_{compressor}$ is the power input to gas compressor in terms of kW-min and price of power per kW-min. ,

4.3. OPTIMIZATION METHODOLOGY: Nonlinear programming based steady state optimization is carried out using Sequential Quadratic Programming (SQP) algorithm with quasi newton line search to enhance convergence. The dependant variables Y, namely power, ***Q_{hyd}-consumed, Qoxygen-reacted, Q_{hyd}-excess, Qoxygen-reacted, $H_{humidifier}$*** required in the objective function are found as function of optimization variables X, namely current and Cphos. The computed variable equations obtained using the model act as the equality constraints. Variables bounds are used as inequality constraints. The converged solution depicts the optimum variables values.

5. OPTIMIZATION RESULTS

5.1. CONSTRAINT BLOCK VALIDATION WITH EXPERIMENTAL RESULTS:

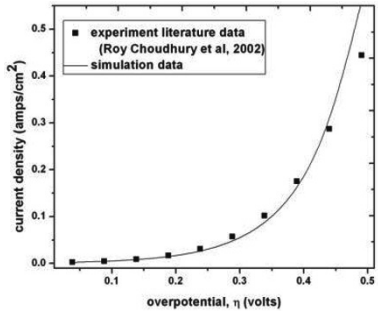

Fig 3. Comparison of Polarization curves.

To validate the model, simulated current density vs. overpotential is plotted in fig 3 and compared to published experimental data by Roy Choudhury et al. (2002). The values match quite well and as expected current density increases rapidly as the overpotential increases since the reaction increases exponentially with respect to the overpotential.

5.2. EFFECT OF OPERATING VARIABLES:

Figs. 4 and 5 show the effect of hydrogen flowrate and humidifier temperature on the electrolyte concentration.

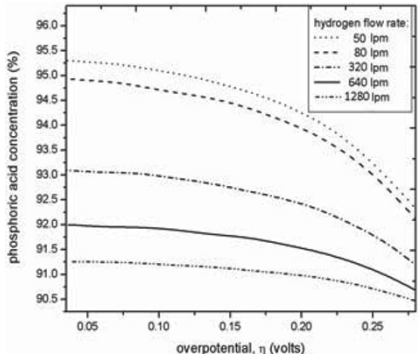

Fig 4 Effect of hydrogen flowrate on electrolyte. concentration

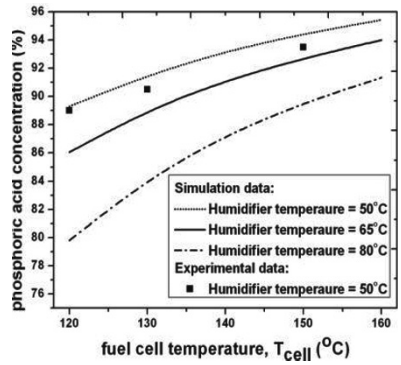

Fig 5. Effect of humidifier temperature on electrolyte concentration

5.2 *CONTOURS FOR ECONOMIC OPTIMIZATION*

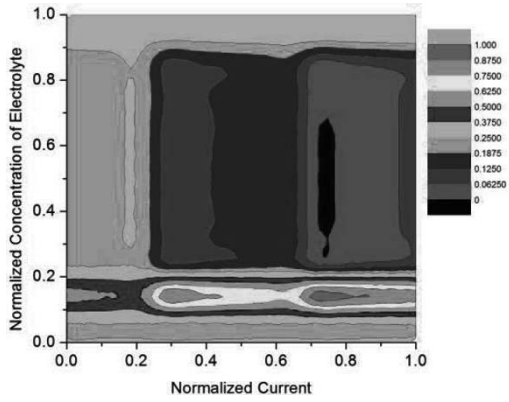

Fig 6. Contour plot of objective function

Fig. 6 shows the contour plot of the negative of objective function (cost function to be minimized) with respect to normalized current and phosphoric acid concentration. At the optimum value of current for a set of electrolyte concentration, the cost function reaches the minima.

CONCLUSIONS

A hierarchical optimization structure is proposed for PAFC Stack. The profit is maximized with respect to the optimizer variables namely load current and electrolyte concentration. A reduced order model validated with experimental data is used as the constraint block of the optimizer. The optimizer shows promising potential for real-life industrial applications..

Platform development for studying integrated energy conversion processes: Application to a power plant process with CO_2 capture

Laurence Tock,a * François Maréchal,a
a Industrial Energy Systems Laboratory, EPFL, Lausanne, Switzerland

Abstract

This paper presents the development of a platform for studying, designing and optimizing complex integrated energy systems. Technology models representing the physical behavior are separated from thermo-economic analysis and multi-objective optimization including energy integration, economic evaluation and environmental impact assessment. Through a Matlab based platform, structured data is transfered between different models. The advantage of dissociating the technology models from the analysis models is that process unit models developed with different software can be assembled in a superstructure for subsequent large processes design and optimization. The approach is illustrated by the thermo-economic modeling and optimization of a power plant with CO_2 capture.

Keywords: Thermo-economic modeling, Process design, Multi-objective optimization, Power plant, CO_2 capture

1. Introduction

In the context of climate change mitigation and energy supply, the development of competitive power plants with CO_2 capture is challenging. To design such complex integrated energy conversion systems taking into account energetic, economic and environmental considerations a systematic approach is developed. The approach relies on previous developments presented in Bolliger et al. (2009, 2010), Gassner and Maréchal (2009) and Gerber et al. (2011). Bolliger et al. first presented a generic approach to analyze energy conversion systems by separating the process unit models from the data needed to model the energy and mass integration in the system. Following this approach, models can be assembled in large superstructures from which system configurations can be extracted and optimized systematically with regard to competitive objectives. Dissociating system models from the system design methods is the main advantage compared to other platforms such as DOME (Pahng et al. (1998)) and CAPE-OPEN (Dickinson (2008)) dealing essentially with the flowsheeting and requiring an explicit definition of the interconnections.

This project is motivated by the need of developing a flexible tool for the conceptual process design combining thermodynamic analysis, energy integration, performance evaluation and multi-objective optimization strategies. Such a platform is particularly useful when studying the design of energy conversion systems, like power plants with CO_2 capture where the quality of the energy integration is a key factor defining the system's efficiency.

*laurence.tock@epfl.ch

2. Methodology

The process design methodology combines process modeling using established flowsheeting tools and process integration models in a multi-objective optimization framework as explained in Gassner and Maréchal (2009). The main features of the methodology are summarized in Figure 1. Chemical and physical models of process units are used to generate the heat transfer requirement of each building block of the process superstructure. The energy-integration model optimizing the heat recovery in the system and the combined heat and power production by applying the pinch analysis concepts is used to calculate the best integration of the process units. The optimal solution is calculated by minimizing the operating cost using a linear programming model as described in Maréchal and Kalitventzeff (1998). Knowing the flows and operating conditions in the selected units of the energy system, the size and equipment cost are estimated in order to calculate the economic and environmental performances of the system. The trade-off between competing performance indicators is assessed by sensitivity analysis and multi-objective optimization defining the optimal values of the decision variables of the system design. The platform consists hence of different layers: the model, the computation type (optimization, sensitivity analysis, one run) and the results extraction.

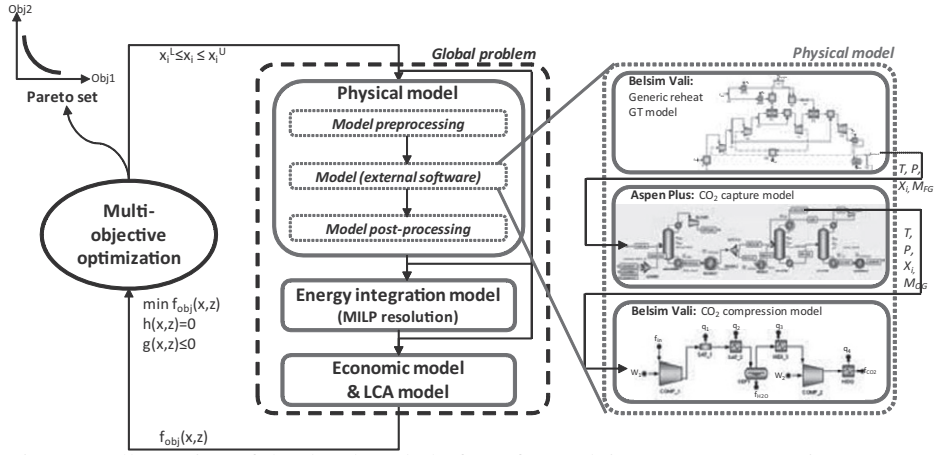

Figure 1: Illustration of the developed platform for studying energy conversion systems

2.1. Physical model

Process models are developed within specially tailored modeling languages using numerical solvers to solve the set of equations describing the thermo-physical and chemical conversion operations of the technology for a given set of decision variables and unit model parameters. Each model follows this calling sequence: the pre-processing phase selects the process model, collects necessary parameters and transfers the decision variables to the model, the simulation phase calculates the process unit using an external flowsheeting software and the post-processing phase extracts from the simulation results the data needed to define the unit interface with the rest of the process. Since each model is organized as an input (decision variables) -output entity, the internal mathematical formulation appears as a black box for the process synthesis model. The communication between different models, the calculation sequence and the process synthesis model set-up is organized in a Matlab code.

2.2. Process synthesis and optimization

From the physical model the platform extracts the data required for the synthesis methods such as the hot and cold streams for the energy integration, the size, the material and the pressure and temperature for the cost estimation and the data required for the life cycle inventory. Aggregating cost and/or environmental impact allows to calculate the performance indicators used as objective function in the optimization. Each process unit carries decision variables that are identified by degree of freedom analysis and whose value will be fixed by optimization. Combined with integer decision variables related to the technology choice (unit existence) and the interconnections, the problem becomes of a mixed integer non linear programming and differentiable problem that is solved with an evolutionary multi-objective optimization algorithm (Molyneaux et al. (2010)). The use of an evolutionary algorithm makes the approach less sensitive to non-convergence problems and the proper definition of the decision variables allows to stabilize the robustness of the model. During the Pareto font generation infeasible solutions are avoided through heuristics embedded in the sizing and cost estimation models.

3. Application: Power plant with CO_2 capture

To illustrate the approach, the integration of CO_2 capture in power plants is studied. Multi-objective optimization is performed to assess the trade-offs between investment and CO_2 emissions. Figure 2 presents the superstructure of different CO_2 capture concepts. It is focused on the study of the potential power plant performance improvement with CO_2 capture by flue gas recirculation (FGR).

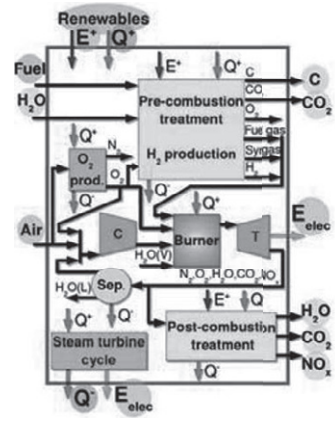

Figure 2: Conceptual superstructure of power plants with CO_2 capture

Process description: The studied process is a natural gas combined cycle with flue gas recirculation and CO_2 capture. The power plant and the CO_2 capture and compression are modeled with different flowsheeting software (Figure 1), while the optimal steam network integration is defined in the energy integration model as explained in Girardin et al. (2009).

Power plant model: The natural gas reheat gas turbine model is developed with the *Belsim-Vali* software. To address the flame stability concerns at high FGR, syngas can be injected. The syngas production is modeled by a high temperature oxygen separation membrane autothermal reforming reactor.

CO_2 capture model: The CO_2 generated in the combustion is separated from the N_2 and excess O_2 contained in the exhaust gas by chemical absorption with monoethanolamine

(MEA). The flowsheet of the CO_2 capture process is described in detail in Bernier et al. (2010). The model is based on the Aspen-Plus rate-based model adapted from the default model available from *AspenTech*. A CO_2 purity over 98%wt is targeted. The CO_2 capture rate is defined by the columns design and the operating conditions. CO_2 compression to 110[bar] for subsequent CO_2 transport and storage is modeled separately in *Belsim-Vali*. The connection between the different models is done by the material streams characteristics, namely composition, massflow, temperature and pressure (Figure 1). Table 1 summarizes the decision variables with their variation ranges. Based on the developed simulation models, the hot and the cold streams are computed for subsequent process integration and the equipment sizes are calculated for cost estimation.

Table 1: Decision variables and feasible range for optimization.

Operating parameter	Range	Operating parameter	Range
FG recirculation [-]	[0-0.56]		
ATR temperature [K]	[1050-1300]	S/C [-]	[1.5-4]
Lean solvent CO_2 loading [kmol/kmol]	[0.18-0.25]	Split fraction [-]	[0-0.7]
Rich solvent CO_2 loading [kmol/kmol]	[0.4-0.5]	Nb stages absorber	[10-17]
Rich solvent pre-heat T [^oC]	[95-105]	Nb stages HP stripper	[8-15]
Rich solvent re-heat T [^oC]	[115-125]	Nb stages LP stripper	[6-10]
LP stripper pressure [bar]	[1.7-2.1]	Absorber diameter [m]	[6-12]
HP / LP pressure ratio [-]	[1-1.5]	HP stripper diameter [m]	[3-6]
MEA % in solvent [-]	[0.3-0.35]	LP stripper diameter [m]	[2-5]
Absorber steam out [kg_{H2O}/t_{FG}]	[306-309.5]		

3.1. Optimal process performance analysis

The energy and economic cost of capturing CO_2 and the impact of CO_2 recirculation on the compressors, turbines, combustion, CO_2 capture and the steam network is assessed. The performance is expressed by the energy efficiency, the electricity production cost, the CO_2 capture rate and the CO_2 avoidance cost $\frac{COE_{CC}-COE_{ref}}{CO_{2,emit,ref}-CO_{2,emit,CC}}$ $\left[\frac{\$/MWh_e}{t_{CO2}/MWh_e}\right]$. Sensitivity analysis have revealed that FGR does not considerably impact the process efficiency but improves the economics of CO_2 capture by increasing the CO_2 concentration in the flue gas and reducing therefore the CO_2 capture cost as reported in Table 2. The multi-objective optimization minimizing the electricity production cost and maximizing the CO_2 capture rate with regard to the decision variables in Table 1, reveals the trade-off between the CO_2 capture rate and the electricity production cost (COE). This is explained by the reduced electricity output due to the energy demand for solvent regeneration and CO_2 compression, and the increased capital cost for the capture equipment. CO_2 capture with 50% FGR reduces the efficiency by around 8% and increases the electricity production cost up to 20% leading to CO_2 avoidance cost in the range of 47\$/$t_{CO2,avoided}$ with a natural gas price of 35\$/MWh_{NG}.

Table 2: Performance results (natural gas price 35\$/MWh_{NG}, operation 8000h/y)

	no CO_2 capture		85% CO_2 capture	
FGR [%]	0	50	0	50
ε [%]	58.88	58.07	49.89	50.04
$CO_{2,emitted}$ [kg/MWh_e]	379	359	64	47
Investment [\$/kW_e]	588	589	949	900
COE [\$/MWh_e]	69.4	69.7	86	84.9
\$/$t_{CO2,avoided}$	-	-	52.5	46.7

4. Conclusion

A Matlab based platform for studying, designing and optimizing complex integrated energy systems is presented. The main goal is to have a flexible tool for the conceptual process design combining flowsheeting models using commercial packages, energy integration, performance evaluation (economic and environmental) and multi-objective optimization strategies. In the proposed approach physical models are separated from the design and integration methods. A key feature is the possibility to connect process unit models developed with different software. The developed platform is applied to study the thermo-economic and environmental impacts of the integration of a CO_2 capture unit in a gas turbine combined cycle.

Abstract

Despite a number of studies of a microgrid, robust optimization of a microgrid has not been studied yet. This is critical to a microgrid because it has lots of uncertainties concerning main grid failure, power quality issues, estimates of demand, energy price, regulation change, etc. It is therefore of importance to study and develop robust optimization strategies that take the uncertainty into account at planning a microgrid. The current study aims at developing a robust optimization model for a microgrid which provides set of robust solutions and decision-making procedure for a best solution. The model enables us to consider various uncertainties including energy price, regulation change, and estimates of demand using scenario based approach. The proposed model is validated with Taichung Industrial Park in Taiwan.

Keywords: Microgrid, Robust Optimization, Taichung Industrial Park

1. Introduction

Nowadays, there is no argument that global climate change is one of most serious global issues that we face with. Among many factors, the electricity sector is a major source of carbon dioxide (green house gas) emissions that contribute to global climate change. Switching a substantial portion of electricity generating capacity away from fossil fuels to renewable energy technologies could have a significant effect in reducing greenhouse gases. In addition, increasing frequency of natural disasters put forward the flexibility and independence of electricity generation from the central generation. In this context, a "microgrid," a local generation of heat and electricity, with renewable energy resources is considered as one of the most promising options to provide a more secure, clean, and efficient energy supply.

There have been many researches on a microgrid regarding autonomous operations (Katiraei et al., 2005; Lopes et al., 2006), control schemes (Barsali et al., 2002; Piagi & Lasseter, 2006), scheduling (Morais et al., 2010), planning (Sayyaadi, 2009 ; Gholap & Khan, 2007; Gebreslassie et al., 2009; Aki et al., 2005; Alarcon-Rodriguez et al., 2010; Ren et al., 2010), etc. However, robust optimization of a microgrid planning has not been studied yet although a microgrid itself has lots of uncertainties concerning main grid failure, power quality issues, estimates of demand, energy price, regulation change, etc. Thus this study aims at developing robust optimization model that take the uncertainty the uncertainty into account at planning utilizing robustness measures.

There has been countless number of researches regarding robust optimization in the field of process engineering. Among them, Kang et al.(2012) propose to consider robustness separately depending on the nature of a variable such as scenario-independent variables, scenario-dependent technical variables (e.g., temperature, pressure, flow rate, liquid holdup, etc.), and scenario-dependent monetary or economic variables (e.g., cost, profit, production yield, etc.). The current study applies the robust optimization model proposed by Kang et al.(2012), a comprehensive robust optimization model which considers both economic and technical robustness together with decision making process. The proposed model was applied to the industrial example, Taichung Industrial Park in Taiwan.

2. Proposed Microgrid Model

The proposed microgrid model produces electricity from solar panels, wind turbine, incineration of municipal solid waste (MSW), internal combustion engine, fuel cells and microturbine (Figure 1). Trigeneration, where the waste heat from electricity production used for heating and cooling is also considered for applicable sources. Excess electricity will be stored in the battery and/or sold to the national grid while the fuels used are natural gas, hydrogen and biofuel. It is assumed that it is a smart microgrid whereby the controller allocates the nearest source to the nearest load.

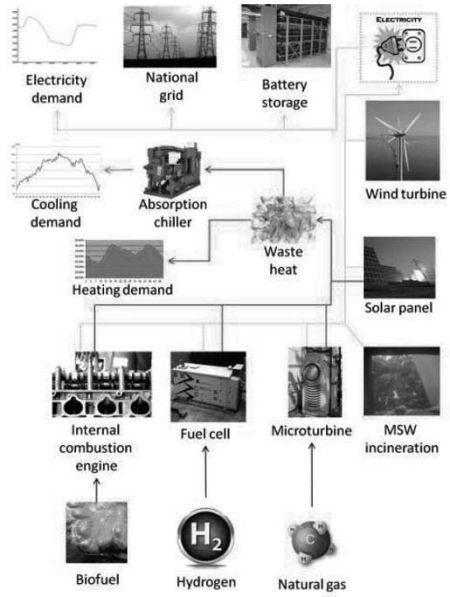

Figure 1. Scehmatic Diagram of the Microgrid

The proposed model employs possible scenarios for prices and demand of electricity concerning uncertainties. The objective is to generate the set of robust alternatives which consider both cost with minimal reliance on the national grid and carbon generated. Thus, three different objective functions will be considered in this paper namely economic robustness, technical robustness, and expected cost.

$$\min_{\mathbf{x},y_1,\cdots,y_N} (U_E(\mathbf{C}), U_{WC}(\mathbf{C}), U_T(\mathbf{y})) \tag{1}$$

where $U_E(\mathbf{C})$ is expected cost, $U_{WC}(\mathbf{C})$ is the worst-case cost of scenario, and $U_T(\mathbf{y})$ is the technical robustness which is the half interval of a technical variable. In principle, there can be many technical robustness functions depending on the number of scenario-dependent technical variables considered in the robust optimization. In this model, we consider the amount of carbon as a technical variable to consider technical robustness. Thus, the objective functions in Equation (1) are expressed as follows:

$$\text{Economic Robustness: } U_{WC}(\mathbf{C}) = \max\{C_s | s = 1, \cdots, N\} \tag{2}$$

where

$$\begin{aligned} C_s = {} & P_{\mathrm{BF}s} * Biofuel_s + P_{\mathrm{H2}s} * Hydrogen_s + P_{\mathrm{NG}s} * NGas_s + \\ & Penalty * \sum_t BuyElecN_{t,s} + Solar_s * ElectricityS_s + \\ & Wind_s * ElectricityW_s + MSW_s + ElectricityM_s \end{aligned} \tag{3}$$

$$\text{Technical Robustness: } U_T(Carbon) = \frac{1}{2}\left(\max_s Carbon_s - \min_s Carbon_s\right) \tag{4}$$

where

$$Carbon_s = \sum_i \sum_t Carbon_{i,t,s} + CarbonSolar_{t,s} + CarbonWind_{t,s} \tag{5}$$

$$\text{Expected Cost: } U_E(\mathbf{C}) = \sum_s p_s C_s \tag{6}$$

We should note that both expected cost and worst case cost of scenario have the same monetary unit and similar range while the technical robustness might have quite different unit and range. It sometimes requires to adjust the range of technical robustness according that of expected cost to implement multiobjective optimization.

The model utilizes predicted demand for electricity and incineration of MSW (assuming that 1% of MSW is incinerated at Taichung Industrial Park and an equal amount of MSW is burnt per day). Regarding to the electricity from solar and wind energy, it will be different depending on the situation including the amount of sun, velocity of wind, and pricing of input materials, expressed as scenarios. The proposed model ensures meeting local demand for electricity, heating and cooling and diversity of the sources of trigeneration with preventing idling of sources. Also, battery has enough power stored to handle power spikes, cannot charge and discharge at the same time and cannot discharge more than the amount stored. Environmental concerns are considered with carbon credits to satisfy regulations.

3. Taichung Industrial Park, Taiwan

In June 2009 Taiwan finally passed its Renewable Energy Development Act, the key legislative framework that is designed to achieve a 16% share of installed capacity for renewables by 2025 against an estimated 8% (dominated by hydropower) in 2010, according to figures from Taiwan's Bureau of Energy, part of its Ministry of Economic Affairs. This has become a key obstacle for an industrial complex, in which the competitive of firms heavily relies on operation efficiency, that is, cheap operating cost. Thus the current study attempts to apply the robust optimization model of a microgrid to Taichung Industrial Park, one of major industrial complex in Taiwan, as a preliminary step for realizing cleaner electricity generation.

The proposed layout of the microgrid for Taichung Industrial Park is described in Figure 2. The wind turbines are located at the south-west in order to capture the winds blowing from sea and not to be obstructed by any buildings. Since Taichung has relatively strong sun all year around with less raining and strong wind, this place can be a good candidate to utilize solar and wind energy efficiently.
The proposed model assumes one day with possible scenarios with a different portion of energy produced by renewable energies. Table 1 describes the hypothesized data.

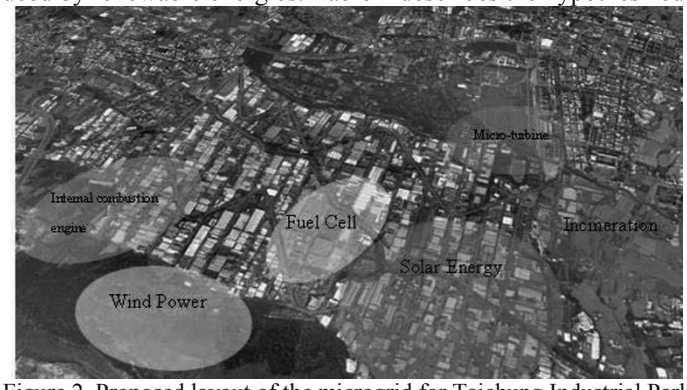

Figure 2. Proposed layout of the microgrid for Taichung Industrial Park

Table 1. Comparison of four scenarios

	Scenario 1	Scenario 2	Scenario 3	Scenario 4
Probability	0.2	0.3	0.3	0.2
P_{BF} (USD/kg)	0.2	0.23	0.26	0.3
P_{H2} (USD/MJ)	0.336	0.37	0.4	0.43
P_{NG} (USD/kg)	0.275	0.3	0.33	0.37
Renewable portion (<=)	20%	30%	40%	50%

4. Results and Conclusion

Figure 3 shows the set of robust alternatives with applying the microgrid model to Taichung Industrial Park in Taiwan attained from the robust optimization model proposed.

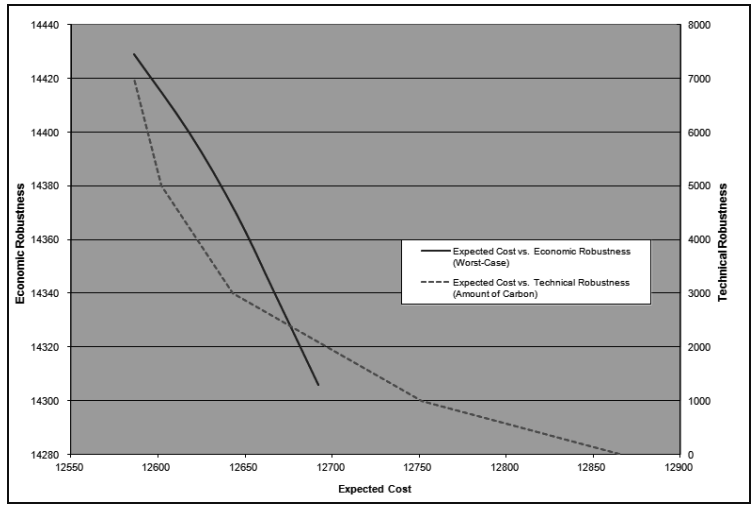

Figure 3. Ranges of robust optimization objectives

Pareto curves show trade-off relationship between expected cost and worst scenario cost (economic robustness) and expected cost and environmental regulation (technical robustness). The results describe that 1about 1% of reduction in worst scenario cost can be achieved by increasing expected cost by 0.1% while 5.5% reduction in technical robustness can be obtained by increasing expected cost by 2.2%. This implies that under the microgrid proposed, reducing technical variability (i.e., reducing the difference in the amount of carbon generated) among scenarios appears requiring more increment in expected cost than reducing economic variability (i.e., reducing worst-case scenario cost). This means that it is more expensive to keep the consistent level of carbon generated under price uncertainty. It calls for the careful consideration to exercise environmental regulation on the industrial complex like Taichung industrial park, in which the competitiveness of firms heavily relies on cost competitiveness.

The current study proposes the robust optimization model for microgrid app

The current study shows how to generate set of robust alternatives with uncertainty in the microgrid. Although limitations exist (e.g. considering limited number of uncertain parameters or using definite probability information), the results obtained can be helpful for planning a microgrid both for economic and technical consideration.

Abstract

Quantitative supply chain modelling has contributed substantially in fields such as automotive, logistic, hardware, etc. However, these methods and optimization have not been employed widely in the food industry despite all the potential benefits they may bring to this sector. The reason is integration of quantitative supply chain models into food industry brings difficulties into the optimisation approaches. The objective of this work is to develop a supply chain model for the food industry based on the relationships between raw material quality, processing conditions and final product quality and customer satisfaction. Moreover, based on the developed model, we have determined key factors in the whole chain that are most likely to affect customer satisfaction and consequently overall demand. Optimum conditions to minimize overall cost and energy consumption have been determined. New methodology has been developed that simplifies and enables the model to find the optimum processing conditions to obtain maximum quality across all quality indicators with minimum cost and energy usage by developing the interrelationships between quality and processing conditions.
Keywords: supply chain management, quality modelling, mixed-integer linear programming, food processing.

1. Introduction

In the FMCG (Fast Moving Consumer Goods) sector the product improvement process is based on fundamental research and development, which is the key factor for the customer satisfaction. Hence a new methodology is developed from time to time to improve the existing product and services, and parallel to this the process is controlled to reduce the cost of the production. Supply chain management is the research area that develops a technique, which finds the bottleneck and optimizes all the steps from supplier to distribution. The supply chain is a series of logistic internal and external activities between companies to increase the efficiency by sharing information between entities to gain customer satisfaction at the lowest possible costing (Shah, 2005).
Integrating the quality and energy control models and food supply chain together would bring difficulties to the system. The reason is the complication of quantifying the food quality and managing the product quality during the process. Controlling the product quality is the most essential food product characteristics to consider (e.g. Smith et al, 2004), and maintaining the high quality product during various processes and processing conditions is an important matter in the food supply chain. The work done by Rong et al (2011) is on optimizing the food quality degradation in the production and distribution planning. This model optimizes the quality of the raw materials throughout the supply chain. The work considered a kinetic model to measure for the quality degradation. It considers only a single raw material and product and generates linear and non-linear results in the case of zero and first order reactions, respectively. This kinetic

model is integrated into the supply chain and mixed –integer linear programming is used for production and distribution. However in this work energy consumption has not been considered as a key factor.

An important factor in food industry is to have flexibility in products and not to have a seasonality problem to satisfy the given demand. Therefore the preparation process is added to the production system to increase the shelf-life of the raw materials. The focus of this paper is on the preparation processes, where it reduces the inventory wastage produced by expired materials. Fresh food materials are source of vitamin, minerals and other bioactive compounds such as pigments and volatile compounds that undergo degradation during drying process (Gregory, 1996). Therefore a quality model is developed to control for the variation in these quality indicators.

The goal of this project is to introduce a new methodology to model and optimise the food quality whilst controlling and minimizing the process energy consumption in such a way that it can be integrated in a mixed-integer linear programming model used for the production system throughout supply chain.

2. Mathematical Model

Two preparation processes are used here, namely freezing and drying processes. The freezing process is a benchmark and will be compared with the drying process. One type of freezing process and two different types of drying processes are used (figure, 1). Therefore in the case of drying processes an optimal blending task is added to achieve the optimum product quality and energy usage wise. As a result two quality models are developed and applied to the drying process, the linear quality model and the quality model with correction factor. This blending model is only applied to the drying process, but the linear quality model as well as energy model is applied to the whole process and all states throughout the system for supply chain scheduling. The following equations are used to measure and constrain the quality:

$$q_{i,s} = B_i + C_i . q_{i,s-1} + \sum_j \gamma_j \sum_D A_{i,D} . u_{j,D} \quad (1)$$

Where $q_{i,s}$ represents the quality of the product after each task of the specific indicator. The $q_{i,s}$ at each state becomes an input quality of the next state. In this model different processes will have different effects. The material processed in the task goes through transformations described by parameters *A, B* and *C*. The variable set *u* is introduced in the model which captures how the quality of the product is also affected by the process degrees of freedom (e.g. temperature, processing time). γ_j is a binary variable and it is 1 if certain task is operating.

$$q_B^k = x_A^k . q_{AD} + (1 - x_A^k) . q_{FD} + M(1 - y_A^k) + Correction^k, \quad \forall k \quad (2)$$

$$q_B \leq q_B^k - M(1 - y_A^k), \quad \forall k0 \quad (3)$$

q_{AD} & q_{FD} are the quality of the product after preparation process, Air-Dry and Freeze-Dry respectively. q_B^k, is the blended quality at every data point. *k* are the data points, these are the fixed points in the model, chosen to apply the correction and calculate the differences between the linear model and the model with correction. The data points suggest what portion of each processing type should be taken. x_A^k is the set of allowed blend fractions of *A* and y_A^k is 1 if and only if the k^{th} value of x_A^k is chosen. *Correction* is a factor which has to apply to the model to increase the accuracy of the results.

Kinetic models are used to measure the quality model parameters. Some of the litriture work used for this are Devahastin & Niamnuy (2010); Kaminski and Tomczak (2000); Giannakourou et al (2002); Martins et al (2006); Simal et al (1996) and Suvarnakuta et al (2007). The quality level of a product at a certain location in the production based on

an initial quality (q_0) and subsequent periods *i=1,...,m* with time interval t_i and degradation rate k_i (depending on temperature T_i), leads to:

$q = q_0 - \sum_{i=1}^{m} k_i t_i$ and $q = q_0 . \exp\left(-\sum_{i=1}^{m} k_i t_i\right)$ (4)

For zero and first-order reaction, where the degradation rate is measured by The Arrehenius equation:

$$k = k_0 \exp\left(-\frac{E_a}{RT}\right) \quad (5)$$

These models together with empirical data are used to develop approximate linear quality models.

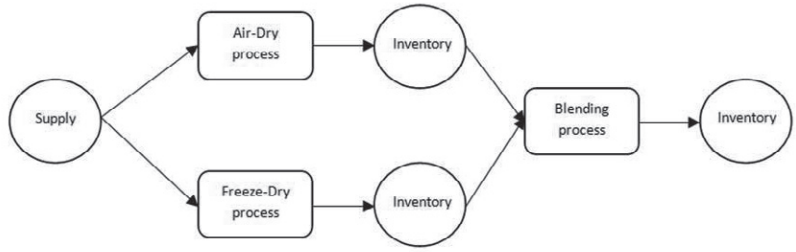

Figure 1. Drying process

The energy of each task on the other hand is modelled as follows:

$Energy_s = \sum_j \gamma_j \left(\sum_D a_{s,D} . u_{j,D} + E_j^{base}\right)$ (6)

Where *a* is the slope of the degree of freedom (e.g. process time or temperature) and *u* is the set variable and is same as the *u* in quality models. E_j^{base} is the base energy required for each task. At the blending state:

$E_b^k = x_A^k . E_{AD} + (1 - x_A^k) . E_{FD}$ (7)

E_b^k is energy after blending. Here *k* is the data point and *x* is the blending fraction.

Parameters *a* are calculated using the experimental data as well as following equation.

$Energy_j = Power_j . t_j$ (8)

This equation states; the electrical energy (kWh) consumed for the process is equal to electrical power supplied (kW) for the process multiplied by the process time in hours (Xu et al 2005). Therefore objective 1 is as follows:

$max\ [\alpha . \sum_s q_s - \beta . \sum_s Energy_s]$ (9)

This objective optimising the quality of the product while minimising the energy. The weightings α and β are given to the variables quality and energy which are 0.9762 and 0.0238, respectively. This is calculated using the ratio of quality and energy at each task and minimum quality and maximum energy. The raw materials stay for sometime in inventory before being used to overcome the seasonality. At this stage scheduling for the supply chain model is applied to measure for how long the materials should stay until they fulfil the given demand with the optimum quality and costing of products. Each time period in the horizon is one week. A coefficient *R* is introduced here for inventory to satisfy the demand. Therefore the inventory state is modelled as follows:

$I_{st} = I_{s,t-1} + \sum_j PR_{j,t} . \propto_{j,s} - D_{s,t} - w_{s,t} + R_{s,t}$ (10)

Where *R* is the residual and it would compensate for the shortage of supply. *D* and *w* are the demand and waste of each state at a time and *PR* is the production rate.

All these constraints are applied to the model to solve for the overall cost minimisation of the whole system to achieve the best quality product with minimum energy consumption, waste and cost.

$min\left(\sum_{s,t} S_{st} . PC_s + \sum_{s,t} I_{st} . SC_s + \sum_{s,t} w_{st} . DC_s + \sum_{s,j,t} PR_{jt} . TC_{sj}\right)$ (11)

3. Sample Results

The regression fitting is used for the linear quality model. Some sample results are generated using literature data for the key feedstocks. These indicate the quality following primary processing. Four raw materials have been used in this example, potato, carrot, onion and green peas. At the initial state the optimisation generates results for optimum quality and energy usage. The optimum results for the variable set *u* generally suggest using the process with low processing time and high/ low temperature in the case of drying/ freezing process. In the case of the drying process however a blending state is added therefore *M* and correction factor is calculated and variable *x* applied to find the optimum solution quality and energy wise. The model suggests blending the products from Freeze- and Air-Dry by portions of 60 and 40 % respectively for potato, 40 and 60% respectively for carrot and green peas and 100% of Air-Dry process for onion. The optimum quality of all products across all indicators after blending is shown in the figure 2.

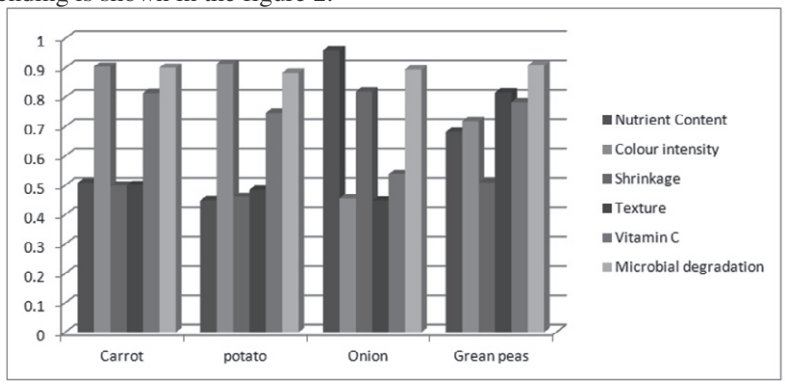

Figure 2, products quality after blending.

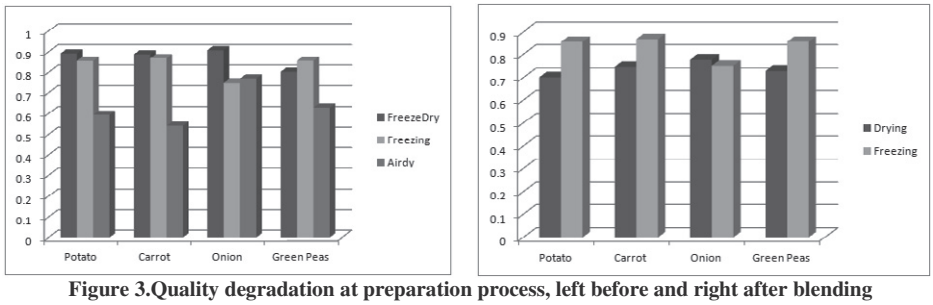

Figure 3.Quality degradation at preparation process, left before and right after blending

Figure 3 and 4 compare the quality and energy usage of the processes before and after blending the drying processes with freezing process. Air-Dry process generates the lowest quality products, but it consumes the lowest energy as well. The Freeze-Dry process on the other hand generates the best quality product for most of materials by using the highest energy. After blending the two drying processes to obtain the optimal material, quality and energy wise, the process is compared with the freezing process. The results show generally the freezing process generates better quality product. The energy consumed for carrot after blending is higher in drying process compare to freezing process. However the fact is by going through the system the energy usage for the frozen material would be much higher. The reason is, at the inventory state the frozen materials have to be stored at low temperature freezers while the dried materials

would be stored at room temperature storage. After the preparation task, the linear quality and energy models are applied to all tasks.

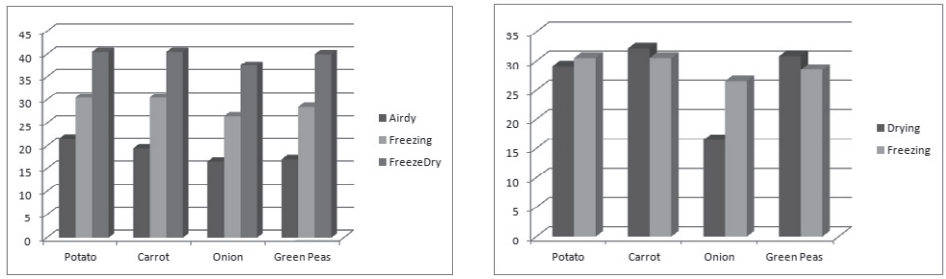

Figure 4. Energy usage at preparation process left before blending and right after blending (*MJ/Kg*).

4. Conclusion

This paper presented a mixed-integer linear programming model for the food processing and manufacturing system with the focus on product quality at the preparation process, which is strongly related to the process degrees of freedom (e.g. temperature and processing time). This is based on quality degradation and energy consumption of the food product raw materials during preparation processes, in order to increase their shelf-life, and inventory. A new methodology is applied to simplify the existing models. These are (*i*) linear quality model, which linearises the quality model and optimises the product quality across all quality indicators and is applied to the process and could also be applied to inventory. (*ii*) Base delta model to relate the energy consumption at every process to the linear quality model. (*iii*) Blending quality and energy model, which show by how much the processes should mix in order to have a product with a maximum quality and minimum energy usage. The quality and energy models are integrated into supply chain model to optimise the costing and wastage of the product throughout the system. Therefore the main contribution is introducing new methodology to simplifying the ways of optimising the quality and parallel to this controlling the energy consumption of the products, where the managing the product quality, energy consumption and controlling the temperature and processing time can be integrated in decision making on production in supply chain management. Also the interrelationships between quality and processing conditions have been developed. The model presented therefore is a useful tool in production and manufacturing in food industry.

Abstract

The production and logistics operations planning in real-life single- or multi-site semicontinuous food industries is addressed in this work. A mixed discrete/continuous-time mixed integer programming model, based on the definition of families of products, is devised. A remarkable feature of the proposed approach is that in the production planning problem timing and sequencing decisions are taken for product families rather than for products. However, material balances are realized for every specific product, thus permitting the detailed optimization of production (including changeovers), inventory, and transportation costs. Additionally, alternative transportation modes are considered for the delivery of final products from production sites to distribution centers. Finally, the efficiency of the proposed approach is demonstrated by solving to optimality an industrial-size case study, for a real-life Greek dairy industry.

Keywords: production planning, distribution, mixed integer programming, case study.

1. Introduction

In this work, we focused on the Food Processing Industry (FPI) sector that has received little attention in the open literature so far. FPIs acquire agricultural raw materials and then process them before further distribution. Processing is defined in a broad sense; ranging from simple packing of fresh products to extensive reforming operations. In food supply chains, logistics management normally refers to the physical material flows and the inventory of products from production facilities to Distribution Centers (DCs) or customers. Here, we consider the simultaneous detailed production and distribution planning in multi-site multiproduct semicontinuous FPIs. McDonald and Karimi (1997) and Verderame and Floudas (2009) addressed a relevant problem, but for chemical industries. Here, a real-life yogurt industry (Kopanos et at., 2010) is studied, and a linear Mixed Integer Programming (MIP) model is developed. In every planning period, the key decisions to be made are: (i) the assignment and sequencing of products (and families) to processing units, (ii) the produced product quantity in each processing site, (iii) the inventory levels for each product, (iv) the assignment of transportation trucks to production sites-DCs, (v) the selection of the available alternative transportation mode, and (vi) the detailed transportation load composition for every truck. The objective is to fully satisfy customer demand at minimum total cost, including production, changeover, inventory and transportation costs. To the best of our knowledge, there is no previous work in the literature presenting an exact method for addressing the challenges of the underlying semicontinuous food processing and distribution planning problem.

2. Mathematical Formulation

In this section, some representative and significant constraints of the proposed modeling approach are presented.

2.1. Material Balance & Distribution Operations Constraints.

The transportation of final products to DCs or customers can be done by three potential transportation modes: (a) trucks owned by the customers, (b) transportation trucks owned by the industry, and (c) contracted transportation trucks from third party logistics companies. Final products $p \in P^a$ whose final destination is the international market or big national supermarket customers are transported to their customers by transportation mode (a). The transportation of final products to the DCs owned by the enterprise can be performed by any of the other two transportation modes (b), and/or (c).

The total quantity of product p produced in production plant s in period n-λ_p, which is ready to ship to DCs (or customers) in period n, is given by:

$$Q'_{spn} = \sum_{j \in (J_s \cap J_p)} Q_{psjn-\lambda_p} \quad \forall s, p, n > \lambda_p \tag{1}$$

where λ_p denotes the days that packed product p should be kept in storage (e.g., for cooling or refrigeration purpose). Q'_{psjn} corresponds to the quantity of product p processed in unit j of production site s during period n. Note that $Q'_{psjn}=0 \ \forall \ s,p,n \leq \lambda_p$. Constraint set (2) expresses the material balance for products $p \in P^a$ whose destination is the international market or big national supermarket clients.

$$I_{spn} = I_{spn-1} + Q'_{spn} - U^a_{spn} \quad \forall s, p \in P^a, n \tag{2}$$

where U^a_{spn} denotes the quantity of product $p \in P^a$ transported from production site s to the international market or big national supermarket clients by customer trucks, at period n, in order to fully meet the demand. I_{spn} corresponds to the inventory level of product p in production plant s at time point n. Note that I_{spn}=0 reflects the initial inventory for product p in production site s. The multiperiod material balance constraints for products $p \notin P^a$ transported to company's DCs are given by:

$$I_{spn} = I_{spn-1} + Q'_{spn} - \sum_{d \in D_s} \sum_{l \in L_{sd}} U_{sdlpn} \quad \forall s, p \notin P^a, n \tag{3}$$

where U_{sdlpn} denotes the quantity of product p transported from production site s to DC d by transportation truck l at period n. Once final products reach DCs, they are stored for a day due to product quality purpose before sending them to final customers. The total load for any transportation truck l that transfers products from production facility s to DC d in period n is given by:

$$U'_{sdln} = \sum_{p \notin P^a} U_{sdlpn} \quad \forall s, d \in D_s, l \in L_{sd}, n \tag{4}$$

Hence, every truck l has a specific minimum and maximum capacity (ε_l^{min} ,and ε_l^{max}, respectively) as given by:

$$\varepsilon_l^{\min} Z_{sdln} \leq U'_{sdln} \leq \varepsilon_l^{\max} Z_{sdln} \quad \forall s, d \in D_s, l \in L_{sd}, n \tag{5}$$

Binary variables Z_{sdln} denote the use of truck l for transporting products from production site s to DC d at period n. Any transportation truck l can transfer products only between one production site s and one DC d during any period n, according to:

$$\sum_{s \in S_l} \sum_{d \in (D_s \cap D_l)} Z_{sdln} \leq 1 \quad \forall l, n \tag{6}$$

2.2. Families of Products Modeling.
Production planning in semicontinuous process industries, such as the FPI, typically deals with a large number of products with similar characteristics. That allows us to group products with similar characteristics into product families. In the proposed approach, *products belong to the same family if and only if* : (i) they come from the same batch recipe, and (ii) there is no need for changeover operations among them. Thus, the production planning problem under question could be partially focused on families rather than on each product separately. Also, sequencing and timing decisions are taken for families and not for each separate product, as Figure 1 shows. The definition of families significantly reduces the size of the underlying MIP model without sacrificing feasibility or optimality. Product lot-sizing, family allocation, sequencing and timing, and batch recipe stage constraints are similar to those presented in Kopanos et al. (2010).

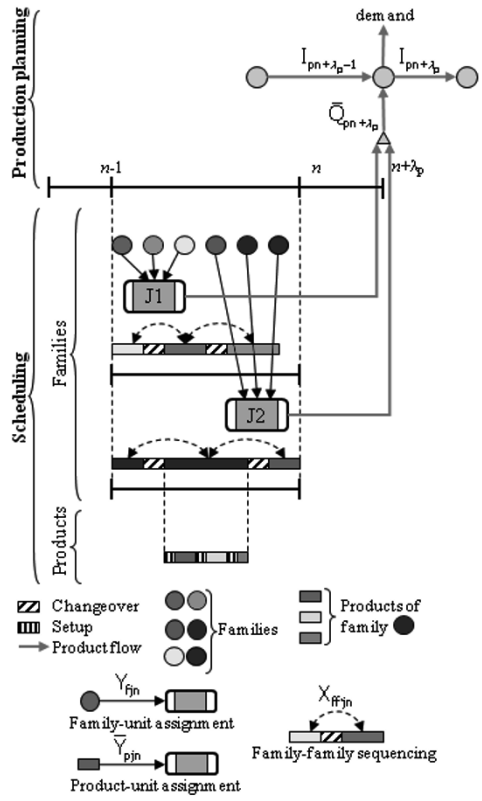

Figure 1. Modeling approach.

A salient feature of the proposed modeling approach is that allows products that belong to the same family to have different: (i) processing rates, (ii) operating costs, (iii) setup times, (iv) inventory costs, (v) transportation costs, and (vi) customer type

2.3. Objective Function.
The optimization goal is the minimization of the total cost including several factors such as: (i) inventory costs, (ii) operating costs, (iii) batch recipes preparation costs, (iv) unit utilization costs, (v) families changeover costs, and (vi) transportation costs.

3. Case Study

An industrial-size multi-site production and distribution planning problem of a real-life Greek dairy industry, producing yogurt, is considered and solved by the proposed MIP model. The production and distribution network under consideration consists of two production sites (located in Serres, and Karditsa) and five DCs, as shown in Figure 2. Processing unit types *J1* to *J4* are installed on the production plant located in Serres while processing units types *J1* to *J3* are installed on the production site of Karditsa. Each production site in owns a pair of transportation trucks, while ten and six third party logistics trucks are available in the plant of Serres and Karditsa, respectively. The production facilities have to fully meet the demand for all products. The relative sequences among families are predetermined. The remaining data are available upon request from the authors.

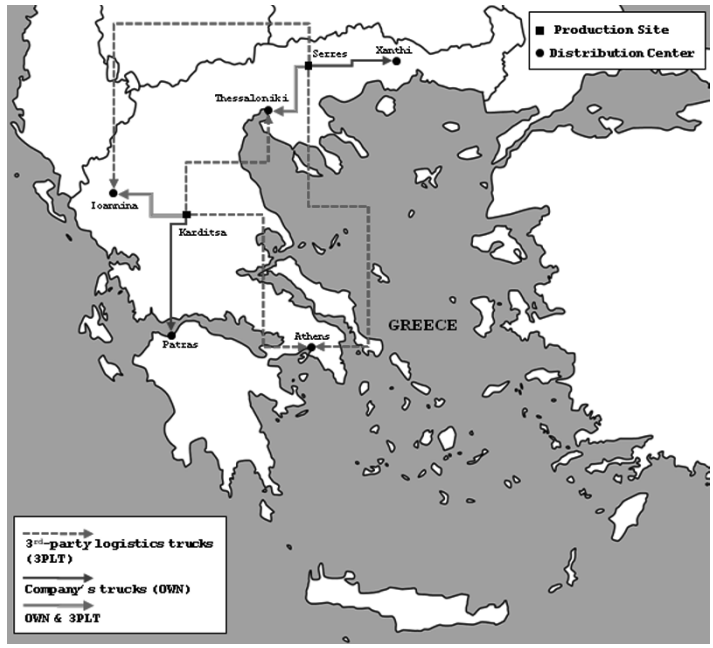

Figure 2. Production and distribution network of the dairy industry.

This case study has been solved to global optimality in a Dell Inspiron 1520 2.0 GHz with 2 GB RAM using CPLEX 11 via a GAMS 22.8 interface. The resulting MIP model consists of 19,371 constraints, 4,070 binary variables, and 35,614 continuous variables. The optimal solution reports 520,047€ of total cost, and it was reached in 379.2 CPU s after exploring 1,837 nodes in the branch-and-bound tree.

Figure 3 illustrates the total, and per production facility, cost breakdown as well as the contribution of each cost term on the total cost. Inventories costs represent 14.5% of the total cost while transportation costs stands for the 35.7% of the total cost. Production costs (i.e., operating, recipe, unit utilization, and changeovers costs) represent 49.8% of the total cost. Also, noted that 62.5% of the total inventory cost, and the 57.5% of the total transportation cost is occurred in production site of Serres; due to the fact that the plant in Serres (wherein 4 units are installed) appears higher overall production capacity than that of the plant in Karditsa (wherein 3 units are installed). The profile of total produced quantities, inventories, and transported quantities for each planning period are shown in Figure 4. The production plants operate from *n0* to *n5* period, where period *n0* is an overtime period (i.e., higher operating costs). The highest production is observed in period *n5*, with 129,723 kg of production. On average, inventory levels are maintained low throughout the planning horizon, with an exception in period *n6* where a relatively high inventory level of 64,702 kg is detected; due to the high demand requirements of the last period. Transportation operations from production facilities to DCs are realized from *n3* to *n7* period, observing the peak in period *n7*, wherein a total of 124,171 kg of products is transferred from the production sites to the DCs. Finally, the proposed MIP model also generates: the detailed production plan for both production plants, and the detailed transportation plan for each product (i.e., assignment of product to truck, assignment of truck to DC, and quantity of product transported by each truck); which are omitted here due to lack of space.

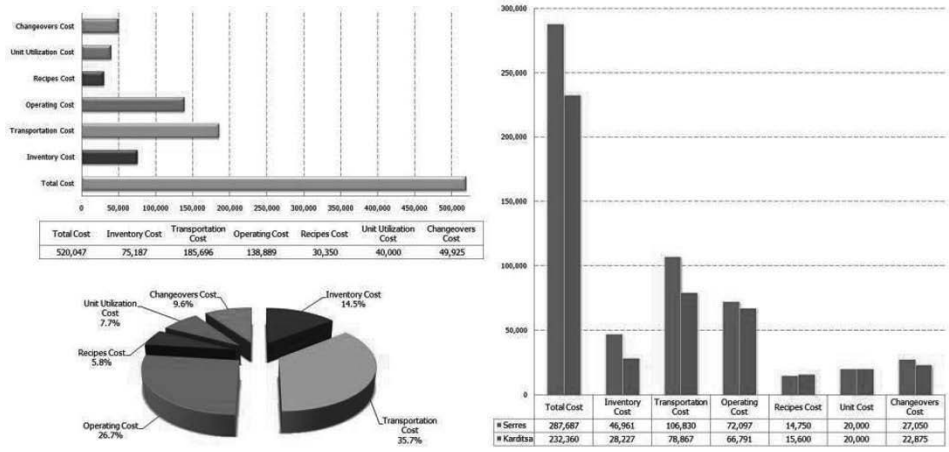

Figure 3. Total cost breakdown (€) and cost terms contribution.

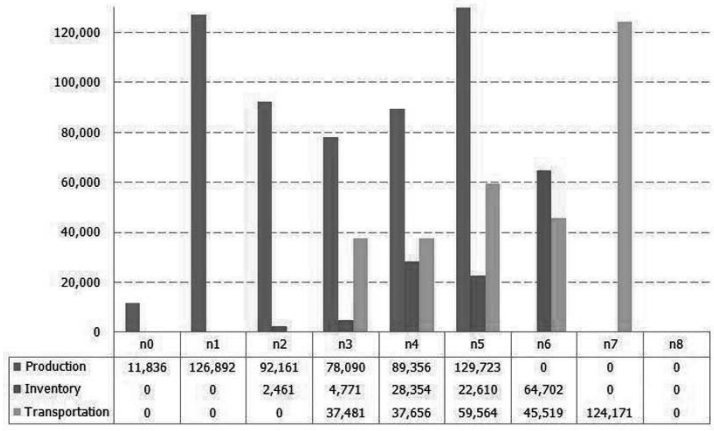

Figure 4. Total production, inventory and transportation profiles (kg) per period.

4. Concluding Remarks

The proposed integrated framework serves as a tool for negotiations between production and logistics departments, allowing them to collaborate more easily to find the best balance between inventory levels, production and distribution efficiency. The proposed approach was successfully validated and approved by the dairy industry considered, and its further improvement and implementation in the firm is currently on the way.

Acknowledgments

Financial support from the Spanish Ministry of Education and Spanish project DPI2006-05673 is gratefully acknowledged. The authors would like to thank Mr. Nikolas Polydorides, production manager at KRI-KRI S.A., for the provision of data and the fruitful comments.

Hybrid Approach for Multi-stage Logistics Network Optimization under Disruption Risk

Yoshiaki Shimizu[a] and Muhammad Rusman[a]

[a]*Department of Mechanical Engineering, Toyohashi University of Technology, 1-1 Hibarigaoka, Ten-paku-cho, Toyohashi 441-8580, Japan*

Abstract

Modern supply chains are subject to a wide range of risks, such as demand uncertainty, natural disasters, and terrorist attacks. Based on some prospects for risk management, this study investigates a logistics network design problem with facility disruption that will be caused by various risks. To find a solution for this design issue, we have formulated a probabilistic programming problem, and propose an effective hybrid method composed of meta-heuristic method and graph algorithm to offset potential losses from the network disruptions. Through numerical experiments, effectiveness of the proposed method is validated.

Keywords: Multistage logistics network design, Hybrid method, Disruption risk, Probabilistic programming problem.

1. Introduction

Under today's global and agile manufacturing, modern supply chains are subject to a wide range risk such as the demand uncertainty, natural disasters, terrorist attacks and so on. Recent disruptions by earthquake and tsunami in Japan (2011) and the massive flooding in Thailand (2011) had dramatic impacts on the supply chains and logistic distribution of many companies. The resulting slowdowns and cessation of operations affected seriously some companies.

Against this, we can anticipate the disruption by considering preventive action viewed as mitigation planning. Toward such mitigation plan, supply chain must build a resilient system that can minimize the impact of the disruption in future by having appropriate backup facilities.

In this study, therefore, we focus on the issue related to facility disruption risk for multistage logistic networks and present a hybrid approach that will provide a resilient design in practice. Finally, effectiveness of such approach will be examined through numerical experiments.

2. Problem Formulation

Among some previous studies, Tomlin (2006), Snyder and Daskin (2005) and Chopra and Sodhi (2004) investigate the impact and/or risk management perspective for two echelon logistic problems. Considering the risk associated with demand fluctuation, Shimizu et al. (2011) give a solution procedure by recourse model for a three echelon logistic problem.

This study takes three echelon networks for which Shimizu and Rusman (2011) carried out a morphological analysis. The network is consisted of distribution centre (DC), relay station (RS) and customer (RE). For RS, we consider two kinds of RS, i.e.,

reliable RS (RRS) and unreliable RS (URS). URS is no longer available for serving customers when the disruption would occur. In contrast, RRS is the hardened one and can continue the business even after the incident.

Figure 1 illustrates the case where RS is potentially being disrupted. Thereat, two DCs distribute products to three relay stations (RSs), which are consisted of two RRSs and one URS. If the demand of the customer is satisfied by RRSs, then only single assignment is sufficient. On the other hand, if the customer is assigned to URS, backup assignment is required besides the primary assignment. This means when the disruption occurs at URS, the demand of customer will be distributed from the backup RRS.

Here, we assume that each facility has the same probability of disruption q ($0<q<1$). Primary assignments occur with probability 1-q under the normal cost while backup assignments occur with probability q under the abnormal cost. Moreover, we consider each RS is possible to receive the product from multiple DCs and customer also from multiple RSs depending on the respective demand of the customer. In the model, we use the following notations for index sets, parameters, and decision variables.

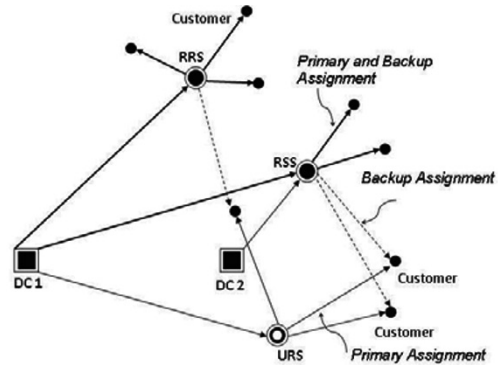

Fig.1 Logistic network under disruption risk

Index sets

I : set of distribution centres (DC)
J : set of relay stations (RS)
K : set of customers (RE)

Parameters

F^U_j : Fixed cost for opening URS j
F^R_j : Fixed cost for opening RRS j
C^P_i : Shipping cost at DC i as primary assignment
C^B_i : Shipping cost at DC i as backup assignment
H^P_j : Handling cost at RS j as primary assignment
H^B_j : Handling cost at RS j as backup assignment
$T1^P_{ij}$: Transport cost from DC i to RS j as primary assignment
$T1^B_{ij}$: Transport cost from DC i to RS j as backup assignment
$T2^P_{jk}$: Transport cost from RS j to customer k as primary assignment
$T2^B_{jk}$: Transport cost from RRS j to customer k as backup assignment
U_j : Upper bounded capacity of RS j
PU_i : Maximum supply ability of DC i
PL_i : Minimum supply ability of DC i
d_k : Demand of customer k
q : Probability of disruption ($0<q<1$)

Decision variables

f^P_{ij} : Shipped amount from DC i to RS j as primary assignment
f^B_{ij} : Shipped amount from DC i to RS j as backup assignment
g^P_{jk} : Shipped amount from RS j to customer k as primary assignment
g^B_{jk} : Shipped amount from RS j to customer k as backup assignment

$$x_j^U = \begin{cases} 1, if\ RS\ j\ is\ opened \\ as\ unreliable\ assignment \\ 0,\ otherwise. \end{cases}$$

$$x_j^R = \begin{cases} 1, if\ RS\ j\ is\ opened \\ as\ reliable\ assignment; \\ 0, otherwise. \end{cases}$$

After all, we can formulate the model as a probabilistic mixed-integer programming problem as follows.

Minimize

$$\sum_{j\in J} F_j^U x_j^U + \sum_{j\in J} F_j^R x_j^R + (1-q)\left(\sum_{i\in I}\sum_{j\in J}\left(C_i^P + T1_{ij}^P\right)f_{ij}^P + \sum_{j\in J}\sum_{k\in K}\left(H_j^P + T2_{jk}^P\right)g_{jk}^P\right)$$
$$+ q\left(\sum_{i\in I}\sum_{j\in J}\left(C_i^B + T1_{ij}^B\right)f_{ij}^B + \sum_{j\in J}\sum_{k\in K}\left(H_j^B + T2_{jk}^B\right)g_{jk}^B\right)$$

subject to

$$x_j^U + x_j^R \le 1, \quad \forall j \in J \tag{1}$$
$$\sum_{j\in J} x_j^R \ge 1 \tag{2}$$
$$\sum_{i\in I} f_{ij}^P \le U_j\left(x_j^U + x_j^R\right), \forall j \in J \tag{3}$$
$$\sum_{i\in I} f_{ij}^B \le U_j x_j^R, \forall j \in J \tag{4}$$
$$\sum_{j\in J} f_{ij}^P \le PU_i, \forall i \in I \tag{5}$$
$$\sum_{j\in J} f_{ij}^B \le PU_i, \forall i \in I \tag{6}$$
$$\sum_{j\in J} f_{ij}^P \ge PL_i, \forall i \in I \tag{7}$$
$$\sum_{j\in J} f_{ij}^B \ge PL_i, \forall i \in I \tag{8}$$
$$\sum_{i\in I} f_{ij}^P - \sum_{k\in K} g_{jk}^P = 0, \forall j \in J \tag{9}$$
$$\sum_{i\in I} f_{ij}^B - \sum_{k\in K} g_{jk}^B = 0, \forall j \in J \tag{10}$$
$$\sum_{j\in J} g_{jk}^P = d_k, \forall k \in K \tag{11}$$
$$\sum_{j\in J} g_{jk}^B = d_k, \forall k \in K \tag{12}$$
$$x_j^R \in \{0,1\}, \forall j \in J \tag{13}$$
$$x_j^U \in \{0,1\}, \forall j \in J \tag{14}$$
$$f_{ij}^P \ge 0, \forall i \in I, \forall j \in J \tag{15}$$
$$f_{ij}^B \ge 0, \forall i \in I, \forall j \in J \tag{16}$$
$$g_{jk}^P \ge 0, \forall j \in J, \forall k \in K \tag{17}$$
$$g_{jk}^B \ge 0, \forall j \in J, \forall k \in K \tag{18}$$

The objective function is expected costs that consist of fixed cost for opening RS, shipping cost at DC, transportation costs between facilities and handling cost at RS.
Equation (1) requires that either of RRS or URS can be open, but not both; Eq.(2) at least one RRS must be opened; Equations (3) and (4) are capacity constraints for RS as primary and backup assignment, respectively; Eqs.(5) and (6) upper bounds for available supply as primary and backup assignment, respectively; Eqs.(7) and (8) lower bounds for available supply as primary and backup assignment, respectively; Eqs.(9) and (10) balances of product flow as primary and backup assignment, respectively: Equations (11) and (12) mean demand of every customer must be satisfied as primary and backup assignment, respectively.
Due to some undisrupted reasons, it makes sense to assume such a relation for each cost parameter that $F_j^R > F_j^U$, $T1_{jk}^B > T1_{jk}^P$, $T2_{jk}^B > T2_{jk}^P$, $C_i^B > C_i^P$ and $H_k^B > H_k^P$.
Since thus formulated problem belongs to a NP-hard class, its solution becomes extremely difficult according to the increase in problem size.

3. Hybrid Approach for Solution

Taking a similar hierarchical logistic network mentioned above, we proposed a method termed hybrid tabu search (Shimizu et al., 2004) and applied its variants both to the

certain and uncertain cases. It is a two-level method whose upper level problem decides the locations of distribution centre and the lower derives the routes among the facilities. At the upper level, evolutionary search is carried out so that the neighbor location is updated by the sophisticated tabu search, in turn. On the other hand, the location pegged problem at the lower level refers to a linear program (LP) that is possible to transform into the minimum cost flow problem (MCF). Finally, we can apply the graph algorithm such as CS2 or Relax 4 to solve the resulting problem extremely fast compared with solving directly the original LP. These procedures will be repeated until a certain convergence criterion has been satisfied. This basic idea is possible to straightforwardly extend to the present solution just by solving the lower level problem both for normal and abnormal cases, respectively and combining them together to compute the expected cost (See right hand side of Fig.2).

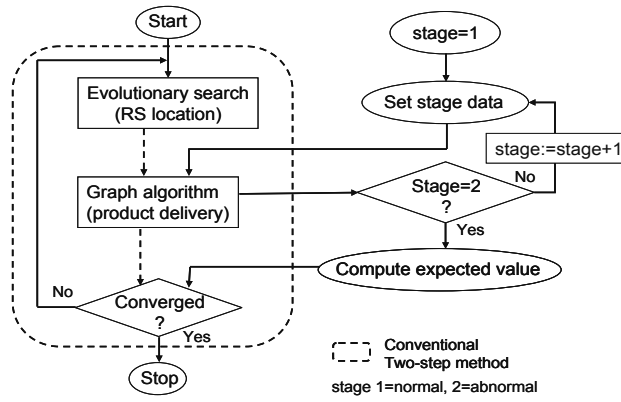

Fig.2 Flowchart of the proposed procedure

4. Numerical Experiment

To verify the effectiveness of the proposed approach, we provide a few benchmark problems whose system parameters are given randomly within the respective upper and lower bounded values.

Result of the hybrid approach for a small model (number of DC/ RS/ Customer = 2/ 5/ 50) is given in Table 1. This coincides with the one derived from commercial software known as CPLEX 12. From this, we know DCs will distribute products from three open RSs (RS#2, RS#4 and RS#5) for every disruption probability except for q=0.4. It is interesting to see that RS#4 is used as the unreliable RS when q is low while it appears as the reliable one at the higher q after it disappears during the middle range of probability. This is because the opening cost of RS#4 is quite cheap among RSs. Hence, opening this RS as URS can save the transportation cost greatly when q is low. In contrast, when q becomes higher, it makes sense to open this RS as RRS to cope with the disruption as well as transportation cost saving. The situation when q=0.4 appears as the transient status of these two cases. These facts can confirm the adequateness of the proposed model.

Relying on this preliminary experiment, we solved several problems with such larger sizes that makes extremely difficult to solve by the commercial software from our previous experiences. For example, Table 2 summarizes the results for different numbers of customer up to 5000 when q=0.1. We also know that the rising rate with the increase in q is almost constant for the primal cost while most remarkable for the backup cost. From Fig.3, as expected a priori, we can observe a rapid increase in CPU time with the problem size.

Table 1 Result for a small problem: DC/ RS/ Customer = 2/ 5/ 50

Probability (q)	0.01		0.1		0.4		0.5	
Relay station (RS)	URS	RRS	URS	RRS	URS	RRS	URS	RRS
Number of RS	1	2	1	2	0	2	0	3
Facilities (RS #)	(#4)	(#2,5)	(#4)	(#2,5)		(#2,5)		(#2,4,5)
Expected cost unit [-]	4,454,105		4,644,056		5,276,776		5,484,457	

URS: unreliable relay station RRS: reliable relay station

Table 2 Results for larger problem size when q=0.1

Problem size (DC/ RS/ Customer)	Expected cost unit	Primal cost unit	Backup cost unit	RRS	URS
10/ 30/ 500	2.75E7	2.61E7	3.95E7	9	5
10/ 30/ 1000	5.70E7	5.44E7	8.11E7	15	2
10/ 30/ 2000	1.43E8	1.37E8	2.00E8	14	1
10/ 30/ 3000	1.94E8	1.83E8	2.95E8	16	8
10/ 30/ 5000	3.24E8	3.08E8	4.68E8	17	7

5. Conclusion

Concerning with supply chain, this study investigates the multi-stage logistics network design that are exposed to various risks. The problem under disruption risk is formulated as a probabilistic programming model. Then to find the optimal solution of this problem in practice, a hybrid method is employed which combines a meta-heuristic method and a graph algorithm in a hierarchical manner. Through the numerical experiment, we have shown the proposed approach is promising to design the resilient logistic networks available for the real world mitigation planning. Future studies should be devoted to enhance the solution ability and consider the more realistic conditions suitable for business continuity plan/management that will provide .

Supply Chain Optimization of Biomass Production Improvement

Mingyen Yu[a] , Franjo Cecelja[a], Seyed Ali Hosseini[a]

[a]*PRISE Center for Process and Information Systems Engineering, Faculty of Engineering and Physical Science, University of Surrey, Guildford, GU2 7XH, UK*

Abstract

Renewable energy, especially biofuels, is seen as a viable solution to replace the depleting fossil fuels. Moreover, tighter environmental regulations across the world force many countries to develop strategic approaches to target and screen relevant replacement of resources and technologies. Because there are significant variations in types of biomass and conversion methods, determining the economical effectiveness of overall supply chain (SC) is a complex task. Thus, a holistic approach which accounts for economic, environmental and production aspects across the SC, starting from cultivation to the final products, and establishing appropriate links among them at each stage is imperative in analyzing overall chain efficiency.

In this work, for analysis of SC, mathematical modelling is paired with linear programming (LP), which accounts for the variability of technologies that uses biomass as input. The analysis includes economic and environmental factors along the SC. Green House Gases (GHG) is analysed in terms of carbon-equivalent units and converted into monetary values to form financial objective. In addition, incentives for each party in the SC to have economical gain have also been considered.

To validate the developed methodology, a case study from Northern Italy is investigated that takes corn stover as a feedstock and targeting production of ethanol with ash, carbon dioxide and DDGS being by-products. It should be highlighted that different types of ethanol conversion technologies are analyzed in terms of overall SC and compliance of GHG emission with existing regulation is also taken into account in the case study.

Keywords: Supply chain management, Optimization, Renewable energy

1. Introduction

With the world's population passed the seven billion mark [1], resources are getting scarce. This is especially true for fossil fuels. At the same time, the increasing emission of Green House Gases (GHGs) is recognized as a problem with climate consequences. Thus, biofuels such as ethanol from corn stover are seen as one of the solutions with respective to supply chain (SC) analysis and design in their core.

So far, the main focus of SC has been on intra-chain issues, e.g. distribution network design, inventory planning, logistics management and production coordination [2] [3]. Also, mathematical analysis for biomass SC has been recognized in the literature. Shah *et al.* [4] demonstrated the use of Mixed Interger Linear Programming (MILP) model to determine production capacity allocation, optimized layout and flow of distributed network for a biomass to heat SC system using a state-task-network (STN) approach. You *et al.* [5] developed a Mixed Interger Non-Linear Programming (MINLP) optimization model framework for economics and responsiveness of multi-site and multi-echelon process SC networks, to consider the trade-offs between net present value

(NPV) and lead time. Bezzo *et al*. [6] [7] addressed the design of bioethanol SC under multiple technological options with the help of MILP optimization and Abedpour *et al*. [8] described the key challenges in bioenergy SC modelling and developed a framework and methodology to show how multi-scale modelling can answer these SC questions.
Recently, because of the ISO 14000 environmental management standards, more attention is given to Environmental SCM (ESCM) and Life Cycle Analysis (LCA) which is seen as the main tool for ESCM. It is a technique for gathering data on environmental care issues which can be used to restructure SC in order to improve the environmental performance [9]. Kumaran *et al.* [10] further proposed the concept of life cycle environmental cost analysis (LCECA), to include eco-costs into the total cost of the products. Ultimately, it aims to reduce the total cost with the help of green or eco-friendly alternatives in all the stages of the life cycle of any product.
In this paper, we present the development and comparison of strategic overall SC, beginning from the supplier to the end customer. The design process is set as an optimized problem, intending to maximize financial performance, which is the NPV, and to minimize environmental effects with focus on GHG emissions.
The paper is organized as follows. Following the analysis and problem statement, SC financial model and LCECA model are developed. A case study on biomass for Northern Italy is presented, as well as the results. Finally, conclusions together with proposed future work are suggested.

2. Model Development

2.1. Supply Chain Financial Model

The SC financial model is defined as a LP optimization problem to maximize NPV, which is used to calculate the final profit of the SC as sum of profit after tax (PAT) for conversion technology k and biomass i, with discount factor df in terms of time t:

$$Obj_{NPV} = (\sum_{k,t} PATtk_{k,t} \times df_t) + (\sum_{i,t} PATbi_{i,t} \times df_t) \tag{1}$$

PAT for technology k and biomass i are given as:

$$PATtk_{k,t} = PBTtk_{k,t} - TAXtk_{k,t} + Subtk^{T}_{k,t} - EnvCos_{k,t} \quad \forall k,t \tag{2}$$

$$PATbi_{i,t} = PBTbi_{i,t} - TAXbi_{i,t} + Subbi^{T}_{i,t} \quad \forall i,t \tag{3}$$

It is obtained by taking the profit before tax, *PBTtk*, and total subsidies given, *Subtk*, for technology k, less the taxation, *TAXtk*, and the environment cost, *EnvCos*, at time t. Similar function is also used to calculate PAT for biomass i, *PATbi*. As environmental cost has already been considered in k in (2), it is not being re-considered again in (3). *PBTtk* and *PBTbi* are given by:

$$PBTtk_{k,t} = Inctk_{k,t} - VarCtk_{k,t} - FixCtk_{k,t} \quad \forall k,t \tag{4}$$

$$PBTbi_{i,t} = Incbi_{i,t} - VarCbi_{i,t} - FixCbi_{i} \quad \forall i,t \tag{5}$$

which is the income for technology k, *Inctk*, and biomass i, *Incbi*, less fix costs, *FixC*, and variable costs, *VarC*, of k and i respectively. It is assumed that the fix costs consist of infrastructure costs only in this model. Only one biomass site, *bs*, is used and the distance between the biomass site and the technology, k, is being considered in terms of variable costs. Next, income for k and i are given by:

$$Inctk_{k,t} = \sum_{j} TIpj_{j,k,t} + \sum_{l} TIpl_{l,k,t} \quad \forall k,t \tag{6}$$

$$Incbi_{i,t} = \sum_{bs} (Capbi_{i,bs,t} \cdot USPbi_{i}) \quad \forall i,t \tag{7}$$

The income for k is calculated by adding the sales of the main product, *TIpj*, and the by-products, *TIpl*. Income for the biomass i is the sum of the capacity of biomass, *Capbi*, with the unit sale price of biomass, *USPbi*, for the biomass site, *bs*.

2.2. Life Cycle Environmental Cost Analysis Model

The environment cost, *EnvCos*, for technology k is calculated as:

$$EnvCos_{k,t} = ETS \cdot (\frac{T\,\mathrm{Im}_{k,t}}{1000}) \quad \forall k,t \tag{8}$$

where *ETS* is the emission trading scheme, which is the price of carbon in the open market. The total environmental impact, *Tim*, is the sum of all the impacts of biomass, *Impbi*, with stages *sbi* (biomass production, *bp,* biomass pre-treatment, *bpt*, and biomass transportation, *bt*) and sum of all the impacts of technology, *Imppl*, with stages *spl* (fuel production, *fp*, and fuel transportation, *ft*), less the sum of all the impacts of carbon credit, *Impec*, with stage *ccd* (emission credit, *ec*):

$$T\mathrm{Im}_{k,t} = \sum_{sbi} \mathrm{Im}\,pbi_{sbi,k,t} + \sum_{spl} \mathrm{Im}\,ppl_{spl,k,t} - \sum_{ccd} \mathrm{Im}\,pec_{ccd,k,t} \quad \forall k,t \tag{9}$$

2.3. Constraints

In order for the SC to be operational, the PBT for technology k and biomass i should be greater than zero to ensure economical gain for all parties in the SC:

$$PBTtk_{k,t} \geq 0 \quad \forall k,t \tag{10}$$

$$PBTbi_{i,t} \geq 0 \quad \forall k,t \tag{11}$$

The conversion of biomass i to main product j and by-products l are given by:

$$MPfbi_{i,j,k,t} = (Captk_{i,k,t} \cdot ConFa\_ij_{i,j}) \quad \forall i,j,k,t \tag{12}$$

$$BPfbi_{i,l,k,t} = (Captk_{i,k,t} \cdot ConFa\_il_{i,l}) \quad \forall i,l,k,t \tag{13}$$

where main product, *Mpfbi*, is obtained by taking the capacity of biomass in k, *Captk*, and conversion factor of biomass to main product, *ConFa_ij*. By-products, *Bpfbi*, is also obtained by converting the capacity of biomass in k with conversion factor of by-products, *ConFa_il*. It is assumed in the model that by-products do not use excess resources when being produced.

The capacity of biomass in k, *Captk*, should be greater than the minimum capacity, *CapMin* of conversion technology, but less than the maximum capacity, *CapMax*, that the plant can hold to ensure that the plant is not either underloaded or overloaded:

$$CapMin_{i,k} \leq Captk_{i,k,t} \leq CapMax_{i,k} \quad \forall i,k,t \tag{14}$$

2.4. Case Study

We use a case study to show the applications and the potential capabilities of the research method proposed. Actual economic and environmental data are used, as

proposed by Bezzo *et al* [6] [7] for biofuel production in Northern Italy, and they have been adopted to evaluate specific modeling parameters. This is compared against the data obtained by Solda *et al* [11]. who also studied different biofuel technologies in Northern Italy. The environmental assessment of the stover-to-ethanol uses the LCECA model, as well as work by Luo *et al* [12] and Bezzo *et al* [6] [7].

The optimization problem is addressed by comparing two SCs in terms of different biomass conversion technologies (Ligno-Cellulosic Ethanol Process (LCEP) and Traditional Dry Milling (C+TDM)), and followed by analyzes of which SC is more profitable for a total duration of three years. In this case study, some factors such as transportation costs for biomass and products are deliberately kept the same so as to hightlight the effects of different technologies on the overall SC.

3. Result Analysis

The case study set up is solved using CPLEX solver in GAMS® modeling tool. It is then plotted into Microsoft Excel 2010® for further verification. As predicted, the result shows conflict between the environmental and the economic objectives understudy.

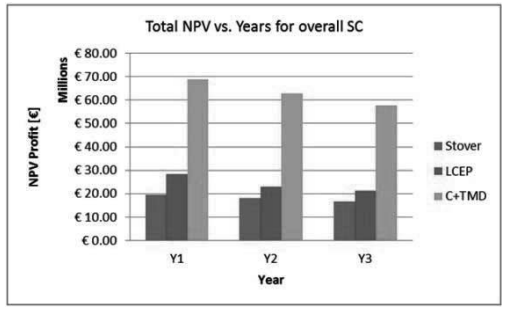

Fig 1 Total NPV vs. Years for overall SC

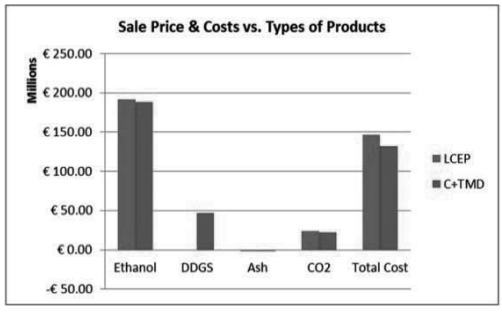

Fig 2 Sale Price & Costs vs. Types of Products

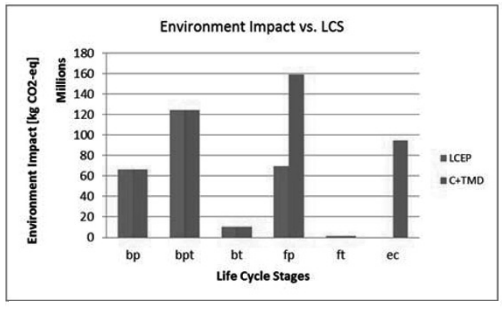

Fig 3 Environmental Impact vs. LCS

Based on the result obtained, the optimized capacity for both SCs are in the ratio of 52.27% for LCEP and 47.73% for C+TDM. The total NPV for the overall SC are shown in Fig 1.

It can be seen that C+TMD has higher NPV profit. Some possible reasons are:

- It has higher conversion factor (0.267 for LCEP vs. 0.288 for C+TDM) on ethanol.
- Compared to LCEP, C+TDM has an additional by-product, DDGS, which helps to generate extra income for the plant (Fig 2).
- As emission credit is only given to C+TDM, the overall GHG impact is lowered, and the environmental cost for C+TDM is reduced. Thus the total cost for C+TDM is lower than LCEP. This is shown in Fig 2.

In terms of environmental impact, stages *bp*, *bpt*, *bt* and *ft* are assumed to have the same GHG emission factor for both technologies, thus the impact for these four stages look identicial. However, without considering the emission credit, life cycle stage *fp* for C+TDM immediately rises to more than 160 million kg CO_2-eq, which is about 2.5 times the amount for LCEP.

At the same time, the emission credit ec for C+TDM is high as well (almost 100 million kg CO_2-eq), which effectively helps to lower the total GHG emission for the conversion technology, as well as increase the profit. This is shown in Fig 3.

4. Conclusion

In this research, different technologies of corn stover to ethanol SC are compared in terms of financial and environmental objectives. The mathematical models for the research as well as a case study comaring LCEP and C+TDM conersion technologies are presented.

Based on the result of the case study, it can be concluded that C+TDM is a more profitable conversion technology compared to LCEP, with the help of the emission credits. Thus for this case study, the maximum capacity of C+TDM is fulfilled before LCEP is used for ethanol conversion.

However, if the emission credit were removed, C+TDM may not have the advantage to be the preferred technology, as the GHG emissions for LCEP is much lower than C+TDM, even though the fixed cost for setting up the LCEP technology is higher than that of C+TDM.

The concept used in this research can be expanded into generic SC model, which can be applied to different SC scenarios other than biomass, to calculate the impact of finance against environment of the whole SC. Other performance criterias may also be added into the model for accessment in future.

Modular Optimization Approach for Process Synthesis and Integration of an Integrated Biorefinery

Douglas H. S. Tay, Rex T. L. Ng, Denny K. S. Ng

Department of Chemical and Environmental Engineering/Centre of Excellence for Green Technologies, University of Nottingham Malaysia, Broga Road, 43500 Semenyih, Selangor, Malaysia

Abstract

An integrated biorefinery is a processing facility that converts biomass feedstocks into a wide range of value added products which include biofuels and specialty chemicals. In order to synthesize a sustainable integrated biorefinery, the environmental and economic performances should be taken into consideration. Via heat and power integration within integrated biorefinery, both performances can be improved. Due to the complexity of the process synthesis and integration problem, it is a need for a systematic approach to address the problem. In this work, modular optimization approach which breaks a large optimization problem into small models is proposed. Each model consists of a process unit and its alternatives (i.e., biomass drying, gasification, synthesis processes, etc.) in different degree of modeling details (i.e., white-, grey- or black-box). This allows designer to 'zoom in' on specific key process units, while, the rest of the model remain as black boxes. Thus, it will be able to reduce the computational effort significantly as compared to pure white-box modeling. By using an effective objective function to maximize the economic potential of the overall preliminary conceptual design, selection of the optimum process alternatives/technologies and products as well as integration of heat and power between process units can be performed simultaneously. A case study is solved to illustrate the approach.

Keywords: Integrated biorefinery, process integration, process synthesis, optimization

1. Introduction

Many existing industries, such as pulp and paper, wood and palm oil have the potential to be converted into integrated biorefineries. The most recent development in the synthesis of integrated biorefinery is focusing on the systematic process synthesis and integration (Kokossis and Yang, 2010). In addition, materials and utilities recovery via process integration are also presented (Tock et al., 2010; Baliban et al., 2011). Although the previous works provide reliable solutions to the problem, complex mathematical models and integration approaches are computationally intensive, labourous and required detailed process data. To address these issues, modular optimisation approach is further extended in this work. Modular optimization approach breaks the process synthesis and integration problem of integrated biorefineries into smaller models, each with different level of modeling details (i.e., white-, grey- or black-box). Each process and its alternatives are independent models which linked with the upstream and

downstream processes. With this approach, the complexity of the overall model can be reduced.

In this work, a large retrofit integrated biorefinery problem is decomposed into six distinct simplified material and energy balance models (i.e., existing processing facilities; biomass pre-treatment processes; production of intermediates processes; conditioning of intermediates processes; synthesis of final products; heat and power integration), as shown in Figure 1. Based on the sensitivity of the overall result to the process parameters or based on the amount of process data available, each part can be modeled at different level of detail (i.e., white-, grey-, or black-box). Each model is then linked with another through the material and energy streams. In this work, black-box process model of the existing processing facility is first developed and then linked to the model for an integrated biorefinery.

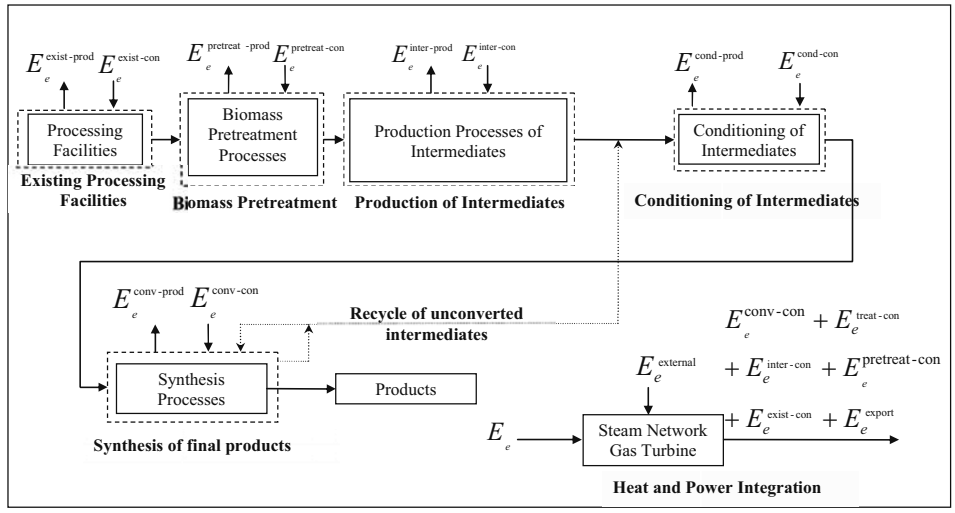

Figure 1: Superstructural Representation of the Retrofit Integrated Biorefinery

2. Problem Statement

Given an existing processing facility with a set of raw material $i^{\text{RM}} \in I^{\text{RM}}$ with the flowrate of $F_{i^{\text{RM}}}^{\text{exist}}$. At a predefined conversion Y_i^{exist} for the raw material processing process to produce the desired product, the existing processing facilities generate a set potential biomass, $i \in I$ with flowrate of F_i. F_i is to be distributed to different biomass pre-treatment technologies $j \in J$ to produce pre-treated biomass $i' \in I'$ at a conversion of biomass to pretreated biomass, $Y_{iji'}$. The flowrate of pre-treated biomass that is ready for production of intermediates is given as $F_{i'}$. In the pre-treatment processes, energy can be consumed or generated. The consumption and generation of energy $e \in E$ per unit of biomass i processed through technology $j \in J$ are given as Y_{ije}^{con} and Y_{ije}^{prod} with the total energy consumed and generated at $E_e^{\text{pretreat-con}}$ and $E_e^{\text{pretreat-prod}}$.

The pre-treated biomass $i' \in I'$ with flowrate of $F_{i'}$ is to be distributed to different biomass conversion technologies $j' \in J'$. Biomass is converted into useful intermediates $p \in P$ at given mass conversion $Y_{i'j'p}$ and the flowrate of intermediates is denoted as F_p. The consumption and recovery of energy $e \in E$ per unit of pre-treated biomass $i' \in I'$

processed through technology $j' \in J'$ are specified as $Y_{i'j'e}^{\text{con}}$ and $Y_{i'j'e}^{\text{prod}}$. The total energy consumption and generation rates of energy at the existing mill are given as $E_e^{\text{inter-con}}$ and $E_e^{\text{inter-prod}}$. In the case where unconverted intermediates p from the synthesis processes or intermediates p that do not meet the requirement of the synthesis processes, they need to be re-conditioned in processes $j' \in J'$ in order to meet the process requirement of the synthesis process. The total flowrate that send for re-conditioning process is denoted as F_p^{Rec}. In most cases, conditioning processes involved additional reactions, separations or pressurisation. Thus, a mass conversion $Y_{pj'',p'}$ is included for the production of conditioned intermediates $p' \in P'$ that meet the specification of synthesis processes. The consumption and generation of energy $e \in E$ per unit of raw intermediates $p \in P$ processed through technologies $j'' \in J''$ are specified as $Y_{pj''e}^{\text{con}}$ and $Y_{pj''e}^{\text{prod}}$. The total energy consumption and generation rates of energy at the existing mill are given as $E_e^{\text{cond-con}}$ and $E_e^{\text{conv-con}}$.

In order to meeting the process requirement of process j''', conditioned intermediates $p' \in P'$ can then be converted to final products, $p'' \in P''$ through synthesis processes $j''' \in J'''$, at the given mass conversion of $Y_{p'j''',p''}$. The consumption and generation of energy $e \in E$ per unit of conditioned intermediates $p' \in P'$ processed through technology $j''' \in J'''$ are specified as $Y_{p'j'''e}^{\text{con}}$ and $Y_{p'j'''e}^{\text{prod}}$. The total energy consumption and generation rates of energy at the existing mill are given as $E_e^{\text{conv-con}}$ and $E_e^{\text{conv-prod}}$.

3. Study Case

In year 2004, Asian Development Bank (2004) found that large part of the wood waste generated by sawmills are disposed as waste. Approximately 50% of the total log processed, in the form of log ends, bark, slabs, saw dusts and lumber edges in wood mills ended up as waste. Therefore, wood industry has huge potential to be converted into integrated biorefinery which produces value-added products (e.g., biofuels, biochemicals), as well as heat and power. Since biomass gasification able to handle various type of feedstock, it is recognized as one of the most promising options for the initial processing of biomass in an integrated biorefinery. To illustrate the propose approach, a gasification-based integrated biorefinery case study adapted from Tock et al. (2010) and Larson et al. (2006) is solved.

3.1. Existing Wood Mill - In this case study, a wood mill with the capacity of 90,000 kg log per day (= 1 kg log/s) is considered. Electricity is consumed in the cutting, debarking and sawing process at 273.6 kJ per kg log processed.

3.2. Wood Waste Pre-treament - As wood waste has high moisture content at 50 wt%, therefore, prior to the gasification process, the wood waste needs to be pre-dried to a moisture content of 25 wt%. As shown in Figure 1, different options of pre-treatment j (i.e., air drying and steam drying) can be taken into consideration.

3.3. Dried Wood Waste Generation - Various biomass gasification technologies are available to convert biomass into syngas. In this case study, different gasification technologies are to be assessed. According to Gassner and Marechal (2009), the product composition and yield of the syngas are often fixed based on type of

gasification technologies. Two types of gasification process *j*' (i.e., direct heated (DHG) and indirect-heated gasification (InDHG)) are taken into consideration.

3.4. Conditioning of Syngas - Syngas produced from biomass gasification may not meet the downstream requirement. Thus, conditioning of the syngas is required. In this case study, water-gas shift and CO_2 removal are identified as the key syngas conditioning processes, apart from the physical cleaning (i.e., filtration) which is not modeled in this work. As syngas composition is crucial for its further use in synthesis processes, water-gas shift (WGS) process is included to adjust the composition of syngas to meet the specification required (i.e., H_2/CO ratio) by additional input of steam.

3.5. Synthesis of Final Products - To further convert the conditioned syngas into final product, synthesis processes such as Fischer-Tropsch (FT) liquids, Dimethyl-ether (DME) and mixed alcohol (Mix-OH) are included in this study. Larson et al. (2006) has carried out an extensive work to simulate various synthesis processes, and their alternative configurations, to produce key biofuels. The synthesis processes consume steams. However, heat from the synthesis reactions can also be recovered to generate ultra-high pressure steam (HHP).

3.6. Heat and Power Integration - With the available data on processes and their alternatives from Sections 3.1 to 3.5, the model can be used to perform heat and power integration. In this case study, electricity (elec), HHP, high pressure steam (HP), medium pressure steam (MP) and low pressure steam (LP) are considered as energy *e*. Excess steam of a higher pressure allowed to be sent to a steam turbine to generate electricity and produce a lower pressure steam.

4. Result and Discussion

The case study is optimized for simultaneous synthesis and integration of a wood mill with integrated biorefinery via commercial optimization software (LINGO, version 10.0, with Global Solver). The result of this case study is presented in Figure 2. As shown, DME is selected as the optimum product. With 1 kg log/s wood mill capacity (0.50 kg/s wood waste), 0.2658 kg/s of DME can be produced. The model simultaneously synthesizes an optimum integrated biorefinery configuration and generates a steam network consisting of HHP, HP, MP and LP steams and gas turbine. Based on the optimum result, the maximum EP is targeted as US$ 0.073/s. Note that 889.8 kW electricity, 0.186 kg/s MP steam and 1 kg/s LP steam are imported in order to meet the demand in the retrofit integrated biorefinery. Note that this model is able to determine the economic performance and serves as benchmark for the detailed design.

5. Conclusion

The modular optimization approach is extended for the simultaneous process synthesis and integration of a sustainable integrated biorefinery with existing processing facilities. The approach allows the overall formulation to be simplified without losing the insights of interest for the effective design and integration of the processes. Based on different optimization objective, the conceptual design of an integrated biorefinery, including the optimum steam and electricity networks can be synthesized.

Abstract

In the current context of a global and very competitive economy, multiple production and distribution activities must be properly coordinated in order to satisfy strict market requirements at the right time and with minimum cost. In typical multi-site systems, products are usually manufactured in one or more factories, moved to warehouses for intermediate storage, and subsequently shipped to retailers or final consumers. In turn, cross-docking platforms may be also used to consolidate multi-product customer demands without storing at intermediate depots. Consequently, the effective operation of complex production and distribution networks involves the management of activities performed in multiple factories, distribution centers (DCs), retailers and end users, which are usually geographical spread in many different cities, countries and/or continents. To optimally manage such complex multi-site systems, an integrated MILP-based framework for production and distribution scheduling with cross-docking in supply chains is proposed. In order to illustrate the applicability and effectiveness of the proposed method, a complex example taken from literature is solved to optimality with modest CPU times.
Keywords: MILP-based approach, supply chain management, cross-docking, logistics.

1. Introduction

Production and transport issues constitute a central activity to be considered within any multi-site manufacturing system. From the operational perspective, both problems have been traditionally treated separately and independently from any supply chain (SC) environment. Numerous efficient methodologies have been proposed in the literature to address the short-term production scheduling problem in the chemical industry. Also, a wide variety of vehicle routing problems have been extensively analyzed and solved by the communities of Operations Research and Process Systems Engineering. Numerous exact and heuristic algorithms have been proposed, focusing mainly on the individual and geographical aspects to reduce high delivery costs. The decoupled production and distribution processes rely on finished goods inventory to buffer both operations. However, higher inventory costs and the trend to operate in a just-in time manner are putting pressure on firms to reduce stocks in their distribution chains. Besides this, many big companies are not only manufacturing the demanded products but also distributing them to the customer location at a given due date, which implies a proper consideration of complex temporal and capacity interdependencies arising between production processes and transportation activities. The efficient synchronization of these complex systems remains as an open and challenging area for research. Only few contributions have been reported so far in this direction, and most of them are mainly focused on the integration at the strategic and tactical levels.

This paper introduces a new optimization approach to the integrated operational planning of multi-echelon multiproduct production and transportation networks with cross-docking platforms for shipment consolidation.

2. Problem Description

Distribution systems comprising multiple factories and warehouses as supply points with product stocks located at both kinds of facilities and the shipments going directly from manufacturers or via warehouses to customers. Thus, the problem addressed in this work is focused on a two-echelon distribution system where a set of nodes involving factories, warehouses and customer locations is considered. The warehouses act as intermediate locations between factories and end customers to both facilitate the consolidation of shipments from different suppliers and meet customer demands. Consolidation consists of combining shipment of similar or different products from several origins at the distribution center -DC-. A customer order may include several products often available at different production sites. Then, the consolidation of shipments from multiple suppliers to intermediate DCs should be made before reaching the customer location. In this work, a transportation infrastructure that allows: (i) direct shipping (ii) shipping via DC, including cross docking and (iii) combination of both types of shipment, is considered. Only one vehicle can stop at each customer site to satisfy every request but several vehicles can stop at the same manufacturing site or warehouse to accomplish pickup or delivery operations. The cross-docking facilities are located in intermediate sites. In turn, this work may also consider flexible time windows. The proposed approach provides a detailed set of coordinated production and distribution schedules to meet all product demands at minimum total transportation cost. In the following section we will introduce a new MILP-based continuous time formulation for the integrated production and distribution problem with cross-docking in supply chain.

3. Problem Formulation

The MILP-based model is divided in three blocks of constraints. The first one corresponds to production scheduling constraints where general allocation, sequencing and timing constraints are considered. The second block comprises the set of constraints to integrate both production and distribution schedules. Finally, the last one considers constraints for dealing with the distribution scheduling problem. In this paper, only the constraints related with cross-docking operation will be developed.

In the integration of production and distribution, the amount of product p loaded by vehicle v is computed by Eq.(1):

$$LOAD_{p,v} \leq \left(\sum_{b \in B} A_{b,v}\right) + AI_{p,v} + \left(\sum_{v' \in V} AV_{p,v,v'}\right) \tag{1}$$

The amount of product p unloaded by vehicle v in warehouse i can be used by all vehicles housed in node i, which is represented by Eq.(2). Eq.(3) defines a new binary variable to determine whether vehicle v' pick-ups goods delivered by vehicle v.

$$UNLOAD_{i,p,v} \geq \sum_{v' \in VB_i} AV_{p,v',v} \tag{2}$$

$$bm * BAV_{v',v} \geq AV_{p,v',v} \qquad \forall\, p \in P, v \in V, v' \in V: v \neq v' \tag{3}$$

The Eq. (4) and (5) computes the earliest start time of every trip.

$$STV_v \geq \left(\sum_{p\in P} LOAD_{p,v} * vvt_v\right) + FT_{b,i} - bm * (1 - Z_{b,v}) \qquad \forall\, i \in F_i, v \in VB_i, b \in B \tag{4}$$

$$STV_{v'} \geq TV_{i,v} + \left(\sum_{p\in P} UNLOAD_{i,p,v} * vvt_v\right) + vft_v + \left(\sum_{p\in P} LOAD_{p,v'} * vvt_{v'}\right) - bm * (1 - BAV_{v',v}) \tag{5}$$

$$\forall\, i \in W_i, v \in V, v' \in VB_i : v \neq v'$$

To maintain the inventory level, the total amount of product *p* loaded by vehicle *v*' in warehouse *i* is enforced to be equal to the amount of product *p* unloaded by other vehicles in node *i*, which is represented by Eq. (6).

$$\sum_{v\in V} UNLOAD_{i,p,v} = \sum_{v' \in VB_i} LOAD_{p,v'} \qquad \forall\, i \in W_i, p \in P \tag{6}$$

The Eq. (7) is the objective function which aims at minimizing the total cost of production and distribution as well as the total tardiness.

$$\begin{aligned} Min \left(\sum_{b\in B}\sum_{u\in U}\sum_{i\in F_i} setupC_u * X_{b,u,i}\right) + \left(\sum_{p\in P}\sum_{u\in U}\sum_{b\in BP_p} TB_{b,u} * pc_{p,u}\right) + \left(\sum_{r\in R}\sum_{v\in V} H_{r,v} * vfc_v\right) \\ + \left(\sum_{i\in(F_i\cup W_i)}\sum_{r\in R}\sum_{v\in V}\sum_{ii\in I}\left(IN_{ii,r,v} * dist_{i,ii} * vvc_v + FI_{ii,r,v} * dist_{i,ii} * vvc_v + \sum_{iii\in I} PR_{ii,iii,r,v} * di.\right.\right. \\ + \sum_{i\in I} co * TSB_i \end{aligned} \tag{7}$$

3.1. Nomenclature

Sets: B batches; BP_p batches of product p; I nodes; F_i factories; FU_i set of production units that operate in i; S_i customers; P products; U production units; V vehicles; VB_i set of vehicles housed in operational base i; W_i warehouses.
Parameters: $dem_{i,p}$ amount of product p demanded by node i; $dist_{i,ii}$ distance between node i and node ii; $inv_{i,p}$ initial stock of product p in node i; $pc_{p,u}$ processing cost of product unit p in production unit u; $setupC_u$ setup cost of production unit u; vvc_v unit distance cost for vehicle v; vfc_v fixed cost of using vehicle v; vft_v fixed stop time of vehicle v in every visited node; co represents the penalty cost per unit tardiness at each node.
Positive Variables: CTV_v overall traveling cost for vehicle v; $CV_{i,v}$ travel cost up to node i for vehicle v; $FT_{b,i}$ end time of batch b in the node i; $ST_{b,i}$ initial time of batch b in node i; STV_v departure time of vehicle v; TSB_i time window constraint violation to arrivals after delivery date; $TV_{i,v}$ travel time up to node i for vehicle v; TTV_v total routing time for vehicle v; $A_{b,v}$ amount of product p from batch b loaded in vehicle v; $AI_{p,v}$ initial stock of product p allocated to vehicle v; $AV_{p,v,v'}$ amount of product p unloaded by vehicle v' and then loaded by vehicle v; $LOAD_{p,v}$ amount of product p allocated to vehicle v; $TB_{b,u}$ batch size of b in processing unit u; $UNLOAD_{i,p,v}$ amount of product p unloaded by vehicle v in node i. Binary Variables: $BA_{v,v'}$ the vehicle v loads goods delivered by vehicle v'; $FI_{i,v}$ node i is the last one visited by vehicle v; $IN_{i,v}$ node i is the first one visited in the route of vehicle v; H_v vehicle v is used; $PR_{i,ii,v}$ node i is visited right before node ii in the route of vehicle v; $VA_{i,v}$ node i is visited by vehicle v; $X_{b,u,i}$ determines if batch b is processed in the production unit u of node i; $Y_{b,bb,i}$ sequencing of batches processing in factory i; $Z_{b,v}$ batch b is assigned to vehicle v.

4. Computational Results

The example presented here corresponds to a supply chain comprising 16 locations (2 factories, 2 DCs and 14 end customers) geographically spread in six European countries. Up to six vehicles are available to carry out the required distribution activities of three different products (P1, P2 and P3) in a cost-effective way.

Each manufacturing plant has two production units to process batches with variable size. The factory housed in Barcelona can manufacture products p2 and p3 whereas in the factory located in Bratislava only p1 and p2 are produced. Production features are described in the Table 1.

Table 1. Production Features

factory	*production unit*	*capacity*		*setup cost (€)*	*production cost (€/units)*			*setup time (h)*	*production time(h/units)*		
		min	*max*		*p1*	*p2*	*p3*		*p1*	*p2*	*p3*
Barcelona	A	50	600	10	-	10	15	0.5	-	0.1	0.1
	B	50	600	10	-	10	15	0.5	-	0.1	0.1
Bratislava	C	50	600	10	18	9	-	0.5	0.1	0.1	-
	D	50	600	10	18	9	-	0.5	0.1	0.1	-

The distribution centers are situated in Madrid and Stuttgart. Six vehicles V1-V6 are available to transport lots of three different products from the bases where they are housed. Each type of product has a different weight and volume. Finally, an initial inventory of finished goods is available in both manufacturing plants and distribution centers. Besides, each end customer has a specific demand that must be satisfied. Problem data is summarized in Table 2.

Table 2. Vehicles Features

The optimal integrated logistics program generated by the proposed MILP-based model is depicted in Fig. 1. Detailed coordinated production and distribution schedules are also tabulated. The example was solved with modest computational effort using GAMS 23.5.2 and CPLEX 12 in a Core Quad PC. A relative optimality tolerance of 0.001 was adopted.

5. Conclusions

In this work an integrated MILP-based framework for production and distribution scheduling with cross-docking in supply chains has been proposed. The formulation developed can be applied to solve complex logistics problems in a reasonable computational time, providing a very detailed set of coordinated production and distribution schedules to meet all products demands at minimum total production and transportation cost.

Abstract

Industrial Symbiosis (IS) is an innovative approach that brings together companies from different sectors in an effort to improve resource efficiency. This paper introduces a semantically enabled web platform that supports and automates the application of IS. The platform is based on the semantic formalisms for the waste and processing technology classifications, further supported by the semantic web services technology in the process of establishing synergies.

Keywords: Ontology, Semantic Web Services, Industrial Symbiosis.

1. Introduction

Industrial Symbiosis (IS) is an innovative approach that brings together companies from different business sectors to process waste into energy and/or material, including water. The process is done with a view to generate revenue and, at the same time, allow for a sustainable management of industrial waste and by-products, as well as municipal waste. Creating a synergy between these companies to form economically, environmentally and socially viable supply chains is a challenging task that requires in-depth knowledge on waste and respective processing technologies. A research study on existing IS systems (Grant et al. 2010) shows that the current process of IS is practiced manually with performance which intuitively depends on practitioners' ability and hence is difficult to apply in rapidly increasing industrial diversity. The input/output matching is mainly accomplished through brute force investigation, serendipitous discovery, organized workshops or coordinated search (Chetrow et al, 2000). The manual operation also results in higher costs and is prone to high inaccuracy in identifying opportunities for synergies. This paper presents the design of a semantically enabled web platform ("eSymbiosis[1]") that supports and automates the operation of IS with the focus on opportunity identification and synergy management. The platform is based on the semantic formalisms for waste and processing technology classifications and characterization which is further expanded by Semantic Web Service (SWS) technology to support the process of establishing synergies. As such, the platform is an affordable and customizable service which improves the companies' planning and decision making for establishing synergies. Industries are presented with more potential choices and opportunities for processing, re-using and replacing their resources and reducing operational costs.

[1] partly funded by eSymbiosis LIFE09 ENV/GR/000300 Project

challenging task (Massard et al., 2006). Current knowledge bases only represent what is known as explicit knowledge and fail to capture the tacit knowledge which is essential for identifying symbiotic synergies. The eSymbiosis platform exploits Semantic Web Technologies in general and ontologies in particular as its "backbone" to enable the presentation of both explicit and implicit knowledge which would allow for intelligent synergy identification. Ontologies, as formalism for knowledge representation, are used to model domain knowledge of IS with a view to support both user registration process and the process of matching partners and ranking the potential synergies by their semantic relevance. SWS technologies are used to describe all participants semantically as services and hence enable semantic and automated matching and possibly composition to form viable synergies. eSymbiosis adopts the Ontology Web Language(OWL) to represent both ontologies and SWS descriptions.

1.1. Ontologies and knowledge representation

An ontology O is defined by its set of concepts C organized in corresponding subsumption H_C, established relation R_C between concepts also organized in a hierarchy H_R, entities I with respective fillers R_I for relations, and axioms A used to infer knowledge from existing ones:

$$O=\{C,H_c, R_c, H_r, I, R_I, A\}$$

Here, the subsumption of concepts has four levels of abstraction; the meta ontology, the upper ontology, the domain ontology and the application specific ontology, as shown in Figure 1 (Trokanas et al, 2011).

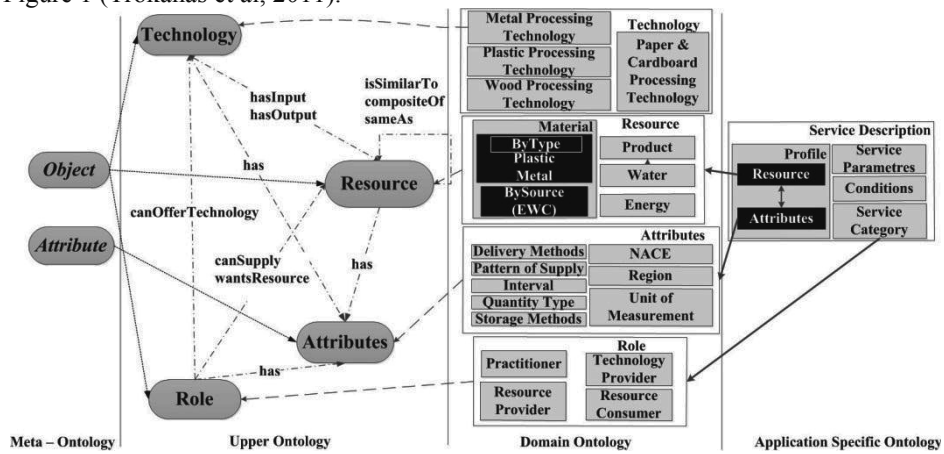

Figure 1 The Conceptual Model

1.1.1. Meta-Ontology

The meta-ontology makes the whole ontology easier to share and reuse (Marquardt et al., 2010). This is achieved by defining general purpose concepts that are independent of the domain and can be applied universally (Action, Role, Entity etc.).The eSymbiosis meta-ontology consists of two general concepts "Object" and "Attribute". Objects are all the tangible assets related to IS practice i.e. a waste or technology. Attributes are the information that define the objects such as physical form, industry codes etc.

1.1.2. Upper Ontology

The upper level of the eSymbiosis ontology includes abstract and general concepts that have application in the IS domain, but also in wider domains such as Industrial Ecology. Resources are the materials, waste, energy, products, water and expertise that a user

might have or want. The Technology concept represents the processing technologies that can process resources (inputs) and produce some others (outputs). The Role concept is very "IS specific" as it represents the different types of users that can take part in the establishment of a symbiotic synergy. Finally, the Attributes concept represents all the additional necessary information of the IS domain including units of measurement and geographical information. This level also includes high level properties that provide the relationships between those concepts such as Technology "hasInput" Resource, which links a technology with the possible inputs (materials, energy, water or products).

1.1.3. Domain Ontology

The domain of IS knowledge is represented with the use of two main ontology models; the Resource and the Processing Technology. The Resource ontology is the core concept of IS practice as it is currently in use and consists of three different classifications. The first (classification by source) is currently in use by IS practitioners. The two other classification are based on products and type of materials. The former helps users with no expert knowledge to classify their waste such as plastic bottle and the latter serves as the main classification of the system as all other concepts are linked to this classification by object properties such as "*hasComposite*". These two classifications are an innovation of eSymbiosis which aim to provide a better service, user experience and identify synergies that would otherwise remain unexplored. The Technology ontology aims in helping IS practice advance by moving one step further, taking into account not only available or requested resources, but also available technologies that can process certain resources into different type of material or energy. The combined use of these two models constitute eSymbiosis as an important planning and decision making tool for sustainable development.

1.1.4. Application Specific Ontology

This level serves features of a specific application. In the case of eSymbiosis, this level includes the service description ontology as explained in the following section.

1.2. Registration Process and the Service Description Ontology

Registration with the eSymbiosis platform is done through a dynamic web portal which is created "on the fly" from the domain ontology which coordinates the whole process. Users are provided with a set of standardized vocabulary (ontology concepts) to describe their resource or technology. While this approach eliminates any syntactic issues that might arise by the use of synonyms, acronyms and "jargon" terminology, it also provides users with greater amount of data than could help them explain their resources. The user can choose one of the three different ways available to classify a resource as explained in section 2.1.3 and from there is navigated through the ontology concepts and properties along with the restrictions on every concept. The data entered by the user is stored as instances within the ontology. The system then creates a semantic service description for every user based on those instances. The eSymbiosis Ontological formalism used for semantic service description is based on universally recognized OWL-S framework (Martin et al. 2004). Every user will be an instance of the OWL-S ontology which has been modified to incorporate properties related to the IS resources, specifically the ones which will be used for finding potential synergies. Some of these properties include the type of resource, quantity, pattern of supply, storage method, annual cost, period of availability, validity format, delivery method and the location where the resource resides. This information is presented in the format of data properties attached to the resource concept. The value assigned to these properties are either numerical or point to a concept within the domain ontology. The semantic service

description for every user results in a machine understandable representation of industries and therefore allows the automation of processing their information

1.3. Synergy Identification (matching)

The process of creating a synergy between two different industries to enable reuse of by-products could be translated to a "matching " process within the eSymbiosis environment. Semantic relevance between waste and technology providers is established by matching respective description ontologies using the purposely designed inference engine and ontology matchmaker (Tara Raafat et al ,2011). The Matching process is performed in stages and includes different levels, as shown in Figure 2. The subsumption matching is pure logical match and the distance measurement is based on graph theory distances. Both of these levels work directly on the domain ontology and take into consideration the resource concepts which are provided or processed by the user. The data property matching takes into account all attributes associated with the resource as explained in 2.2. Based on semantics, the matching process will extract/discover not only the ideal matching industries (e.g. a technology that processes exactly what the requester produces as waste) but also matches which are able to partially satisfy the requirement or if combined with other results are capable of fulfilling the requirement. Furthermore using inferred knowledge from the ontology through properties such as "*hasApplicationIn*"; where material is associated with industries that could benefit from it, the system is capable of offering the user with alternative synergy possibilities. Final ranking of discovered synergies accounts for economic, environmental and social factors. Requesters are also provided with estimations on performance improvement prior to the establishment of the synergy to aid their decision making.

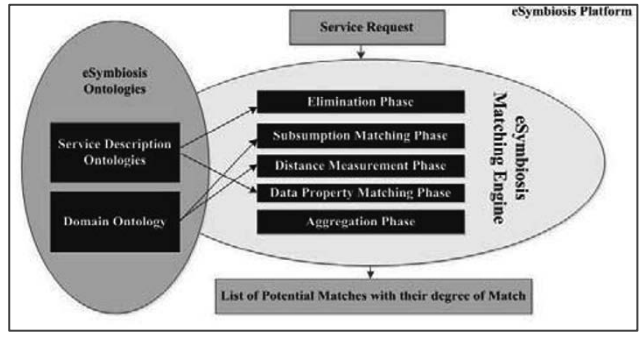

Figure 2 eSymbiosis Matching Engine

2. Use Case Validation

The platform has been validated against a set of test cases that have been developed based on data extracted from representative process industries located in the target region. One Scenario is represented in Figure 2. We assume a region with four different types of available waste registered with eSymbiosis and four available processing technologies. The platform can identify synergies between the users that have a high semantic relevance and rank them based on the degree of relevance. In the case of the Canteen Food waste for example, the food recycling technology gives a 60% match while the composting only a 40%. Both scores are low which is due to the fact that the waste cannot be completely processed by any of these technologies but each technology is capable of processing part of this waste which means they can be presented as a partial match. The use of the platform as a planning tool also supports the introduction

of new processing technologies in areas that have an excess of certain types of waste. In this case the canteen food waste does not have a match that can be turned into a synergy and therefore, the system suggests the introduction of an anaerobic digestion processing technology - a technology that can process both food and packaging waste. The introduction of such a technology will lead to a symbiotic synergy with a high matching score. Moreover, this technology will also have the potential to process other waste such as municipal waste that are not fully exploited. The results indicate that the eSymbiosis platform can be used as management tool for environmental planning and also for the promotion of sustainable development which is the aim of IS.

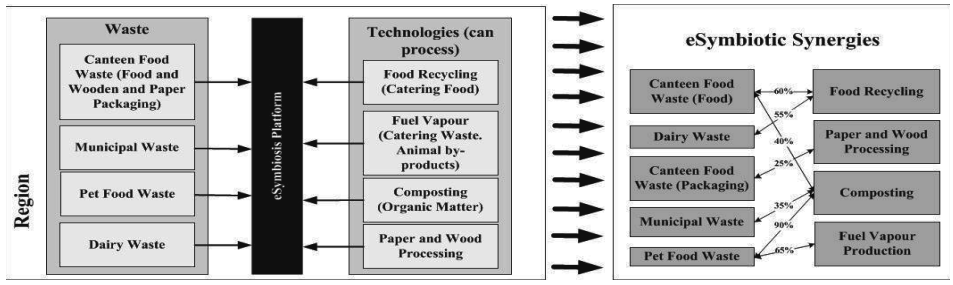

Figure 3 Symbiotic Synergies and innovative solutions

3. Conclusions and Future Work

The eSymbiosis system aims to enhance the semantic matching process and increase the accuracy of matches to the maximum possible level, to enhance and automate the creation of synergies between potential industries aiming to reduce the consumption of natural resources (raw materials, energy, and utilities), the environmental strain and the waste stream to landfills. The semantic approach furthermore allows coping with the constant emerging and changing systems. The current system will be expanded to allow feeding new knowledge gained through successful synergies into the ontology achieving continuous improvement and update of the system.

Modeling and Optimization of Superstructure-based Stochastic Programs for Risk-aware Decision Support

John D. Siirola,* Jean-Paul Watson

Discrete Math and Complex Systems Department; Sandia National Laboratories; Albuquerque, NM, USA

Abstract

This manuscript presents a unified software framework for modeling and optimizing large-scale engineered systems with uncertainty. We propose a Python-based "block-oriented" modeling approach for representing the discrete components within the system. Through the use of a modeling components library, the block-oriented approach facilitates a clean separation of system superstructure from the details of individual components. This approach also lends itself naturally to expressing design and operational decisions as disjunctive expressions over the component blocks. We then apply a Python-based risk and uncertainty analysis library that leverages the explicit representation of the mathematical program in Python to automatically expand the deterministic system model into a multi-stage stochastic program, which can then be solved either directly or via decomposition-based solution strategies. This manuscript demonstrates the application of this modeling approach for risk-aware analysis of an electric distribution system.

Keywords: Superstructure optimization, Generalized disjunctive programming, Stochastic programming

1. Introduction

Process design and expansion planning are cornerstones of the Process Systems Engineering literature. While there are many challenges involved in design and planning, a central issue is managing discrete choices throughout the process: which chemical pathway to exploit, how many trays in a distillation column, how to arrange columns in the separation train, where to build the plant, where to site the distribution system, et cetera. In each of these examples, one approach to the problem is to systematically construct a superstructure of all possible discrete alternatives and then rely on a numerical optimization algorithm to select the best realization (Grossmann, 1996). While conceptually straightforward, actually implementing the superstructure as a mathematical program is an arduous task that requires careful bookkeeping. Further complicating the design problem is that the decision-maker must at some point make these discrete decisions in the face of uncertainty (e.g., material prices, demands, and construction times). Again, while systematic approaches exist for expanding the deterministic model into a stochastic model, the process is rather tedious and typically implemented by hand as a "one-off" activity.

In this manuscript we present a unified, systematic infrastructure for modeling and solving superstructure-based stochastic optimization problems based on the Pyomo[1] open source

*jdsiiro@sandia.gov

[1]Pyomo: *Python Optimization Modeling Objects:* `http://software.sandia.gov/pyomo`

optimization modeling environment (Hart et al., 2011). Pyomo provides native Python support for expressing structured models, and includes extensions for Generalized Disjunctive Programming (Raman and Grossmann, 1994) with standard automated transformations for both Big-M and Convex Hull relaxations (Lee and Grossmann, 2000). Pyomo provides "block-oriented" algebraic modeling facilities that allow the modeler to explicitly represent the superstructure and connections independently of the actual equations and variables employed within the individual sub-components. This separation greatly simplifies model management, allowing the modeler to easily substitute different component representations or propose new superstructures. Further, the open nature of the modeling environment facilitates the construction of custom optimization algorithms that can directly leverage the block structure of the superstructure model. Finally, we address model uncertainty via the PySP[2] stochastic programming package (Watson et al., 2012). PySP is built on Pyomo and can automatically generate the extensive form of a stochastic program given a deterministic Pyomo model and a characterization of parameter uncertainty. Additionally, it provides a general implementation of the Rockafellar and Wets (1991) Progressive Hedging scenario-based decomposition algorithm, including extensions for problems with discrete decision variables (Watson and Woodruff, 2011).

We demonstrate our approach through a series of operational and planning models for the electricity grid: (stochastic) unit commitment, $N-1$ reliability, and combined generation/transmission multi-period expansion planning. In these examples, we model both operational and investment decisions as disjunctive alternatives. Both generating technologies and transmission segments are modeled as discrete blocks, completely separating the distribution superstructure from the individual components. This separation allows us to rapidly explore alternative transmission approximations (e.g., DC or AC power flow, with or without line loss) and different generation technologies (e.g., new carbon sequestration and/or renewable generation technologies). Our approach also facilitates the rapid conversion of the superstructure to different structural simplifications (e.g., single bus, aggregated buses, full network model).

2. Modeling Approach

A significant challenge in constructing optimization models for engineering decision support is the dichotomy between the graph-like structured representation used to describe the engineering problem and the general algebraic form required by most optimization algorithms. To address this challenge, we formulate superstructure optimization models using "equation blocks" in Pyomo. A Pyomo equation block is a collection of modeling components (e.g., variables, parameters, constraints, and sub-blocks), and has many features in common with other block-oriented optimization modeling environments (notably JModelica.org[3]; Åkesson et al., 2010). A block represents a single component in the system and consists of the constraints, parameters, and variables that describe the behavior of that component. Individual blocks then form the "nodes" in the graph-like engineering representation of the superstructure. To facilitate connecting a block (component) to other blocks in the superstructure model, each block declares a series of "connectors" and associates each connector with one or more variables local to the block. Arcs in the original superstructure are simply equality constraints between two block connectors.

[2]PySP: *Python Stochastic Programming:* `http://software.sandia.gov/trac/coopr/wiki/PySP`
[3]JModelica.org: `http://www.jmodelica.org/`

This mechanism provides a powerful separation of concerns: the definition of the system superstructure relies only on the list of blocks and connectors, and is independent of both the component constraints and the variables that are associated with the connectors. Modelers can then develop and leverage libraries of components and substitute different component models using the same superstructure definition, provided the components all declare the same set of connectors.

We additionally leverage the Pyomo block modeling capabilities to implement key switching decisions within the superstructure model using Generalized Disjunctive Programming. Conceptually, a disjunct (single term within a disjunction) is a block of constraints that are enforced based on the logical value of an associated indicator variable. The `coopr.gdp` extension to Pyomo implements this as a specialized type of block and provides an additional constraint type for expressing the "exclusive or" relationship among the blocks in a disjunctive expression. This supports both directly modeling the switching decisions in the superstructure using disjunctive programming and creating specialized switchable components using disjunctions nested within a component block.

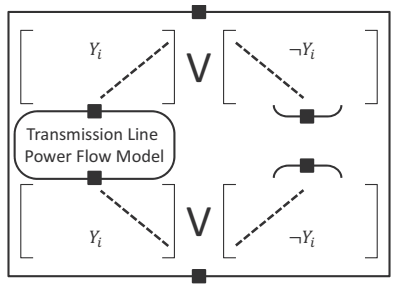
Given a superstructure model, Pyomo transforms the nested block structure into a "flattened" mixed-integer (non-)linear program via two steps. First, Pyomo expands expressions involving block connectors by replicating the expression for corresponding variables within the connectors. The `coopr.gdp` extension then relaxes each disjunction using either a Big-M or Convex Hull transformation (as specified by the user). The result is a deterministic mathematical program equivalent to the original superstructure optimization problem, suitable for input to a standard solver.

To capture uncertainty in the superstructure model, we leverage the PySP package to convert the (single scenario) deterministic model into a multi-scenario stochastic model. PySP takes as input a deterministic Pyomo model and a description of the system uncertainties expressed as a scenario tree. PySP then creates individual instances of the superstructure model corresponding to each scenario. If the problem is sufficiently small, PySP can generate the extensive form of the stochastic problem by including each scenario instance as a sub-block in a master problem and adding the appropriate constraints to enforce non-anticipativity. For larger problems, PySP provides an implementation of Progressive Hedging that iteratively and gradually enforces non-anticipativity across the scenario sub-problems.

3. Case Study: Electric Grid Operation and Planning

To demonstrate the utility of the proposed framework, we consider the case of electricity grid operation and expansion planning. This illustrative example possesses many of the features observed in process industries, including multiple candidate component models (e.g., AC and DC power flow models), multiple potential design and operational goals (e.g., cost and reliability), and significant system uncertainty (e.g., demand and production from renewable sources). This example also has a significant advantage as a case study: there are accepted constituent models that vary in complexity from linear (DC power flow) to non-convex nonlinear (full AC power flow). For this case study, we will consider the following aspects of the problem: short-term unit commitment (UC), $N-1$ reliability constraints, and combined generation-transmission expansion (CGTE).

Three fundamental modeling components are common to each of these problems: a node (bus), a transmission line, and a generation/load entity. Given an assumed underlying constituent model (e.g., DC power flow), we form a block definition for each component.



(a) conceptual disjunctions

```
def switchable_line(model, line):
  line.pf_model = Block(rule=DC_line_model)
  line.IN = Connector(dup=line.pf_model.IN)
  line.OUT = Connector(dup=line.pf_model.OUT)
  def active_rule(model, disjunct):
    disjunct.line_in = Constraint(
        expr=line.IN == line.pf_model.IN )
    disjunct.line_in = Constraint(
        expr=line.OUT == line.pf_model.OUT )
  line.active = Disjunct(rule=active_rule)
  def inactive_rule(model, disjunct):
    disjunct.line_in = Constraint(
        expr=line.IN == model.NO_FLOW )
    disjunct.line_in = Constraint(
        expr=line.OUT == model.NO_FLOW )
  line.inactive = Disjunct(rule=inactive_rule)
  line.switch = Disjunction(
      expr=[line.active, line.inactive] )
```

(b) implementation in Pyomo

Figure 1: General switchable components. Forming disjunctions over the connections preserves the separation between the component models and the network superstructure.

Node models are perhaps the simplest, as they must only enforce Kirchhoff's current law (conservation of charge). Transmission line models range from a simple 3-variable linear equality constraints (in the case of DC power flow) to multiple non-convex non-linear expressions (for AC power flow with line losses). Similarly, generator models may range from a simple constant power injection term to a full active / reactive power model with internal constraints for ramp rates, costs, emissions, and environmental impacts.

For the first problem (UC), we construct a straightforward optimal power flow (OPF) model by connecting these basic building blocks into a network through the use of connections (equality constraints between component block connectors). To model unit commitment, we replicate (index) the OPF model for each scheduling time period. An additional set of connections associate generator blocks across time, allowing the generators to enforce time-dependent constraints (e.g., ramp rates). We note that the UC model is completely independent of the model selected to represent the base OPF components.

For the second problem ($N-1$ reliability), we begin with the UC model and replace the transmission and generation component models with corresponding *switched* component models. However, unlike other power flow switching models (e.g., Hedman et al., 2010), we do not modify the model equations directly. Instead, we form disjunctive constraints over the *block connections* (e.g., see Figure 1), preserving the separation between the model structure and the component implementation. Following Hedman et al. (2010), we replicate the switched UC model for each contingency, with the disjunctive indicator variables fixed to *True* or *False* corresponding to the failure state of each component in each contingency. While the use of "fixed" disjunctions and numerous equality constraints yields a significantly larger raw MI(N)LP model, this complexity is easily reduced through the application of relatively straightforward presolve steps before handing the model to the optimization engine.

The third example addresses combined generation-transmission expansion planning. For this problem, we posit a superstructure of possible generators and transmission by adding additional switched components (transmission lines and generators) to the base OPF

model. Replicating the superstructure model similarly to the method used for generating the UC model (using significantly longer time steps) results in a deterministic multi-period CGTE model. Finally, we combine demand and cost forecasts to generate a family of potential expansion scenarios. Using PySP, we combine the scenario data with the deterministic model to form a large-scale stochastic expansion planning model.

4. Summary

This paper presents a unified software infrastructure for posing and solving large-scale superstructure-based optimization problems. Block-oriented modeling concepts facilitate re-use of core model components and yield model representations that can more closely reflect the "graph-like" nature of the original superstructure. Native support for generalized disjunctive programming expressions and automated transformations simplify the management of switching components in and out of the superstructure. Finally, a general purpose stochastic programming environment facilitates the automated transition from a deterministic superstructure model to a stochastic model for risk-aware analysis.

Accessing Direct and Indirect Effects within a LCA Based Multiobjective Synthesis of Bioproducts Supply Chains

Lidija Čuček,[a] Jiří Jaromír Klemeš,[b] Zdravko Kravanja[a]

[a]*Faculty of Chemistry and Chemical Engineering, University of Maribor, Smetanova ulica 17, 2000 Maribor, Slovenia, e-mail: lidija.cucek@uni-mb.si*

Abstract

This contribution proposes the integration besides direct effects of systems on the environment, also indirect effects caused by system's substitution. The direct effects of systems on the environment represent direct burden of the systems. The indirect effects are set of impacts causing indirect unburden or benefit on the environment.
This approach is applied within two Life Cycle Assessment (LCA)-based concepts - relative sustainability index (*RSI*) and eco-profit (*EP*). Within *RSI* different sustainability indicators are composed using certain weights. *EP* is defined as a difference between unburdening (eco-benefit - *EB*) and burdening (eco-cost - *EC*) the environment. *EP* and economic profit (*P*) can be merged together and the preferred solutions are those with maximal total profit (*TP*). Both concepts are illustrated on the biogas production from different raw materials under different anaerobic conditions. The results indicate that considering total effects enable the obtaining of more realistic solutions, than in those cases when only direct effects are considered.

Keywords: relative sustainability index, eco-profit, LCA, optimisation.

1. Introduction

Sustainability and especially environmental indicators are usually defined on the LCA based principles. LCA is commonly referred to as a "cradle-to-grave" analysis and takes into account the system's full life-cycle. However, LCA methodology still has certain major limitations. Among the limitations are i) the high degree of uncertainty arising from the life-cycle inventory, and ii) the lack of a systematic method for generating and identifying sustainable solutions (Grossmann and Guillén-Gossálbez, 2010; Mele et al., 2011).
This contribution presents two approaches based on sustainability metrics, which overcome the second limitation of LCA. Beside the direct, also indirect effects are included. One approach is based on the relative direct sustainability index (*RDSI*), replaced by relative total sustainability index (*RTSI*). *RDSI* is only composed of direct impacts on the environment and society, whilst *RTSI* also includes the unburdening relating to the substitution of harmful products by newly-produced benign products, and refers to current situations. Note that with this approach, subjective weighting between different environmental and/or social indicators cannot be avoided.
The second approach is an absolute approach and is based on the concept of *EC* (Vogtländer et al., 2010), and on a novel concept of *EP* (Čuček et al., 2012). *EC* is a

measurement for expressing the amount of environmental burden by a product on the basis of preventing that burden, where the calculations are based on LCA. On the other hand, *EP* includes besides burden (*EC*) also unburden (*EB*) on the environment, and is defined as a difference between *EB* and *EC*. The preferred solutions are those with maximal *TP*. *EC*, *EB*, *EP*, and *TP* are expressed in a monetary value per time unit.
Both approaches are illustrated through a case study that is comprised of integrated bioprocesses for the production of biogas from organic and animal wastes, with or without the rendering plant (Drobež et al., 2009, 2011).

2. Direct, Indirect and Total Effects

The direct effects of systems on the environment and society represent the direct burdens of those systems due to the extraction of resources, preprocessing and processing, maintenance, product use, and product recycling and/or disposal, including all transportation and distribution steps. On the other hand, the indirect effects are those sets of impacts that indirectly unburden or benefit the environment. The total effect is the sum of direct and indirect effects.

2.1. Relative Sustainability Index (RSI)

Sustainability usually considers three dimensions: environmental, economic, and social dimensions. Therefore, the *RSI* is composed of economic, environmental, and social indicators (Tallis et al., 2002).

2.1.1. Economic, environmental and social indicators

A key element of sustainability is usually the economic performance of a system. As economic indicators, either yearly profit (*P*) or the net present value (*NPV*) can be used, and maximised, or operating cost, which is minimised.
Environmental indicators are typically grouped into resource usage (material, energy, water and land), and pollution indicators as global warming, atmospheric acidification, photochemical smog formation, human health effect, etc. (Tallis et al., 2002).
The social indicators deal with measuring the quality of life. Social indicators relate to housing and ecology, employment, human rights, poverty, education, health and safety etc., and are usually overlooked since their assessment is not a straightforward task.

2.1.2. Relative sustainability index

Different indicators are expressed within different units, e.g. environmental indicators are usually expressed as a burden per some functional unit. Since their units are different, they cannot be composed unless they are normalized.
A two-level mixed-integer (non-)linear programming (MI(N)LP) system synthesis is performed. At the first level, an economically-effective synthesis is carried out in order to obtain a solution which is then considered as a base-case or reference solution for the multi-objective MI(N)LP synthesis, performed at the second level. The ε-constraint method is applied, and a set of Pareto optimal solutions are generated. When the indicators (I_f) of a studied alternative are compared to those of the selected base-case (I_f^0), relative indicators are obtained, which can then be composed into a *RSI*, by suitable weighting factors (w_f, $\sum_{f \in F} w_f = 1$):

$$RSI = \sum_{f \in F} w_f \cdot \frac{I_f}{I_f^0} \tag{1}$$

where $f \in F$ is a sustainability (economic and/or environmental and/or social) indicator. If only the direct effects on the environment and society are considered, then the *RDSI* is obtained (Eq. 2), and if in addition indirect effects are considered, than the *RTSI* is

obtained (Eq. 3), which shows how much better is *RTSI* than *RDSI* because of the substitution effect:

$$RDSI = \sum_{f \in F} w_f \cdot \frac{I_f^d}{I_f^{d,0}} \tag{2}$$

$$RTSI = \sum_{f \in F} w_f \cdot \frac{I_f^{\mathrm{d}} + I_f^{\mathrm{ind}}}{I_f^{\mathrm{d},0}} = \sum_{f \in F} w_f \cdot \frac{I_f^t}{I_f^{\mathrm{d},0}} \tag{3}$$

where I_f^{d} stands for the direct indicator, I_f^{ind} for the indirect indicator, and I_f^{t} for the total indicator.

Values of *RSI* < 0 are beneficial, while *RSI* > 0 are bad for the environment, and the higher the value, the worse for the environment.

2.2. Eco-Cost, Eco-Benefit and Eco-Profit

The *EC*, *EB*, and *EP* coefficients, defined in monetary unit/time unit, have the advantage of being directly incorporated into the objective function, together with a given economic objective. Therefore the weighting step is not required in the eco-costs system.

EC is an indicator based on LCA and describes an environmental burden on the basis of preventing it. It is a sum of the marginal prevention costs during the life-cycle, the sum of *EC* regarding materials' depletion, the *EC* of energy and transport, and the *EC* of emissions. *EC* are those costs which should be made in order to reduce environmental pollution and material depletion to a level which is in line with the carrying capacity of the Earth (Vogtländer et al., 2010).

EB is defined as a sum of the positive impacts of unburdens on the environment. Positive impacts are related to i) raw materials that mainly benefit the environment when used; e.g. the utilization of waste, since their direct harmful impact on the environment is thus avoided, and to ii) products that benefit the environment, e.g. if they are substitutes for harmful products. They are defined by the substitution factor, as the ratio between the quantity of conventional and produced product.

EP is defined as an analogy with *P*, as the difference between unburdening (*EB*) and burdening (*EC*) the environment, (*EP* = *EB* - *EC*). In the synthesis problem, where i) *P* and *EC* are summed, the preferred solutions are those with maximal net profit (*NP, NP* = *P* – *EC*), and where ii) *P* and *EP* are maximised simultaneously, the preferred solutions obtained are those with maximal *TP* (*TP* = *P* + *EP)*.

3. Industrial Case Study of Biogas Processes

The two above described LCA-based approaches are applied to a case study of the synthesis of biogas processes with the option of rendering plant. The mathematical model of these integrated processes developed by Drobež et al. (2009, 2011) was now upgraded by the *RDSI*, *RTSI*, *EC* and *EP*.

3.1. Relative Sustainability Index

Since the ε-constraint method was applied with *P* in the objective function, the *RSI* was composed only of environmental indicators. For this case study, the social indicators were undefined. A new set *R* for environmental indicators was defined using the elements $r \in R$ = {carbon footprint (CF), agricultural land footprint (ALF), water consumption (WS), nitrogen footprint (NF)}. The environmental indicators were mostly obtained using the LCA software package GaBi® (PE, LBP, 2011) and the Ecoinvent database (Frischknecht et al., 2007). The intention was to obtain solutions with considerably smaller CF; therefore it was decided to take a weighting factor for the CF

1/2 and the same also for the rest of environmental indicators together (ALF, WS and NF):

$$RSI = \frac{1}{2}\cdot\frac{CF}{CF^0} + \frac{1}{2}\cdot\frac{1}{3}\cdot\left(\frac{ALF}{ALF^0} + \frac{WS}{WS^0} + \frac{NF}{NF^0}\right) \quad (4)$$

All the indicators are normalized by their values as obtained at the first level MI(N)LP synthesis (superscript 0). The Pareto optimal solutions were obtained for *RDSI* (Fig 1) from the maximum *P* (3.668 M€/y) and *RDSI* (*RDSI*=1), to a solution with the *RDSI* by the zero *P* (*RDSI* ≈ 0.05). The most economically-optimal solution was the environmentally the worst one, and vice versa. By considering the direct effects only, the obtained solutions were wrong since they indicated that biogas production is unsustainable. By taking into account also indirect effects in *RTSI*, the 'opposite' solutions were obtained, namely biogas production is sustainable alternative along the whole set of non-trade-off solutions within the whole range of *P* – from the maximum *P* (3.668 M€/y) and minimal *RTSI* (*RTSI* ≈ -3.74), to a solution with the *RTSI* by the zero *P* (*RTSI* ≈ -0.15). Those solutions were non-trade-off solutions, since with increasing *P*, even more and more sustainable solutions were obtained. The optimal solution comprised the selection of the thermophilic process and the closed water system.

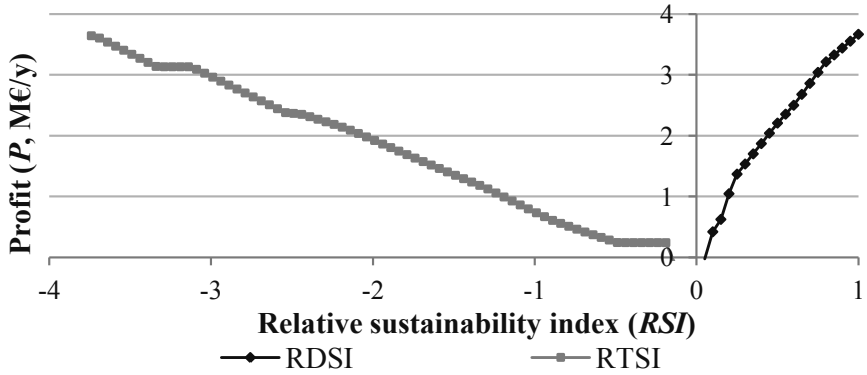

Figure 1. A Pareto curve for *RDSI* and a set of non-trade-off solutions for *RTSI*

3.2. Eco-cost and Eco-profit

Three single-objective optimisations were performed where i) the *P*, ii) the *NP*, and iii) the *TP* were maximised. The obtained results are shown in Table 1.

Table 1: Solutions obtained by maximisation of different profits

	Maximised *P*	Maximised *NP*	Maximised *TP*
Economic profit (M€/y)	**3.668**	0	3.591
Eco-cost (M€/y)	5.306	0	/
Eco-profit (M€/y)	2.667	/	2.917
Net profit (M€/y)	-1.638	0	/
Total profit (M€/y)	6.336	/	**6.508**
Income (M€/y)	7.354	0	7.249
Biogas production (m^3/d)	43,281	0	42,623
The amount of used waste (t/y)	122,861	0	121,180
RDSI | *RTSI*	1 | 1	0 | 0	0.989 | -3.725

In contrast to the non-trade-off solutions of *RDSI*, with *EP* the optimal trade-off could be established at the point of maximal *TP* (*TP* = 6.508 M€/y, with *P* = 3.591 M€/y and *EP* = 2.917 M€/y). The optimal solution included the use of a thermophilic process

converting the liquid pig manure and other substrates with no additional water and the open water system. Also, those raw materials far away from the plant were not selected because of the considerable *EC* of transportation. Note that by the maximisation of *NP*, considering direct effects only, a zero solution with no biogas production was obtained, which indicates that without considering indirect effects, as in *EP*, wrong or even no solutions can be obtained.

4. Conclusion

This contribution presented two multi-objective approaches for sustainable system synthesis based on sustainable metrics: i) a relative approach based on a *RDSI* and *RTSI*, and ii) an absolute approach based on the concept of *EC* and *EP*. These approaches have been performed through a case study of an integrated biogas process and rendering plant. All the results when considering only direct effects on environment showed that biogas production is unsustainable alternative, whilst when considering also indirect effects, the biogas production is a sustainable alternative that benefits the environment. The selection of alternatives that unburden the environment the most would have higher priority than the rejection of those with only smaller burdening impacts.

Abstract

In today's global and competitive markets, managing supply chain disruptions is a key factor in the success of any business. Disruption management, however, can be a challenging issue as disruptions can occur for a wide variety of reasons and the approaches to handle these risks are also ample. Moreover, evaluating the disruption impact and possible treatments is not a trivial task for a complex supply chain with many actors and different types of interactions. This calls for appropriate modeling and simulation frameworks. This paper presents a simulation-based risk analysis approach using an agent-based model and its application for a specific case of a lube oil supply chain.

Keywords: Agent based modeling, risk management, disruption, supply chain.

1. Introduction

A global supply chain faces many types of disruptions in the daily operation. One of suppliers might have an emergency shutdown which leads to the late delivery of raw materials to the plants; the transportation of raw material might be delayed due to difficulties in the shipment or the unexpected rise in customer orders might interrupt the planned operation of a supply chain. All these disruptions can have a significant impact on the performance of supply chain. To make the necessary actions to mitigate supply chain risks, a company needs to have an evaluation of the extent of this impact and also the effectiveness of different alternatives for managing disruptions. This evaluation, however, can be a great challenge; firstly because modern supply chains are highly complex systems consisting of many actors with many forms of interdependencies (physical/social/informational). Moreover, supply chain disruptions can occur for a wide variety of reasons. Likewise, the possible approaches to handle disruption are also ample. For example, to handle the risk of supplier failure, multiple sourcing (Tang, 2006), extra inventory carrying (Wilson, 2007) and demand management (Stecke and Kumar, 2009) are some of possible actions suggested in the literature. With these two challenges, a profound modeling and simulation, which provides decision makers with a flexible test-bed to model different disruptions and disruption management strategies, is a necessity.

Handling disruptions in supply chains takes two different forms: "Mitigation" vs. "Reaction" (Thun and Hoenig, 2009). Some activities and measures are taken by companies beforehand to minimize the exposure to potential disruptions (Mitigation Phase). However, despite all the efforts, disruptive events happen and the influence on the supply chain operation must be managed by defining and implementing appropriate

response (Reaction Phase). The modeling and simulation approaches can be used to support the disruption management process in both phases. The application of agent-based modeling for disruption reaction has been discussed before by Behdani et al. (2009,2010). In this paper, the focus is on mitigation of risk in supply chains. We discuss how an agent-based model can support the disruption assessment and treatment decisions in a chemical supply chain for cases in which the probability distribution of disruption occurrence and an estimation of its duration is available –e.g., based on historical data. The rest of the paper is organized as follows. Section 2 describes a simulation-based supply chain risk analysis approach followed by an illustrative case to elaborate the presented approach. Finally, Section 4 gives some concluding remarks.

2. Simulation-based Risk Analysis Approach

Supply chain disruptions are generally uncertain events happening randomly during the operation of supply chain. Of course, some sources of information such as expert opinion and statistical time series are sometimes available to assess the probability distributions for specific disruptions; however, the exact time of occurrence and the level of severity (e.g., the duration of supplier failure) are uncertain parameters. Considering this issue, the risk analysis approach of this paper is based on repeated simulation of different possible scenarios with an agent-based model (Figure 1). Firstly, based on a probabilistic description of the disruption, we generate disruption scenarios that define the day of occurrence and the duration of a potential disruption. For each scenario, the agent-based model is then used to model different possible disruption management actions and assess the impact of disruption on the supply chain performance. The steps of this approach are discussed in more details in the following.

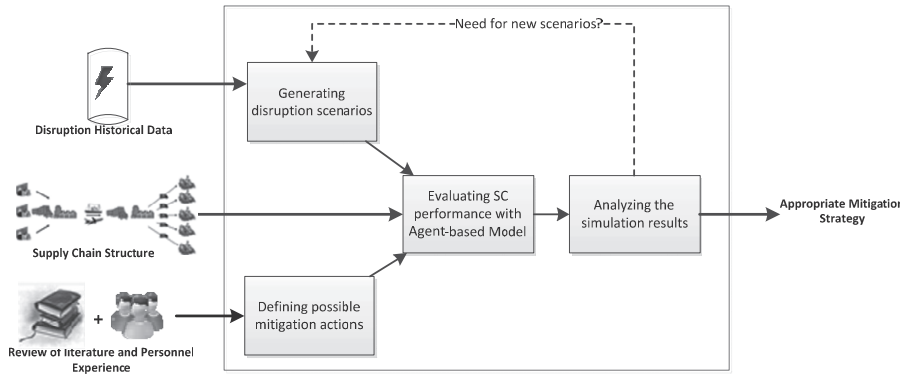

Figure 1. Simulation-based Risk Analysis Approach

Generating disruption scenarios:

A disruption scenario is a description of a particular event and how it is expected to happen and evolve in time in order to be a basis for experimentation with the model. For instance, one disruption scenario could be that a supplier has an emergency shutdown for a 10-day period starting at day 118 and another production stoppage at day 312 which lasts for 5 days. Therefore, each scenario defines the time of disruption occurrence and the severity of disruption.

To define the disruption scenarios, we assume that an estimation of disruption likelihood and its expected magnitude (e.g, the duration) is available. Historic information on supply, demand, cost, lead times etc. can be used to estimate the probability distribution for disruptive events.

As the number of plausible scenarios can be infinite, we start with a random sample of scenarios and based on analysing the simulation results, the decision for defining more scenarios can be made.

Defining possible mitigation actions:
To manage each potential disruption in supply chain, many different responses can be defined and implemented. A good review of supply chain risk mitigation strategies can be found in Tang (2006) and Stecke and Kumar (2009). Expert opinion and personnel brainstorming are other possible sources for defining the risk mitigation actions (Norrman and Jansson, 2004).

Evaluating SC performance with Agent-based Model:
Once a list of mitigation actions is generated, the agent-based model can be used to estimate the impact of disruption under different mitigation actions in each disruption scenario. The structure of model is out of scope of this paper and extensively described in Behdani et al. (2010).

Analysing the simulation results:
With a primary set of disruption scenarios, decision makers can compare the alternative responses and choose the best one for each scenario. Subsequently, the disruption response which is dominant in most scenarios must be determined. However, to be sure that the chosen strategy is a robust strategy and is generally dominant, it is necessary to generate a new sample of disruption scenarios and study the appropriate disruption management action for this new set of scenarios. If new set of scenarios leads to similar best disruption response, it can be selected as the final option to implement. Otherwise, the process must continue with defining a new set of disruption scenarios. With such an iterative process, the final disruption management action can be determined.

3. An Illustrative Case

In this section, the risk analysis approach is illustrated with a case of global lube oil supply chain (Adhitya and Srinivasan, 2010). The supply chain consists of three main components: the focal enterprise, its customers and (raw material) suppliers. This multi-plant enterprise has a global sales department (GSD) that directly interacts with customers and three production plants in different geographical locations. Each production plant itself has several functional departments, each with a specific role and performing certain tasks. Receiving a new order from one customer, the GSD passes the order to the scheduling department of each plant. Consequently, different production plants send their first possible time (FPT) for fulfilling this new order. The GSD then assigns the order to the production plant with the minimum of FPT. If none of the plants is able to produce and deliver the product on time, the GSD starts negotiation with customers for extending the order's due date. Within each plant, the operations department manages the conversion of raw materials to product based on the pre-specified recipe for each product. Following this production step the transportation of the finished order is arranged by the logistics department. Based on this description, an agent-based model with 10 agent types (customer, GSD, production plant, scheduling department, operations department, storage department, packaging department, procurement department, logistics department and supplier) has been developed in Java using Repast simulation platform. The developed model can be used to formulate many experiments related to potential disruptions, study the performance of supply chains

under different scenarios and find effective strategies to handle the effects of possible disruptions. In this paper, we specifically focus on the "Supplier Disruption" which results in the late delivery of raw material orders to the production plants.

3.1. Disruption scenarios

The supply chain is subject to random supplier disruptions. These supplier disruptions are assumed to occur with probability 0.01. The duration of a disruption is also sampled from a triangular distribution with a minimum value of 5 day, a most likely value of 10 days, and a maximum value of 20 days. With these inputs, different scenarios for disruption occurrence are generated. The procedure to generate a disruption scenario is given in Figure 2. First, the occurrence of disruption for each "day" in the simulation horizon (which is one year) is checked and in the case of disruption occurrence, the random duration of disruption is determined. Consequently, each scenario describes the starting date(s) and the duration of supplier failure in one year.

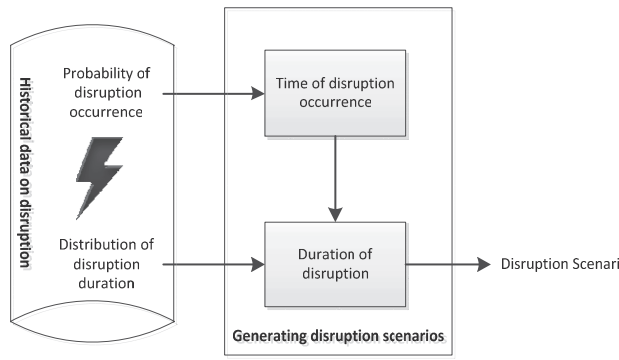

Figure 2. Procedure for scenario generation

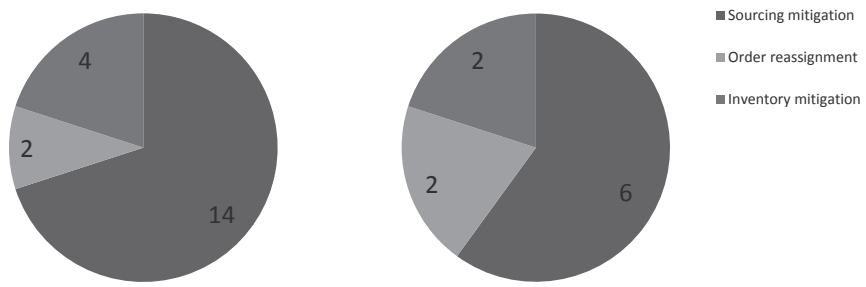
3.2. Disruption management practices

Three strategies to handle supplier disruptions are modelled:

- **Inventory mitigation:** the production plants source exclusively from one supplier but carry some excess inventory to mitigate disruptions (the reorder point is considered 30% instead of 25% for other cases).
- **Sourcing mitigation:** the production plants source from two suppliers; one global low-cost supplier and a second backup supplier for the cases that there is an interruption in the raw material delivery from main supplier (the raw material price for local supplier is assumed 20% higher than main supplier).
- **Order reassignment:** to handle the disruption in supplier, GSD collects the orders from all plants and re-assigns them to the plants considering the new raw material constraint for affected plant.

3.3. Analysis of results

To understand the average system behavior, we started running the model for 20 disruption scenarios. For each scenario, all three strategies are compared with each other and also with the case of no action. Each simulation run yields different results; however, in general the sourcing mitigation strategy was the best choice for managing supplier disruptions in most scenarios (Figure 3). To evaluate the robustness of choosing this strategy, we generated 10 new disruption scenarios and ran the model for each scenario. In these new set of scenarios, the sourcing mitigation was again the best option in 6 disruption scenarios. With this analysis, it can be concluded that sourcing mitigation is the proper strategy to handle supplier disruptions in lube oil supply chain.



(a) (b)

Figure 3. The distribution of best mitigation strategy for: (a) first 20 scenarios; (b) for 10 extra scenarios

Table 1. Effect of disruption management on the enterprise profit (standard deviation in brackets)

	No disruption management	**Sourcing mitigation**	**Order reassignment**	**Inventory mitigation**
Average profit for 20 scenarios	9614726 (1576567)	10822740 (643339)	9730474 (1379282)	10116794 (1098405)
Average profit for 30 scenarios	9520082 (1384050)	10781721 (581979)	9792676 (1287398)	10196026 (947985)

Table 1 shows the mean value for enterprise profit over 20 and 30 scenarios. As can be seen the mean profit for sourcing mitigation is higher comparing with two other options in both cases. Moreover, the "mean" profit is relatively similar for 20 and 30 scenarios which reinforce the argument of selecting *sourcing mitigation* as final choice.

4. Concluding Remarks

In this paper a simulation-based approach for mitigating supply chain disruptions is presented. The presented approach can be used to define different disruption scenarios and evaluate the alternative mitigation strategies for a specific disruption in supply chain. The approach is, however, flexible to include multiple disruptions in defining scenarios if the probability of occurrence and an estimation of the magnitude of disruption are available for all disruptions. This is especially important as in some real cases, one specific mitigation strategy may address more than one potential disruptions. For instance, carrying extra inventory may reduce the risk of supplier emergency shutdown and also transportation disruption due to a port strike.

Abstract

Semi-continuous plants are abundant in bulk manufacturing chemical process industries. However, scheduling of semi-continuous plants has received rather lower attention as compared to batch plants in the literature. In this paper, we develop a novel continuous–time formulation for short-term scheduling of semi–continuous processes using a multi–grid approach. For this, we adopt the unit-slots framework proposed by Susarla et al. (2010) to ensure accurate resource balances. We allow a number of storage configurations (no, constrained, and unconstrained) with either dedicated or multipurpose storage units. Also, we consider various wait policies (no, limited, and unlimited) for all materials. In addition, we consider resources such as utilities, equipment, etc. and allow operational scenarios such as sequence-dependent transition times. Numerical evaluation shows gains in solution efficiency as compared to the literature models in terms of better solutions, fewer variables, constraints and computation time.

Keywords: Semi-continuous plants; unit slots; multi-grid formulation; short-term scheduling.

1. Introduction

Semi-continuous plants are abundant in bulk manufacturing chemical process industries such as consumer goods, polymer, solvent extraction, bulk pharmaceuticals manufacturing, food processing, and beverage. These plants usually produce multiple products in bulk quantities using a pool of shared resources. Dealing with large material quantities and multiple products, semi-continuous plants pose various challenges mainly pertaining to inventory handling, product transitions, and resource utilizations on the manufacturer. Given such a scale and intense of operations, it is not surprising that a large share of total costs are associated with the production operations. Thus, it becomes imperative for the plant management to continuously seek the best operational schedules and strategies for optimally utilizing the plant resources.

Scheduling of batch plants has received a fair amount of attention from the researchers around the globe. On the other hand, scheduling of semi-continuous plants has rather received a limited attention in the academic research. Lim and Karimi (2003) improved and extended the model of Karimi and McDonald (1997) for short-term scheduling of semi-continuous processes based on a multi-grid slot-based approach and introduced the concept of "checkpoints" to ensure correct resource balance. Shaik and Floudas (2007) improved the continuous-time and unit-specific event-points based model of Ierapetritou and Floudas (1998). They imposed a number of timing constraints to ensure correct resource balance and to eliminate violation of storage capacities. Later, Li et al.

(2010) and Shaik and Floudas (2009) showed that many unit-specific based models including Shaik and Floudas (2007) may fall short in ensuring accurate resource balance for a number of scenarios. This creates a need for scheduling models that can efficiently handle both shared resources and industrial scale problems.

In this paper, we develop a novel continuous–time formulation for short-term scheduling of semi–continuous processes using a multi–grid approach. For this, we adopt the unit-slots framework proposed by Susarla et al. (2010) to ensure accurate resource balances. We allow a number of storage configurations (no, constrained, and unconstrained) with either dedicated or multipurpose storage units. Also, we consider various wait policies (no, limited, and unlimited) for all materials. Although we consider only materials and equipments as resources in this paper, our model is also capable of handling other resources such as utilities, manpower, etc. To demonstrate the performance of our model, we solve a number of examples from the literature (including the benchmark example from a consumer goods company) and compare results with other existing models.

2. Problem Statement

A semi-continuous plant (F) comprises of **J** semi-continuous units ($j = j1, j2, \ldots, J$) that perform **I** tasks ($i = i1, i2, \ldots, I$) involving **S** material states ($s = s1, s2, \ldots, S$). A recipe diagram (Susarla et al., 2010) of F gives the information on processing tasks, tasks to unit suitability $\mathbf{I}_j = \{i \mid \text{unit } j \text{ can perform task } i\}$, and mass ratios ($\sigma_{sij}$). R_{ij}^{L} (R_{ij}^{U}) denote the minimum (maximum) rate (mass per unit time) at which unit j can process task i. In case of a task changeover (say, i to i') in a unit j, a sequence-dependent transition time ($\tau_{ii'j}$) is required for cleaning, setup, and attaining steady state or desired output quality. $\tau_{ii'j} = 0$ for $i \notin \mathbf{I}_j$ or $i' \notin \mathbf{I}_j$. With this, the short-term scheduling problem in this paper can be stated as follows. Given (1) the scheduling horizon [0, H], (2) J processing units, their suitable tasks, limits on processing rates, minimum run lengths, transition times, and clean up times, (3) intermediate storage units, intermediate storage policies, initial inventories, and limits on their holdups, (4) cost of or net revenue from the sale of products, we determine (1) the sequence of tasks that each processing unit should perform over time, processing rates, and production quantities, (2) the inventory profiles of all material states and storage units, assuming (1) deterministic operations with no unit failures or operational interruptions, and (2) supply of all raw materials is instantaneous and unlimited. The objective is to maximize a weighted function of product sales.

3. MILP Formulation

We postulate **K** ($k = 1, 2, \ldots, K$) contiguous time-slots (Figure 1) of unknown lengths for each processing unit (j) and storage ($s = s1, s2, \ldots, S$) during [0, H]. Let T_{jk} ($k = 0, 1, \ldots, K$; $T_{j0} \geq 0$, $T_{jK} \leq H$) denote the end time of slot k on processing unit j. The time before the start of slot 1 is slot 0 ($k = 0$). A slot k on a unit j starts at $T_{j(k-1)}$, ends at T_{jk}, and has a slot length $T_{jk} - T_{j(k-1)}$. While each unit or storage has K slots, the slot times (T_{jk} and T_{sk}) may vary across different units and storages. Thus, we use a multi-grid approach, also known as unit-slots approach (Susarla et al., 2010).

We assume that the transfer to a unit or storage always begins at the start of a slot, but may end at any time during the slot. δ_{jk} / δ_{sk} denote the idle time within a slot.

$$T_{jk} \geq T_{j(k-1)} + \delta_{jk} \qquad j1 \leq j \leq J,\ k1 \leq k \leq K \tag{1a}$$

$$T_{sk} \geq T_{s(k-1)} + \delta_{sk} \qquad s1 \leq s \leq S,\ k1 \leq k \leq K \tag{1b}$$

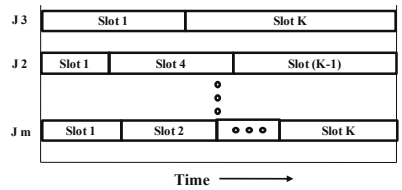

Figure 1 Design of unit-slots

We use the following binary variable (y_{ijk}) and 0-1 continuous variable (ye_{jk}) to denote the allocation of a task to a slot and its end within a slot, respectively.

$$y_{ijk} = \begin{cases} 1 & \text{if task } i \text{ is allocated to slot } k \text{ of unit } j \\ 0 & \text{otherwise} \end{cases} \qquad i \in \mathbf{I}_j,\ i = 0,\ 0 \le k \le K$$

$$ye_{ijk} = \begin{cases} 1 & \text{if the current task allocation ends during slot } k \text{ of unit } j \\ 0 & \text{otherwise} \end{cases} \qquad i \in \mathbf{I}_j,\ i = 0,\ 0 \le k \le K$$

Now, every slot in a unit j must have a task and any slot in a unit cannot have more than one task. So, we write,

$$\sum_{i=0, i \in I_j} y_{ijk} = 1 \qquad k1 \le k \le K \tag{2}$$

Note that we do not write Eqs. 2 for $k = 0$ because y_{ij0} can be fixed based on the status of a unit at time zero. Then, a task may continue its run from k to (k+1), only if it is allocated to both. Here, $ye_{jK} = 1$, as we do not allow any unfinished task at the end of the scheduling horizon.

The length of a slot must be equal to the sum of the processing time (PT_{ijk}) and the idle time (δ_{jk}, if any) within that slot. This gives us,

$$\sum_{i \in I_j} PT_{ijk} + \delta_{jk} = T_{jk} - T_{j(k-1)} \qquad j1 \le j \le J,\ k1 \le k \le K \tag{3}$$

If a task i is not allocated to a slot k of a unit j (i.e., $y_{ijk} = 0$) then the corresponding processing time must be zero. Also, if a task i does not end in a slot k and continues from slot k to k+1, then the idle time in that slot must be zero. Furthermore, we ensure that the length of each run of a task is greater than or equal to the desired minimum.

Next, we define the following 0-1 continuous variable to denote the latest allocation.

$$x_{ijk} = \begin{cases} 1 & \text{if is the latest/current allocation in slot } k \text{ of unit } j \\ 0 & \text{otherwise} \end{cases} \qquad i \in \mathbf{I}_j,\ 0 \le k \le K$$

As a unit processes only one task in any slot, there can be only one latest allocation at any slot. According to the definition of x_{ijk}, if a non-idle task i ($i \neq 0$) is allocated to a slot k of unit j, then i must be the latest allocation in that unit. However, if an idle task (i = 0) is allocated to a slot k of unit j, then the latest task is the last non-idle or a real task ($i \neq 0$) allocated in unit j before slot k. Thus, we write,

$$x_{ijk} \ge y_{ijk} \qquad i \in \mathbf{I}_j,\ k1 \le k \le K \tag{4}$$

$$x_{ijk} \ge x_{ij(k-1)} + y_{0jk} - 1 \qquad i \in \mathbf{I}_j,\ k1 \le k \le K \tag{5}$$

Then, we demand that the idle time in the slot preceding the start of a new task is sufficiently longer to accommodate an appropriate transition time. So, we write,

$$\delta_{j(k-1)} \ge \tau_{i\prime ij}(y_{ijk} + x_{i\prime j(k-1)} - 1) \qquad i, i' \in \mathbf{I}_j,\ i \neq i',\ k1 < k \le K \tag{6}$$

Following the discussion in Susarla et al. (2010) for shared resources, we write the following constraints for material transfers with dedicated intermediate storage.

$$T_{j(k-1)} \ge T_{s(k-1)} - H(2 - ye_{j(k-1)} - \sum_{i \in I_j, \sigma_{sij} < 0} y_{ijk} \qquad j1 \le j \le J,\ k1 \le k \le K,\ s: \sum_{i \in I_j} \sigma_{sij} < 0 \tag{7a}$$

$$T_{j(k-1)} \le T_{s(k-1)} + H(2 - ye_{j(k-1)} - \sum_{i \in I_j, \sigma_{sij} < 0} y_{ijk} \qquad j1 \le j \le J,\ k1 \le k \le K,\ s: \sum_{i \in I_j} \sigma_{sij} < 0 \tag{7b}$$

$$T_{jk} - \delta_{jk} \geq T_{sk} - H(2 - ye_{jk} - \sum_{i \in I_j, \sigma_{sij} > 0} y_{ijk} \quad j1 \leq j \leq J, k1 \leq k \leq K, s: \sum_{i \in I_j} \sigma_{sij} > 0 \tag{8a}$$

$$T_{jk} - \delta_{jk} \leq T_{sk} + H(2 - ye_{jk} - \sum_{i \in I_j, \sigma_{sij} > 0} y_{ijk} \quad j1 \leq j \leq J, k1 \leq k \leq K, s: \sum_{i \in I_j} \sigma_{sij} > 0 \tag{8b}$$

For multipurpose storage vessels v (v = 1, 2, …, V) capable of storing a set $\mathbf{S}_v$ of materials, we ensure that only a material that is stored has a non-zero amount and rest all are zeros. For this, we define the following binary variable.

$$z_{svk} = \begin{cases} 1 & \text{if } s \text{ is stored in vessel } v \text{ during slot } k \\ 0 & \text{otherwise} \end{cases} \qquad s \in \mathbf{S}_v,\ 1 \leq v \leq V, k1 \leq k \leq K$$

Now that materials are stored exclusively in a vessel, only one material is allowed at any given time. Thus, we demand,

$$\sum_{s \in S_v} Z_{svk} = 1 \qquad 1 \leq v \leq V, k1 \leq k \leq K \tag{9}$$

Also, only a material s that is stored in a vessel v during slot k may have a non-zero amount present in the storage. So, we set the amount (A_{svk}) of all other materials to zero whenever they are not stored in the vessel v. So, we write the following,

$$A_{svk} \leq A_v^U Z_{svk} \qquad s \in \mathbf{S}_v,\ 1 \leq v \leq V, k1 \leq k \leq K \tag{10}$$

Let $q_{ijk} = R_{ij}^L PT_{ijk} + dq_{ijk}$ ($j1 \leq j \leq J$, $i \in \mathbf{I}_j$, $k1 \leq k \leq K$) be the total amount of all the materials that task i processes in unit j during slot k. Here, R_{ij}^L is the minimum material processing rate of task i in unit j. If a task i is not allocated to unit j during a slot k, then we set $q_{ijk} = 0$. Also, if a task i is allocated to unit j during a slot k, then the total amount of materials processed must not exceed the maximum capacity of the unit. In other words, the material processing rate of task i in unit j must not exceed the maximum allowable processing rate (R_{ij}^U). Therefore, we have,

$$dq_{ijk} \leq \left(R_{ij}^U - R_{ij}^L\right) PT_{ijk} \qquad i \in \mathbf{I}_j, j1 \leq j \leq J, k1 \leq k \leq K \tag{11}$$

Aforementioned discussion and constraints allow us to write the following inventory (I_{sk}) balance for each material s, at the end of a slot k.

$$I_{sk} = I_{s(k-1)} + \sum_j \sum_{i \in I_j, \sigma_{sij} \neq 0} \sigma_{sij} (R_{ij}^L PT_{ijk} + dq_{ijk}) \qquad s1 \leq s \leq S, k1 \leq k \leq K \tag{12}$$

One of the most widely used objectives in the literature is revenue maximization. Here, it is assumed that all the products produced are sold and they must either satisfy a minimum demand or must fall within a given range of the demand. So, we have the following demand constraint applicable as required,

$$D_s^L \leq \sum_k \sum_j \sum_{i \in I_j, \sigma_{sij} > 0} (R_{ij}^L PT_{ijk} + dq_{ijk}) \leq D_s^U \qquad s1 \leq s \leq S \tag{13}$$

where, D_s^L and D_s^U are the lower and upper limits of the demand for a material s.

The total revenue through sales (SR) of the products is given as the following.

$$SR = \sum_s \sum_k \sum_j \sum_{i \in I_j, \sigma_{sij} > 0} p_s \sigma_{sij} (R_{ij}^L PT_{ijk} + dq_{ijk}) \tag{14}$$

where, p_s is the market price for a material s. $p_s = 0$, if s in not a product.

This completes our model (Eqs. 1 – 14) for scheduling semi-continuous plants.

4. Numerical Evaluation

We consider two scenarios of an industrial case study from fast moving consumer goods (FMG) manufacturing plant, which is extensively studied in the literature. The plant follows a common production sequence: mixing, storage, and packing. All examples are solved on a Dell precision PWS690 (Intel® XeonR 5160 with CPU 3 GHZ and 16 GB memory) running Windows 7 using CPLEX 11/GAMS 23.7.

4.1 Example 1

In this example, we consider four raw materials (S1-S4), 4 mixers (M-101 to M-104), and 3 packing lines (PL-101 to PL-104, 5 intermediates (S5-S9), and 5 final products

Each intermediate has its dedicated storage tank and the maximum capacities are 60 ton of S5, 200 ton of S6, 200 ton of S7, 200 ton of S8, and 200 ton of S9, respectively. Storage bypassing is allowed. While the model of Shaik and Floudas (2007) found a solution that is not feasible, our model obtains a feasible solution with objective value of 360.27 k$.

4.2 Example 2

In this case, we consider one raw material (S1), 1 mixer (M-101), 3 packing lines (PL-101 to PL-104, two intermediates (S2-S3), and 5 final products. Two flexible storage tanks (ST-101 and ST-102) are available with a maximum capacity of 40 ton. Storage tank ST-101 can store states S2 and S3, while ST-102 can hold only S3. Storage bypassing is not allowed. Both our model and the model of Shaik and Floudas (2007) attain the optimal solution of 268.7 k$ with 4 slots. Table 1 lists the model and solution statistics.

Table 1 Model and Solution Statistics

	Example 1		Example 2	
	Ours	S & F	Ours	S & F
Events/ Slots	6	-	4	4
Binary Variables	236	-	108	108
Continuous Variables	445	-	301	337
Constraints	1137	-	908	1249
MILP	360.27	-	268.70	268.70
CPU time (s)	8	-	190	540

S & F: Shaik and Floudas (2007)

5. Conclusion

We have successfully developed and demonstrated a new multi-grid MILP formulation based on unit slots for scheduling semi-continuous plants. Our model showed a better performance over the literature models. In addition, our model features many features such as sequence-dependant transition times, various storage policies, etc. We are currently working on further reduction of variables and constraints in our model to improve its performance.

A Continuous-Time Approach for Scheduling Bidirectional Pipeline Operations

Vanina G. Cafaro,[a] Diego C. Cafaro,[a] Jaime Cerdá[a]

[a]*INTEC (UNL-CONICET), Güemes 3450, (3000) Santa Fe, Argentina*

Abstract

Scheduling pumping operations in multiproduct pipelines is a complex logistic task that requires efficient supporting tools. Several approaches have been proposed for solving the pipeline scheduling problem for different pipeline configurations, but up to now the problem of sizing and sequencing oil product batches moving through bidirectional pipelines could not be tackled by continuous-time representations. This work introduces a mixed integer linear programming formulation standing for the first rigorous approach effectively solving the short-term operational planning of bidirectional pipelines.

Keywords: Bidirectional pipelines, Continuous-time formulation, MILP approach.

1. Introduction

For the logistics of crude oil and refined products, pipeline transportation offers superior reliability at relatively low cost. Since different products are transported through the same line without separation devices, the mixing of adjacent batches produces volumes of degraded products that increase the operative costs. Hence, planning the size and sequence of new batches to be pumped into the pipelines, and the simultaneous deliveries to depots located across the system is a complex logistic task that requires efficient supporting tools. In the last decade, a considerable amount of work has been done for solving the multiproduct pipeline scheduling problem for different pipeline configurations. From the simplest case comprising a unidirectional pipeline with a single origin and a single destination, to mesh-structured pipeline networks connecting refineries, distribution centers and customers' facilities, a broad class of problems has been tackled by using decomposition approaches,[1] heuristic-based techniques,[2] discrete representations,[3] and continuous-time optimization models.[4-8] The latter appears to be the most efficient choice in terms of the computational burden required. However, up to now, the problem of sizing and sequencing oil product batches moving through bidirectional (also called reversible) pipelines has not been solved in a rigorous way.

Bidirectional pipelines normally connect a refinery tank farm to a harbour, or inland distribution terminals between themselves. The same pipeline is used to convey products either from the refinery to the harbour, or from the harbour to the refinery, and the flow can be inverted during the planning horizon according to terminal demands and tank availability. A key aspect of bidirectional pipelines is the fact that after sending all the demanded products in one direction, it is necessary to fill the pipeline with another product to push the batches out of the line into the terminal tanks at the other extreme. A large batch of a filler product is usually inserted to push the batch sequence in the line. Once the inputted batches have reached their destination, the flow direction can be switched. At that moment, the receiving terminal turns to be the input terminal and begins to pump batches at the other extreme, in the opposite direction. Then, the filler product gradually returns to the assigned tanks. This procedure is repeated each time the flow is inverted, thus resulting in undesirable time delays and higher costs. To the best

of our knowledge, only approximate approaches have been proposed for solving the bidirectional pipeline scheduling problem.[1,9,10] They rely on discrete MILP models that divide both the pipeline volume into single-product packs, and the planning horizon into time intervals of fixed duration. As a result, they will not provide feasible schedules unless a fine discretization is adopted. Besides, the starting flow direction is not a model decision but a user specification, and it can be inverted only once over the time horizon. Contrary to previous techniques, this work introduces the first rigorous approach for the operational planning of reversible pipelines. It consists of an MILP continuous-time formulation that accounts for the possibility of inverting the flow direction many times, at the proper time instants. Batch movements are rigorously traced along the line in both directions, and inventory levels are efficiently monitored in a continuous way. The model can optimally select pump rates and choose the most convenient product to be pumped as the filler batch. The problem goal is to find the optimal sequence of pumping and delivery operations that permits to satisfy terminal requirements at minimum total cost, including pumping, mixing, backordered demand, and inventory carrying costs.

2. Mathematical Formulation

Similar to previous formulations of the pipeline scheduling problem,[6] the continuous-time model for bidirectional pipelines is based on the following sets: the ordered set of batches $I = \{i_1 \ldots i_n\}$, the sequence of future pumping runs $K = \{k_1 \ldots k_m\}$ and the terminal set $J = \{j_1, j_2\}$ comprising the depots at both extremes of the pipeline. The set of batches I is built as follows: (i) The first r elements $\{i_1 \ldots i_r\}$ stand for new batches to be pumped from node j_2 (in reverse flow) during the future horizon; (ii) the following l elements $\{i_{r+1} \ldots i_{r+l}\}$ represent the old bathes initially into the pipeline at the start of the time horizon; and (iii) the last d elements $\{i_{r+l+1} \ldots i_{r+l+d}\}$ are new bathes to be subsequently pumped in direct flow in future runs. Hence, $I = I^{rev} \cup I^{old} \cup I^{dir}$, as shown in Fig. 1.

Fig. 1. Ordered set of batches to be transported through the bidirectional pipeline.

Besides, the MILP model comprises the following 0-1 variables: (a) $y_{i,p}$ assigning product p to batch i; (b) $x_{i,j}^{(k)}$ stating that a portion of batch i is delivered to terminal j during run k; (c) $u_{i,k}$ denoting that terminal j_1 pumps product into batch $i \in I^{dir}$ during run k (direct flow); and (d) $v_{i,k}$ denoting that terminal j_2 pumps product into batch $i \in I^{rev}$ during run k (reverse flow). The following sections present the main model constraints.

2.1 Pumping run sequence. The execution of a new pumping run should start after completing the previous operation. Variable C_k is the completion time for run k, L_k is the run duration, and $h_{\max}$ is the length of the scheduling horizon, all measured in time units.

$$C_k - L_k \geq C_{k-1} \quad ; \quad L_k \leq C_k \leq h_{\max} \quad \forall k \in K \tag{1}$$

2.2 Determining the flow direction. At every active run, products move in direct or reverse flow, depending on the terminal demands at one or the other extreme of the pipeline. Contrary to previous approaches,[1,9] the flow direction is a model decision, and can be inverted as many times as necessary over the planning horizon. Besides, if the pipeline is operated in direct flow, the model selects a single batch to pump at terminal j_1. On the contrary, in reverse flow, a single batch departs from terminal j_2.

$$\sum_{i\in I^{dir}} u_{i,k} + \sum_{i'\in I^{rev}} v_{i',k} \le 1 \qquad \forall k \in K \tag{2}$$

Every fictitious operation k verifies $u_{i,k} = 0$ and $v_{i',k} = 0$ for all $i \in I^{dir}$ and $i' \in I^{rev}$.

2.3 Sizing lot injections. If $Q_{i,k}$ denotes the volume of lot i injected during the pumping run k, its value is bounded by Eq. (3), either in direct or reverse flow operation.

$$u_{i,k}\, q_{dir}^{\min} \le Q_{i,k} \le u_{i,k}\, q_{dir}^{\max} \quad \forall i \in I^{dir}, k \in K \quad ; \quad v_{i',k}\, q_{rev}^{\min} \le Q_{i',k} \le v_{i',k}\, q_{rev}^{\max} \quad \forall i' \in I^{rev}, k \in K \tag{3}$$

2.4 Time duration of a new pumping run. Depending on the flow direction, the pipeline admits different pump rates that must be controlled at every operation. If the interval $[vb_f^{\min}; vb_f^{\max}]$ represents the feasible pump rate range for direction f, then:

$$\sum_{i\in I^{dir}} Q_{i,k} / vb_{dir}^{\max} + \sum_{i'\in I^{rev}} Q_{i',k} / vb_{rev}^{\max} \le L_k \le \sum_{i\in I^{dir}} Q_{i,k} / vb_{dir}^{\min} + \sum_{i'\in I^{rev}} Q_{i',k} / vb_{rev}^{\min} \quad \forall k \in K \tag{4}$$

2.5 Product sequence. Every non-fictitious lot i will contain a single refined petroleum product. Depending on the source node, the set of available products to be inputted may be different. If the set P_j stand for all the products that can be pumped from node j, then:

$$\sum_{k\in K} u_{i,k} = \sum_{p\in P_{j1}} y_{i,p} \le 1 \quad \forall i \in I^{dir} \quad ; \quad \sum_{k\in K} v_{i',k} = \sum_{p\in P_{j2}} y_{i',p} \le 1 \quad \forall i' \in I^{rev} \tag{5}$$

The aim of Eq. (5) is twofold: (a) every new batch that is injected into the pipeline must contain a single product; and (b) every non-fictitious batch can be injected only once over the planning horizon. Moreover, the chronological order of product injections should be established. In direct flow, the injection of lot i must precede the pumping of lot i+1, as usual. But in reverse flow the injection of lot i' must succeed the pumping of lot i'+1, because of the order given for the set I (see Fig. 1). Therefore:

$$u_{i,k} \le \sum_{l<k} u_{i-1,l} \quad \forall i \in I^{dir} \quad ; \quad v_{i',k} \le \sum_{l<k} v_{i'+1,l} \quad \forall i' \in I^{rev} \tag{6}$$

In this way, fictitious lots never pumped into the pipeline (featuring $y_{i,p} = 0\ \forall p \in P$), in direct or reverse flow, lay at the end of the associate batch sequence I^{dir} or I^{rev}. Finally, the injection of a new batch i produces a new interface, whose size can be estimated by:

$$\begin{aligned} &WIF_{i,p,p'} \ge ifd_{p,p'}\,(y_{i,p} + y_{i-1,p'} - 1) && WIF_{i',p,p'} \ge ifr_{p,p'}\,(y_{i',p} + y_{i'+1,p'} - 1) \\ &\qquad \forall i > first(I^{dir}), (p,p') \in P_{j1} && \qquad \forall i' < last(I^{rev}), (p,p') \in P_{j2} \end{aligned} \tag{7}$$

Parameters $ifd_{p,p'}$ and $ifr_{p,p'}$ stand for the size of the interface between products p' and p when sequentially pumped in direct or reverse flow, respectively. However, these estimations should be adapted for the first injection reversing the pipeline flow. This issue is left for an extended version of the work.

2.6 Batch tracking. The size of a batch i at time C_k ($W_{i,k}$) can be updated by:

$$W_{i,k} = W_{i,k-1} + Q_{i,k} - \sum_{j\in J} D_{i,j}^{(k)} \quad \forall i \in I, k \in K \tag{8}$$

For $k = 1$, $W_{i,k-1}$ is the size of the batches in the initial linefill (wo_i), and is equal to zero for $i \in I^{dir} \cup I^{rev}$. For old batches $i \in I^{old}$, variable $Q_{i,k}$ should not be considered. Besides, the last term in Eq. (8) accounts for two possible situations: (a) a batch first injected at terminal j is later discharged into the opposite terminal j' (common movement), and (b) a batch first injected at j later returns to j after a pipeline flow reversal. On the other hand, the continuity of the flow into the pipeline is imposed by Eq. (9). Moreover, each operation (in direct or reverse flow) must respect the input/output material balance.

$$F_{i,k} - W_{i,k} = F_{i+1,k} \;\; \forall i \in I, k \in K$$
$$\sum_{i \in I^{dir}} Q_{i,k} = \sum_{l \in I} D_{l,j2}^{(k)} \quad ; \quad \sum_{i' \in I^{rev}} Q_{i',k} = \sum_{l \in I} D_{l,j1}^{(k)} \qquad \forall k \in K \tag{9}$$

Note that an injection from j_1 only admits diversions into terminal j_2, and vice-versa.

2.7 Diversion feasibility. In direct flow, a product lot i can be discharged into j_2 during run k only if the end of the pipe is reached by such lot during the same run, i.e. $F_{i,k} \geq pv$, where pv stands for the overall pipeline volume. But in reverse flow, the possibility of diverting a lot i into terminal j_1 implies the condition $F_{i,k}$ - $W_{i,k} \leq 0$, given that the lot is moving in the opposite direction and the terminal j_1 is located at the pipeline origin (zero coordinate). Both conditions are imposed through Eq. (10).

$$d_{\min} x_{i,j}^{(k)} \leq D_{i,j}^{(k)} \leq d_{\max} x_{i,j}^{(k)} \qquad \forall i \in I, j \in J, k \in K$$
$$F_{i,k} \geq pv \; x_{i,j2}^{(k)} \quad ; \quad F_{i,k} - W_{i,k} \leq pv \, (1 - x_{i,j1}^{(k)}) \qquad \forall i \in I, k \in K \tag{10}$$

2.8 Injected and diverted products. To identify the product p that is injected into or diverted from the pipeline during a single run k we introduce the variables $QP_{i,p}^{(k)}$ and $DP_{i,p,j}^{(k)}$. Just in case product p is assigned to lot i ($y_{i,p}$ = 1) both variables can take positive values. Otherwise, they will be null, as stated by Eqs. (11) and (12).

$$QP_{i,p}^{(k)} \leq q_{dir}^{\max} \; y_{i,p} \quad \forall i \in I^{dir}, k \in K, p \in P_{j1} \quad ; \quad Q_{i,k} = \sum_{p \in P_{j1}} QP_{i,p}^{(k)} \quad \forall i \in I^{dir}, k \in K$$
$$QP_{i',p}^{(k)} \leq q_{rev}^{\max} \; y_{i',p} \quad \forall i' \in I^{rev}, k \in K, p \in P_{j2} \quad ; \quad Q_{i',k} = \sum_{p \in P_{j2}} QP_{i',p}^{(k)} \quad \forall i' \in I^{rev}, k \in K \tag{11}$$

$$DP_{i,p,j}^{(k)} \leq d_{\max} \, y_{i,p} \quad \forall i \in I, j \in J, k \in K, p \in P \quad ; \quad D_{i,j}^{(k)} = \sum_{p \in P} DP_{i,p,j}^{(k)} \quad \forall i \in I, j \in J, k \in K \tag{12}$$

2.9 Inventory control and demand fulfillment. If $DM_{p,j}^{(k)}$ stands for the total amount of product p sent from depot j to local markets (usually by truck) during the time interval $[C_{k\text{-}1} ; C_k]$, its value is limited by the maximum discharge rate admitted by terminal j, i.e. $vm_{p,j}$. Moreover, the total amount of p delivered from j to customers during the time horizon should be high enough to fulfill market demands. Otherwise, a backorder of size $B_{p,j}$ will arise, thus delaying the order completion and increasing operational costs.

$$DM_{p,j}^{(k)} \leq (C_k - C_{k-1}) \, vm_{p,j} \quad \forall p \in P, j \in J, k \in K; \quad \sum_{k \in K} DM_{p,j}^{(k)} = dem_{p,j} - B_{p,j} \quad \forall p \in P, j \in J \tag{13}$$

On the other hand, we assume that both terminals receive a continuous flow of certain products from neighboring refineries and/or harbors all over the time horizon at a fixed rate of $vp_{p,j}$ units per hour. As a result, the inventory level of product p in tanks of depot j at the end time of every operation k, i.e. $ID_{p,j}^{(k)}$, can be determined through Eq. (14).

$$ID_{p,j}^{(k)} = ID_{p,j}^{(k-1)} + \sum_{i \in I} DP_{i,p,j}^{(k)} - \sum_{i \in I^*} QP_{i,p}^{(k)} + vp_{p,j}(C_k - C_{k-1}) - DM_{p,j}^{(k)} \quad \forall p \in P, j \in J, k \in K \tag{14}$$

The set I^* stands for direct lots $i \in I^{dir}$, when $j = j_1$, and reverse lots $i' \in I^{rev}$, when $j = j_2$. Finally, the stock level of product p at terminal j should remain within the admissible range during the entire horizon. Hence, $(id_{\min})_{p,j} \leq ID_{p,j}^{(k)} \leq (id_{\max})_{p,j}$ for every run $k \in K$.

2.10 Objective function. The goal of the proposed MILP model is to minimize the total operational cost of the pipeline schedule including: (a) pumping costs, (b) backorder costs, (c) interface costs, (d) inventory carrying costs, and (e) the fixed cost paid for every pipeline flow reversal (see Eq. 15). Term (d) is based on the average inventory levels, whose values are estimated by summing product stocks at the end of every run,

and dividing the result by the number of runs $|K|$. Besides, term (e) can be derived from the values of the binary variables $u_{i,k}$ and $v_{i',k}$ at subsequent injections k-1 and k. Hence, a continuous variable w_k is introduced to detect a flow reversal at the start of run k, by imposing: $w_k \geq u_{i,k} + v_{i',k-1} - 1$, and $w_k \geq u_{i,k-1} + v_{i',k} - 1$, for all $i \in I^{dir}$, $i' \in I^{rev}$, and $k > 1$.

$$z = \sum_{j\in J}\sum_{p\in P_j} cp_{p,j} \sum_{i\in I^*} QP_{i,p}^{(k)} + \sum_{p\in P}\sum_{j\in J} cb_{p,j}\, B_{p,j} + \sum_{p,p'\in P} cf_{p',p} \sum_{i\notin I^{old}} WIF_{i,p,p'} + \sum_{j\in J}\sum_{p\in P} \frac{cid_{p,j}}{|K|} \sum_{k\in K} ID_{p,j}^{(k)} + cr \sum_{k\in K} w_k \quad (15)$$

3. Case study

The proposed MILP formulation was applied to a modified version of a case study first introduced by Magatao et al. (2011)[5] comprising a time horizon of 129 h. Though the flow direction can be reversed as many times as necessary, results show that the model naturally tends to reverse the flow only once over the time horizon, to reduce pumping costs. Fig. 2 illustrates the optimal sequence of product injections, similar to the one reported by previous authors.[5] In this case, however, lots are first pumped in direct flow, and then in the opposite direction, requiring no "plugs" to separate incompatible products. *P4* and *P5* are automatically chosen as filler products in direct and reverse flow, respectively. Batch sizes and pump rates take continuous values, since no time nor volume discretization is required. The model, with 315 binary vars, was solved in 197 s on an Intel Xeon CPU using GAMS/ GUROBI 3.0. Optimal solutions to larger problems can also be obtained in reasonable CPU times.

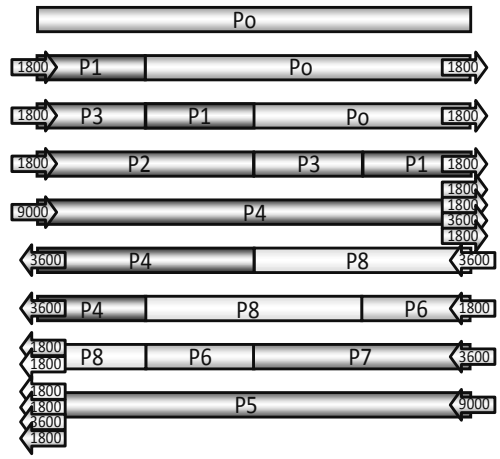

Fig. 2. Optimal pipeline schedule.

4. Conclusions

We presented the first rigorous approach effectively solving the short-term operational planning of reversible pipelines through an MILP continuous-time formulation. Batch sizes, product sequences, pump rates, and flow directions can be determined all at once, and product stocks at depots can be continuously controlled. Additional problem features like high-cost energy periods will be included in future works.

Abstract

An efficient MILP-based approach is presented to solve flow shop scheduling problems in automated manufacturing systems. The problem comprises complex production constraints and stringent storage policies in a multiple product multistage batch process. Automated transfers accross the entire system, recicle flows and different production recipes are also considered in the process scheme. The proposed decomposition approach was able to solve the entire problem in a sequential manner by dividing it into two major stages that are iteratively solved to find near optimal results with an acceptable CPU time. The effectiveness of this method is tested and compared with a monolithic MILP formulation by solving a real-world problem.
Keywords: MILP-based model, Automated Manufacturing System, Multiple products multistage batch process, Flow shop scheduling problems, Industrial applications.

1. Introduction

Most common automated manufacturing systems consist in a complex flow shop production process in where a set of units, as machines, baths or tanks, are arranged in a single production line for processing batches of different jobs in a sequential way under specific intermediate storage policies (Crama, 1997). Automated material-handling devices, like hoists or robots, are used to move wafer's lots between units and buffers.

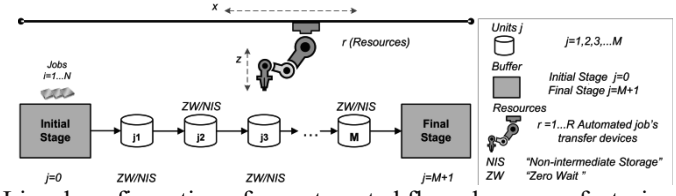

Fig. 1: Lineal configuration of an automated flow shop manufacturing system.

This type of modern automated production facilities is used in many different practical applications such as surface treatments of metal components or in the manufacture of printed circuit boards (PCBs) in electronics plants (Phillips & Unger, 1976; Shapiro & Nuttle, 1988). In these plants material handling devices, called hoists, are used to move parts from one to another machine undergoing a sequence of different operations in successive tanks. This type of production operations are also found in the automated wet-etch station (AWS) in semiconductor manufacturing facilities (Bhushan & Karimi, 2003; Aguirre et al., 2011; Zeballos et al., 2011; Castro et al., 2011). In this station, automated rail-guide vehicles (AGVs), like robots, are used to perform transfer operations by following a predefined sequence of chemical and water immersion processes between consecutive baths. Many research works have been developed in this area in recent years by using several methods like heuristic and meta-heuristics

procedures, full-space mathematical models (Bhushan & Karimi, 2003; Aguirre et al., 2011), constraint programming formulations (Zeballos et al., 2011) and also hybrid approaches (Castro et al., 2011).

One of the major assumptions that have been taken into account in these problems is the consideration of a unique production sequence for all jobs. But in most of industrial applications this simplification does not exist. Usually, a set of jobs with different production recipes, also called products, must be processed following a series of stages with a single processing unit per stage. Also, re-entrant and possible recycle flows can be found in these processes. Flexible timing operations depends on the job processed and the production stage followed. According to this, every job has a minimum processing time and a limited residence time that has to be strictly fulfilled in every stage. After the processing time, every lot has to be immediately transferred to the following stage in the recipe. The transfer operations in the system must be exactly coordinated due to no intermediate buffer exists between these stages. In order to perform transfer activities, automated material handling devices with finite capacity, are available.

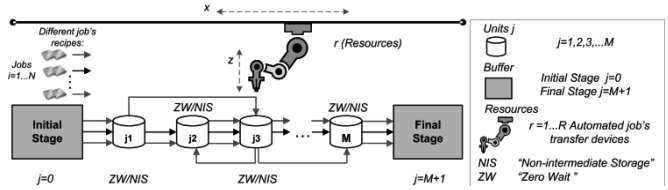

Fig. 2: Process scheme in automated manufacturing systems.

As we can see, the use of different processing recipes and shared transportation resources forces, the decision maker, to do a more detailed and synchronized schedule of all the processing and transportation activities in the system. These practical limitations faced by many real-life industries nowadays become the automated flow shop scheduling problem of multiple products in a real complex challenge for researches and practitioners.

In this work, a novel computationally efficient MILP-based mathematical formulation for the multiple product scheduling problems in a real-world automated manufacturing system is proposed. The principal aim is to find a robust solution approach for industrial scale application problems that provides good-quality results with an acceptable computational effort.

2. Flow shop MILP-based model

The model presented in this work lies on the MILP-based approach proposed by Aguirre et al., (2011) to AWS scheduling problems. The new model is devised to flow shop scheduling problems with an automated material-handling robot in a single production line. The multi-product multistage batch process under study has reentrant and possible recycle flows to the same unit. In addition, flexible processing times and transferring times are also considered.

2.1. Notations

I, S, J	Jobs $(i=i_1,...,N)$, Stages $(s=s_1,...,L)$, Units $(j=j_1,...,M)$
S_i , L_i	Stages belonging to the production sequence of job i
$j_{i,s}$	Unit j belonging to job i in production stage s
$Seq_{(i)}$	Product recipe of job i
$Ts_{(i,s)}$, $Tf_{(i,s)}$	Start time and Final time of job i in stage s

$t^{min}_{(i,s)}$, $t^{max}_{(i,s)}$	Minimum and Maximum processing time of job *i* in stage *s*
$\pi_{(i,s)}$,	Transfer time of job *i* from stage *s-1* to *s*
$\pi^{min}_{(i,s)}$, $\pi^{max}_{(i,s)}$	Minimum and Maximum transfer time of job *i* from stage *s-1* to *s*
$X_{(i,i',s,s')}$, $Y_{(i,i',s,s')}$	Job sequencing and Transfer sequencing decisions
M_T , MK	Large value (Big-M parameter); Makespan Criterion

2.2. Main Features

In the following model, Eqs. 1-2 and Eqs. 3-5 are defined to handle flexible processing times $t_{(i,s)}$ in a single unit and flexible transferring times $\pi_{(i,s)}$ for the robot. Then, Eqs. 6-7 and Eqs. 8-9 are proposed to manage job's sequencing $X_{(i,i',s,s')}$ and transfer's sequencing $Y_{(i,i',s,s')}$ decisions. Finally, Eqs. 10-11 are developed to reduce the computational complexity of the model by fixing certain variables of jobs belonging to the same production recipe $Seq_{(i)}$. The objective function *(MK)* is presented in Eq. 12. Then, Eq. 13 is proposed to provide alternative job's sequences to the entire problem.

2.3. Flexible processing times

$$Tf_{(i,s)} \geq Ts_{(i,s)} + t^{\min}{}_{(i,s)} \qquad \forall i \in I, s \in S_i \tag{1}$$

$$Tf_{(i,s)} \leq Ts_{(i,s)} + t^{\max}{}_{(i,s)} \qquad \forall i \in I, s \in S_i \tag{2}$$

2.4. Flexible transferring times

$$Ts_{(i,s)} = Tf_{(i,s-1)} + \pi_{(i,s)} \qquad \forall i \in I, s \in S_i : s > 1 \tag{3}$$

$$Ts_{(i,s)} \geq \pi_{(i,s)} \qquad \forall i \in I, s \in S_i : s = 1 \tag{4}$$

$$\pi^{\min}{}_{(i,s)} \leq \pi_{(i,s)} \leq \pi^{\max}{}_{(i,s)} \qquad \forall i \in I, s \in S_i \tag{5}$$

2.5. Sequencing decisions in the same unit

$$X_{(i,i',s,s')} = \begin{cases} 1 & \text{if task } i,s \text{ is processed after task } i',s' \text{ in the same unit } j \\ 0 & \text{otherwise} \end{cases}$$

$$Ts_{(i,s)} \geq Tf_{(i',s')} + \pi_{(i,s)} + \pi_{(i',s'+1)} - M_T(1 - X_{(i,i',s,s')}) \;\; \forall i,i' \in I : (i > i'), s \in S_i, s' \in S_{i'}, j_{i,s} = j_{i',s'} \tag{6}$$

$$Ts_{(i',s')} \geq Tf_{(i,s)} + \pi_{(i',s')} + \pi_{(i,s+1)} - M_T(X_{(i,i',s,s')}) \;\; \forall i,i' \in I : (i > i'), s \in S_i, s' \in S_{i'}, j_{i,s} = j_{i',s'} \tag{7}$$

2.6. Sequencing decisions in different units

$$Y_{(i,i',s,s')} = \begin{cases} 1 & \text{if transfer } i,s \text{ is processed after transfer } i',s' \text{ in different units} \\ 0 & \text{otherwise} \end{cases}$$

$$Ts_{(i,s)} \geq Ts_{(i',s')} + \pi_{(i,s)} - M_T(1 - Y_{(i,i',s,s')}) \;\; \forall i,i' \in I : (i > i'), s \in S_i, s' \in S_{i'}, j_{i,s} \neq j_{i',s'} \tag{8}$$

$$Ts_{(i',s')} \geq Ts_{(i,s)} + \pi_{(i',s')} - M_T(Y_{(i,i',s,s')}) \;\; \forall i,i' \in I : (i > i'), s \in S_i, s' \in S_{i'}, j_{i,s} \neq j_{i',s'} \tag{9}$$

2.7. Reducing the computational complexity of the problem

$$X_{(i,i',s,s')} = 1 \qquad \forall i,i' \in I : (i > i'), s \in S_i, s' \in S_{i'}, Seq(i) = Seq(i') \wedge s \geq s' \wedge j_{i,s} = j_{i',s'} \tag{10}$$

$$Y_{(i,i',s,s')} = 1 \qquad \forall i,i' \in I : (i > i'), s \in S_i, s' \in S_{i'}, Seq(i) = Seq(i') \wedge s \geq s' \wedge j_{i,s} \neq j_{i',s'} \tag{11}$$

2.8. Objective Function: Makespan Minimization

$$MK \geq Ts_{(i,s)} \qquad \forall i \in I, s \in S_i : s = L_i \tag{12}$$

Additional integer cuts to provide alternative job's sequences

$$\left(\sum_{\substack{i,i'>i \\ X^{old}_{(i,i',s,s')}=1}}^{N} \sum_{s \in Si}^{Li} \sum_{s' \in Si'}^{Li'} X_{(i,i',s,s')} \right) \leq \left(\sum_{i,i'>i}^{N} \sum_{s \in Si}^{Li} \sum_{s' \in Si'}^{Li'} 1 \right) + \left(\sum_{\substack{i,i'>i \\ X^{old}_{(i,i',s,s')}=0}}^{N} \sum_{s \in Si}^{Li} \sum_{s' \in Si'}^{Li'} X_{(i,i',s,s')} \right) - 1 \tag{13}$$

3. Two-Stage MILP-based solution approach

An MILP-based iterative solution method is presented here for dealing with this complex optimization problem in a sequential manner. Thus, an adapted version of bi-level approach, developed by Bhushan and Karimi (2003) and later used by Aguirre et al. (2011) for flow shop scheduling problems in the AWS, is proposed in Figure 3. The solution algorithm allows solving the whole problem in two stages. In the first stage, a relaxed model is solved without considering transfer constraints and the best job's sequence of this problem is provided. Then, in the second stage, transfer constraints are added into the model and then a reduced model is solved by fixing the job's sequencing decisions provided before. Here, it is worth to remark that the job's sequence of the first stage may not always provide a feasible solution in the second stage when sequencing transfer decisions are included. According to this, additional integer cuts are applied in each iteration to provide alternative job's sequences that generate feasible solutions and also improved results. In addition, variable $Ts_{(i,s)}$ and $Tf_{(i,s)}$, are copied in each sub-model to accelerate the convergence. The algorithm ends when an iteration limit is reached.

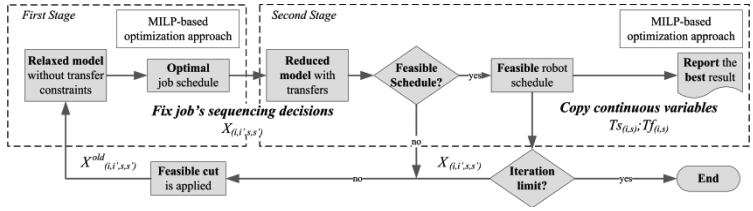

Fig. 3: Sequential procedure followed

4. Application example

An application example of real-life operations in a metal industry is presented here. In this process, jobs i_1-i_{10} have to be schedule in units j_1-j_{35} following their own production recipes $Seq_{(i)}$. The information on processing times $t_{(i,s)}$ of every task i,s and sequences $Seq_{(i)}$ of units j followed by each job i is presented in Table 1. Flexible transfer times between $\pi^{min}_{(i,s)} = 3'$ and $\pi^{max}_{(i,s)} = 6'$ are considered for every transfer.

Solutions obtained for this particular example by our iterative method and by a monolithic model, computing the CPU time and the *MK*, are compared in Table 2.

Table 1. Minimum $t^{min}_{(i,s)}$ and Maximum $t^{max}_{(i,s)}$ processing times of task i,s in unit j

Seq	jobs	s_1	s_2	s_3	s_4	s_5	s_6	s_7	s_8	s_9
1	i_1-i_5-i_6 -i_9-i_{10}	j_3:12-15'	j_5:5-15'	j_7:1'	j_9:10-15'	j_{35}:30-60'	-	-	-	-
2	i_2-i_3	j_3:12-15'	j_5:5-15'	j_4:6-10'	j_5:5-10'	j_7:1'	j_9:10-15'	j_{35}:30-60'	-	-
3	i_4-i_7-i_8	j_3:12-15'	j_5:5-15'	j_7:8-10'	j_8:5-10'	j_9:5-10'	j_{16}:56'	j_{18}:5-10'	j_{30}:5-15'	j_{35}:30-60'

Table 2. Statistics and Results of the example analyzed

Units x Jobs	Statistics	Monolithic MILP-based model with transfers	Iterative Solution Method	
			Relaxed model	Reduced model
35x10	Binary Var.	2485	203	2282
	Cont. Var.	335	335	538
	Equations	5505	941	5505
	MK*(min)*	**404**	**400**	**404**
	CPUtime(s)*	360	19.5	0.5

**Total CPU time by using Gurobi 6.0 in a PC Intel Core 2 Quad 2,5 GHz with parallel processing (4 threads)*

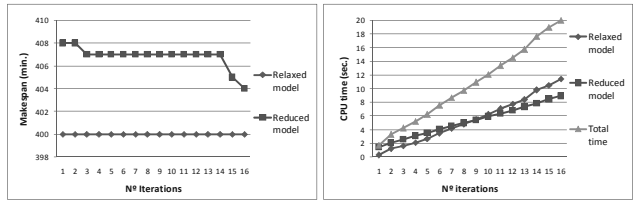

Fig. 4: Behavior of the Sequential approach

Figure 4 shows that the initial feasible solution of our iterative approach $(MK_{(min.)}=408)$ can be progressively enhanced, generating alternative job sequences with the same objective value $(MK_{(min.)}=400)$. The results in Table 2 and Figure 4, illustrate that the sequential procedure is able to provide an optimal solution $(MK_{(min.)}=404)$ in a few number of iterations even with less computational time (20 sec.) than the full-space model (360 sec.) A detailed schedule of this optimal solution is provided in Figure 5.

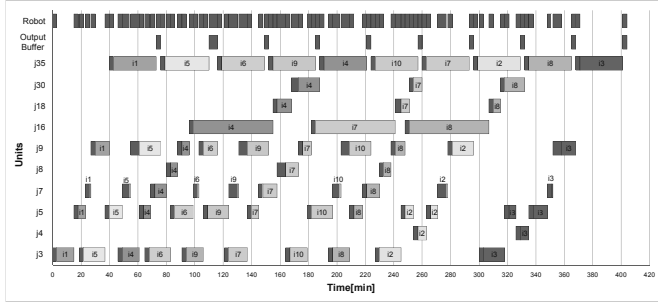

Fig. 5: Integrated manufacturing and transfer schedule

5. Conclusions

An MILP-based procedure was developed for the scheduling of multiple products in automated manufacturing systems. The sequential approach allows finding near-optimal schedules of processing and transfer operations with a reasonable computational effort, by using an adapted version of a widely known two-stage solution method, previously proposed to AWS scheduling problems. Finally, our solution method was compared favorably with an exact mathematical approach in a real-world example, providing an optimal result in few iterations with modest CPU cost.

Integrated Scheduling and Control of Continuous-Time Blending Processes

Kathrin Frankl, Josef Beenken, Wolfgang Marquardt

AVT - Process Systems Engineering, RWTH Aachen University, Turmstr. 46, 52056 Aachen, Germany

Abstract

Scheduling and control of multiproduct blending processes is important in many fields of process systems engineering. It is characterized by nonlinear process dynamics, numerous product specifications and discrete state variables. Due to the high complexity of the resulting mixed-integer dynamic model, integrating all these properties simultaneously in continuous time has not been addressed for blending processes in literature so far. In this contribution, a novel modeling framework for integrated scheduling and control of continuous-time multiproduct blending problems is presented. The framework incorporates the flexible handling of production and transition stages. Moreover, product demand is treated as continuous-time specification of the production process with possible discrete demand due dates. The resulting non-convex mixed-integer dynamic optimization problem is solved by means of a single-shooting method embedded in a branch & bound framework. The novel methodology is illustrated by means of a blending case study with a variety of feed streams with different property compositions and numerous specifications for each of the three manufactured products.

Keywords: optimal control, nonlinear dynamic systems, mixed-integer dynamic optimization, blending, scheduling.

1. Introduction

Integrated scheduling and control of multiproduct blending processes is a difficult task in process operations. The overall model includes (i) discrete decisions for determining the optimal production sequence, (ii) nonlinear process dynamics of the blender and associated units and (iii) a variety of product specifications. The scheduling of blending processes has been addressed in literature for medium-scale plants comprising several blenders and other up- or down-stream units. However, the dynamics of the blenders are neglected and nonlinearities are often reformulated as linear problems, as, e.g., by Mendez et al. (2006). Tousain (2002), for example, considered the integrated scheduling and optimal control of a small-scale blending process in continuous time. However the nonlinearities are avoided by linear reformulations. Nevertheless, integrated scheduling and control has been successfully applied to continuous, nonlinear multiproduct processes before (e.g., Prata et al. (2008)).

In this contribution an integrated approach for scheduling and optimal control of continuous-time blending processes is presented. In addition to the characteristics (i)-(iii) above the proposed modeling framework allows a more flexible handling of the production sequence, and takes continuous-time demand variations as well as discrete demand due dates into account. The resulting nonlinear mixed-integer dynamic optimization problem is solved by a single-shooting method embedded in a branch & bound framework to handle the discrete decisions.

This contribution is structured as follows: Section 2 states the problem class considered. Section 3 introduces the modeling formulation, which is applied to a case study in Section 4. The blending process consists of a blender with 9 feed streams. Three products may be manufactured, each specified by 17 grades. Section 5 presents some conclusions.

2. Problem class

A single, well-mixed blender constitutes the core of the blending process. Let *C* denote the set of components fed to the blender and *P* the set of products to be manufactured in the blender. The multistage modeling approach of Oldenburg et al. (2008) is used. To this end, the time horizon is divided into stages $k \in K$ with final times t_k. Each stage $k \in K$ is either a production or a transition stage. The binary $y_{k,p}$ is true, if product $p \in P$ is manufactured in stage *k*. The binary $w_{k,p}$ is true, if product $p \in P$ is manufactured in stage *k+1*; hence, stage *k* is a transition stage. The $F_{k,c}^{in}$ denote the volumetric flow rate of the stream of component $c \in C$ and F_k^{out} the outlet stream of the blender in stage *k*. Figure 1 illustrates the nomenclature. $F_{k,p}^{out}$ denotes the inflow volume stream into the storage tank for product *p*. The availability of components *c* is assumed to be unlimited. The blender is assumed to hold a constant volume *V* which is completely filled during the whole time horizon, thus $\sum_{c \in C} F_{k,c}^{in} = F_k^{out}$ if additive mixing is assumed. The time-dependent volume of component *c* during stage *k* is denoted by $V_{k,c}$. Each component $c \in C$ is characterized by a set *E* of properties $\rho_{c,e}, e \in E$. The grade of the blend is specified by the volume fraction of component *c*, $\phi_{k,c} = V_{k,c} / V$ and the average property $\pi_{k,e} = \sum_{c \in C} \rho_{c,e} \cdot \phi_{k,c}, e \in E$, in the blender. The degrees of freedom are the volumetric flow rates of the feed streams $F_{k,c}^{in}$, the final times t_k and the production sequence, i.e., $y_{k,p}$ and $w_{k,p}$.

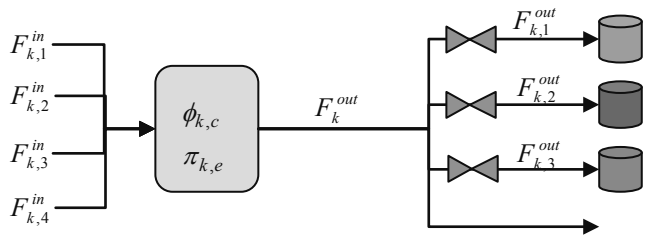

Figure 1: Schematic illustration of a continuous blender with 3 storage tanks and 4 feed streams.

3. Problem formulation

3.1. Blender and product specifications

The volume $V_{k,c}$ of component $c \in C$ inside the blender is determined by the differential equation $\dot{V}_{k,c}(t) = F_{k,c}^{in} - \phi_{k,c} \cdot F_k^{out}$. If product *p* is manufactured in stage *k*, the volume fraction $\phi_{k,c}$ and the medium property $\pi_{k,e}$ have to fulfill certain quality

bounds during the stage. $\underline{\phi}_{c,p}, \overline{\phi}_{c,p}$ denote the lower and upper bounds of $\phi_{k,c}$ and $\underline{\pi}_{e,p}, \overline{\pi}_{e,p}$ the respective bounds of $\pi_{k,e}$. Thus the following path constraints are formulated in each stage *k:*

$$-M_{\phi} \cdot (1-y_{k,p}) + \underline{\phi}_{c,p} \le \phi_{k,c} \le \overline{\phi}_{c,p} + M_{\phi} \cdot (1-y_{k,p}) \quad \forall t \in [t_{k-1}, t_k], \forall c \in C, \forall p \in P$$

$$-M_{\pi} \cdot (1-y_{k,p}) + \underline{\pi}_{e,p} \le \pi_{k,e} \le \overline{\pi}_{e,p} + M_{\pi} \cdot (1-y_{k,p}) \quad \forall t \in [t_{k-1}, t_k], \forall e \in E, \forall p \in P$$

with M_{ϕ}, M_{π} being sufficiently large and suitably chosen constants. If product p is manufactured in stage *k+1*, analogous equations have to hold with respect to $w_{k,p}$ at the final time of stage *k*.

3.2. Storage and product demand

The demand of product p may be continuous or discrete with respect to time. If the demand is continuous in time for $p \in P$, $d_{k,p}$ specifies the time-dependent demand on stage *k*. Then, the storage volume $V_{k,p}$ for product p is determined by the differential equation $\dot{V}_{k,p} = F_{k,p}^{out} - d_{k,p}$. Path constraints have to guarantee a storage hold-up between bounds $\underline{V}_p, \overline{V}_p$, i.e. $\underline{V}_p \le V_{k,p} \le \overline{V}_p, \forall t \in [t_{k-1}, t_k], \forall p \in P, \forall k \in K$. If the demand is discrete, the slot-based approach of Mendez et al. (2006) is applied. Hence, the discrete due date is assumed to coincide with the final time of a certain stage $\widetilde{k} \in K$. The $d_{k,p}$ denote the demands of product p at discrete due date at the end of stage $k = \widetilde{k}$; for other stages, $d_{k,p}$ is zero. Thus $V_{k,p}$ is determined by $\dot{V}_{k,p} = F_{k,p}^{out}$ and the endpoint constraint $V_{k,p} \ge \sum_{\hat{k} \le k} d_{\hat{k},p}, \forall t \in \{t_0, ..., t_k\}$ has to be included in the model.

3.3. Synchronization

Each stage has to be either a production or a transition stage, thus $\sum_{p \in p} y_{k,p} + w_{k,p} = 1$. If the current stage is a transition stage, then the respective product has to be manufactured in the next stage, thus $y_{k+1,p} - w_{k,p} \ge 0$. Hence, a product may be manufactured during several stages in sequence. If product p is manufactured in stage *k*, the outlet stream of the blender is directed to the respective feed stream to the storage tank, thus $F_{k,p}^{out} = y_{k,p} \cdot F_k^{out}$. All differential variables are mapped continuously across the stage borders.

3.4. Objective function

The goal is to minimize Ψ, the overall costs of consumed components $c \in C$, fed to the blender. Thus $\Psi = \sum_{k \in K} \int_{t_{k-1}}^{t_k} \sum_{c \in C} D_c \cdot F_{k,c}^{in}$, where the D_c denote the cost of component *c*.

4. Case Study

The model formulation is illustrated by means of a slightly modified case study taken from Mendez et al. (2006). The volume of the blender considered is *V=2500 l.* 9 components are fed to the blender and each component owns 8 properties, thus */E/=8* and */C/=9*. The blender manufactures 3 products, thus */P/=3*. The desired product specifications as well as the initial values and other constants are summarized below in

Section 4.1. The time horizon of *140 h* is divided into 10 stages. For products 1 and 2, the demands of *50 l/h* and *30 l/h,* respectively, are continuous in time. An amount of *5000 l* of product 3 has to be delivered at a discrete due date of *100 h*. The due date coincides with the final time of stage 6. To allow a cyclic behavior of the production process, the constraints $V_{1,p}(t_0) = V_{|K|,p}(t_{|K|}),\ p \in \{1,2\}$, are added. The control variables $F_{k,c}^{in}$ are discretized by two piecewise constant functions. The overall mixed-integer dynamic optimization problem is solved by a branch & bound algorithm, which handles the discrete decisions and the software DyOS, developed at AVT.PT, to solve the underlying optimal control problems.

4.1. Product specifications and other constants

The bounds of the average properties of the blend and the component properties are displayed in Table 1 and 2. The lower bounds of the volume fraction are defined as follows: $\underline{\phi}_{1,p} = \underline{\phi}_{2,p} = \underline{\phi}_{3,p} = \underline{\phi}_{5,p} = \underline{\phi}_{6,p} = 0,\ \forall p \in P$. Moreover, $\underline{\phi}_{4,p} = 0\ \forall p \in \{1,2\}$ and $\underline{\phi}_{7,p} = \underline{\phi}_{8,p} = \underline{\phi}_{9,p} = 0\ \forall p \in \{2,3\}$ and $\underline{\phi}_{4,3} = 0.1$, $\underline{\phi}_{7,1} = \underline{\phi}_{8,1} = \underline{\phi}_{9,1} = 0.05$. The upper bounds of the volume fraction are defined as $\overline{\phi}_{3,p} = 0.1$, $\overline{\phi}_{5,p} = 0.25$, $\overline{\phi}_{6,p} = 0.1$, $\forall p \in P$. Moreover, $\overline{\phi}_{1,p} = 0.25$, $\overline{\phi}_{2,p} = 0.24$, $\overline{\phi}_{4,p} = 0.23$, $\overline{\phi}_{7,p} = \overline{\phi}_{8,p} = \overline{\phi}_{9,p} = 0.02$ $\forall p \in \{2,3\}$ and $\overline{\phi}_{1,1} = 0.22$, $\overline{\phi}_{2,1} = 0.2$, $\overline{\phi}_{4,1} = 0.06$, $\overline{\phi}_{7,1} = \overline{\phi}_{8,1} = \overline{\phi}_{9,1} = 1$. The initial values of the volume in the product storage tanks are $V_{1,p}(t_0) = 5000l,\ p \in \{1,2\}$, $V_{1,3}(t_0) = 0l$ and of the volumes of component c in the blender are $V_{1,c}(t_0) = V/|C|, c \in C$. The bounds of the storage tanks are $\underline{V}_1 = 2500$, $\underline{V}_2 = 3000$ and $\overline{V}_1 = 8000$, $\overline{V}_2 = 7500$. The component prices are $D_1 = 24$, $D_2 = 20$, $D_3 = 26$, $D_4 = 23$, $D_5 = 24$ and $D_6 = D_7 = D_8 = D_9 = 50$ €/l.

Table 2: Component properties $\rho_{c,e}$ used in the case study

4.2. Results

The optimal objective function is 667,59 € with the production sequence l-2-3-1-2. This is about 9% better than, for example, the objective of the sequence 2-1-3-1-2. Figure 2

displays the optimal control functions $F_{k,c}^{in}$ for $c=2,4,7$ and the product specifications $\pi_{k,5}$ and $\phi_{k,7}$. The vertical dotted lines denote the stage boundaries. Odd stages are transitions, while even stages are production stages. As shown in Figure 2, the product specifications are not constant in general during the production phases, but vary inside their boundaries depending on the products manufactured in the preceding and next stage. The control profiles strongly differ in the transition and production phases. This suggests using finer discretized control variables for future works. The computing time is at most 5 minutes for a branch & bound node. All-in all, 22 nodes were calculated, which is of similar complexity than for total enumeration, since this example is of small integer complexity.

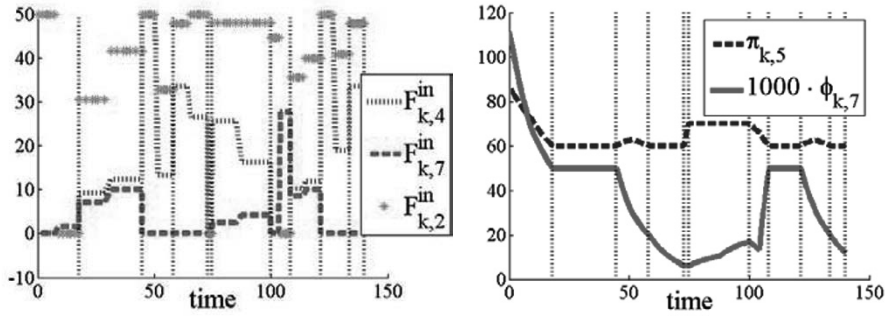

Figure 2: Control functions $F_{k,c}^{in}$ for c=2,4,7 and product specifications $\pi_{k,5}$ and $\phi_{k,7}$ for the optimal production sequence 1-2-3-1-2.

5. Conclusions

This contribution incorporates for the first time both nonlinearities and process dynamics into the modeling framework for continuous-time multiproduct blending processes, to allow a better control of the transition and production phases. Case studies with increasing complexity, in particular in product scheduling, as considered e.g. in Mendez et al. (2006), require further research for efficiently solving large-scale mixed-integer dynamic optimization problems.

De-risking Scale-up of a High Shear Wet Granulation Process Using Latent Variable Modeling and Near Infrared Spectroscopy

Koji Muteki, Ken Yamamoto, George L. Reid, Mahesh Krishnan

Pfizer Worldwide Research & Development, Eastern Point Rd, Groton, CT 06340, United States

Abstract: In the development of wet granulated drug products, two primary sources of variance (disturbance) include the operational scale of the high shear wet granulation (HSWG) process and active pharmaceutical ingredient (API) lot-to-lot variability, particularly for formulations containing a high drug load. This paper presents a novel Process Analytical Technology (PAT) strategy using latent variable modeling (LVM) with near infrared spectroscopy (NIRS) to reduce risk in scale-up operations of the HSWG process while simultaneously accounting for API lot-to-lot variability, even with limited manufacturing history. The process involves building a partial least square (PLS) model among the API material properties, the HSWG process parameters and the NIRS end points of the HSWG process based on small scale design of experiment (DOE) batches. The PLS model is then used in an optimization framework to find suitable small scale mechanical process parameters (impeller/chopper speed) that approximate a previous large scale operation so as to keep the NIRS end point of large scale operation constant. Prior to making additional large scale batches with a new lot of API, NIRS end points of large-scale HSWG with the new API lot are predicted based on the PLS model developed from the small-scale operation. If the predicted NIRS end point for the HSWG using the new API lot is not within the target region, the risks associated with the scale-up operation can then be significantly reduced by modifying other HSWG process parameters such as the total amount of water added or total granulation time to achieve the target region. A case study is presented that demonstrates the effectiveness of this methodology during development and scale-up of a drug product manufactured using a HSWG process. The detailed full paper of this study has been published in (Muteki et al., 2011).
Keywords: Latent Variable Modeling, Process Analytical Technology, Quality by Design, Scale-up, Optimization, High Shear Wet Granulation

1. Introduction

In the development of wet granulated drug products, two primary sources of variance (disturbance) are the operational scale of the high shear wet granulation (HSWG) process and raw material lot-to-lot variability, particularly with respect to active pharmaceutical ingredient (API) material. Due to a limited supply of API in the early stages of development, it is often challenging to obtain adequate manufacturing experience and understanding of granular and tablet properties. Clinical supply requirements often necessitate rapid scale-up to intermediate or higher scale (e.g. 10L, 70L, 250L, 900L, etc). Under such circumstances, it is valuable to de-risk scale-up operations of the HSWG process while simultaneously accounting for raw material lot-to-lot variability to ensure timely clinical supply of drug products during development. This paper presents a novel process analytical technology (PAT) strategy using latent

variable modeling (LVM) with NIRS to de-risk scale-up operations of the HSWG process when there is limited batch experience while simultaneously accounting for API lot-to-lot variability. The goal is to scale-up and supply drug product that meets target tablet properties with minimum number of batches, i.e., minimal API consumption.

2. Modeling methodology

This methodology is developed based on small scale DOE batches with various combinations of process parameters and API material lots and with a minimum of one large scale batch manufacture. The models were utilized to de-risk additional large scale-up operations using a new lot of API with different physical properties. The mechanical process parameters (impeller/chopper speed) used for the additional large scale batches are fixed to those used for previous large scale operations.

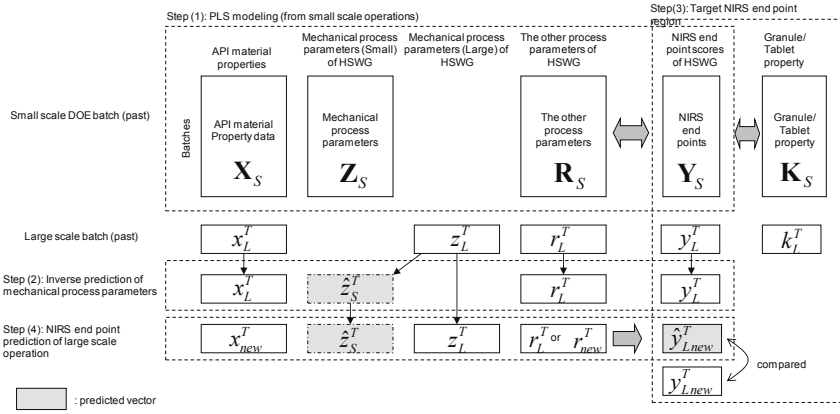

Fig. 1 Overall data structure and procedure of de-risking scale-up operations

The overall data structure and procedure of the proposed methodology are shown in Fig.1, which consists of the following four steps: ***Step (1)*** A PLS model is built with small scale DOE batches to represent the quantitative relationship among API material properties $\mathbf{X}_S$, the mechanical process parameters (impeller/chopper speed) of small scale $\mathbf{Z}_s$, other process parameters (a total amount of water, total batch time) of small scale $\mathbf{R}_s$ and NIRS end points of small scale operations $\mathbf{Y}_s$ (represented as scores by principal component analysis (PCA) using only NIRS data in advance).; ***Step (2)*** The mechanical process parameter (impeller/chopper speed) of small scale operation $\hat{z}_S^T$ approximating that of the previously run large scale batch (with z_L^T) is inversely predicted based on the PLS model built in Step (1) through an optimization computation to keep the NIRS end point of large scale operation (y_L^T) constant.; ***Step (3)*** A suitable target region of NIRS end points is determined from the desired downstream properties such as flow and tablet properties (small scale granule/tablet properties $\mathbf{K}_S$ and large scale tablet properties k_L^T).; ***Step (4)*** The NIRS end-points of additional large scale batches using a new API lot (x_{new}^T), the predicted mechanical process parameters of small scale $\hat{z}_S^T$ (the mechanical process parameter of a past large scale z_L^T is actually used) and the other process parameters (r_L^T or r_{new}^T) are predicted based on the PLS model built in Step (1), on the condition that additional large scale mechanical process

parameters (impeller/chopper speed) are kept fixed to the past large scale operation z_L^T. The predicted NIRS end-points of additional large scale operations are investigated whether they can achieve the target NIRS end point region determined in Step (3). If the predicted NIRS end points are not contained within the target region, the scale-up operation can be then de-risked by suitably updating process parameters such as the total amount of water or total batch time (r_L^T or r_{new}^T) to achieve the desired NIRS end point for the wet granulation process.

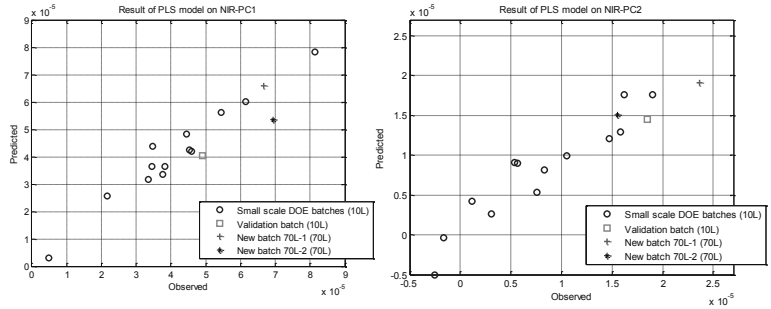
3. Experimental

The tablet formulation used for this study consists of 76% API and 24% excipients. As the API is the largest formulation component its properties could potentially be a major source of variance. A total of nine API properties $\mathbf{X}_S$ were used for the PLS model: 4 particle size distribution parameters (*D10, D43, D50, D90*), 1 bulk density, and 4 moisture sorption parameters (GAB model coefficients *Xm, K, C* and moisture sorption at relative humidity 90%). A Collette Ultima PRO^{TM} equipped with a 10L bowl and a MGT-70S model with a 70L bowl were used to conduct the HSWG experiments. Note, these granulators are dissimilar relative to their impeller diameter, shape, blade type and wall friction, etc. It was not possible to apply the previously reported scale-up rules (e.g. tip speed, Froude number, shear stress, etc.) due to lack of geometrical similarity. The HSWG process was executed sequentially: dry mixing, water addition, and wet massing. A MPA^{TM} (Bruker Optics Inc) was used to collect the NIRS spectra at a 8cm^{-1} spectral resolution and 240 co-adds per spectra. A 13 batch DOE (designed by Plackett-Burman method) was conducted to investigate four process variables and API lot-to-lot effects (3 lots) using a small scale (10L) equipment.

4. Results

4.1. PLS modeling (Step(1))

A PLS model was built to investigate the effect of 9 API properties $\mathbf{X}_S$, 2 mechanical process parameters (impeller/chopper speed) ($\mathbf{Z}_S$), 2 additional process parameters $\mathbf{R}_S$ (total amount of water and total batch time) on 2 NIRS end point scores ($\mathbf{Y}_s$ = [NIRS-PC1 NIRS-PC2]).



(a) (b)

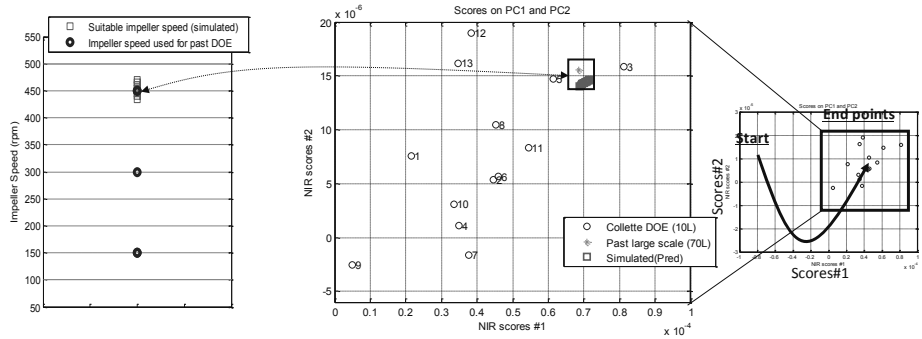
Fig. 2 Result of PLS modeling and validation on: (a) NIRS-PC1; (b) NIRS-PC2

The observed vs. predicted plots on the NIRS-PC1 and NIRS-PC2 are shown in Fig. 2(a) and Fig. 2(b), respectively. The R2 of the PLS models on NIR-PC1 and NIR-PC2 are 95.6% and 88.6%, respectively. The four PLS components for these models were selected to maximize the Q2 value (result of cross validation) and avoid over-fitting.

The PLS model ability is good enough to predict the NIRS end point scores $\mathbf{Y}_s$. Note the four PLS components used are much smaller as compared to the total variable dimensions of $\mathbf{X}_{all}$(i.e. 13).

4.2. Impeller speed relationship across scale (Step (2))

The prediction result of small scale (10L) impeller speed approximating the large scale (70L) is shown in Fig. 3. The NIRS end point score plots of small scale DOE batches are labeled blue "o" with the batch number in Fig. 3(b), the NIRS end point score of the past large scale (70L) batch is labeled green "*" in Fig. 3(b), and the impeller speeds used in the small scale DOE batches are labeled blue "o" in Fig. 3(a). The simulated results of the suitable impeller speed for the 10L scale to achieve the desired NIRS end point score range (depicted by black square) were labeled red "□"in Fig. 3(a). An impeller speed of 450 rpm for the 10L granulator will be used to predict HSWG conditions for the 70L granulator having an impeller speed of 225 rpm.



(a) (b)

Fig. 3 Result of suitable impeller speed of small scale to achieve the NIRS end point of past large scale operation: (a) Impeller speed; (b) NIRS-PC1 vs. NIRS-PC2 plot

4.3. De-risking further large scale (70L) batches (Step(3),(4))

The target NIRS end point region was therefore determined based on the FFC (flowability), as shown in Fig.4. Prior to manufacturing additional large scale (70L) granulations, a developmental small batch (10L) using the new API lot (x_{new}^T) was manufactured in order to validate the PLS model. The prediction results and observed are shown in Fig.2 and Fig.4. The PLS model provided good prediction on both NIRS-PC1 and NIRS-PC2. This small scale batch manufacture was necessary not only to validate the PLS model but also to investigate any possible risk (effect) of unknown (unmeasured) API property which was not accounted for in the PLS model. Performing just one small scale (10L) batch prior to the large scale (70L) operation greatly de-risks and increases the confidence level of scale up process. Prior to performing the 70L batches with the new API lot, a simulation was performed. The process condition used in the past large scale batch (38% total water, 18 minute batch granulation time) was first selected. The predicted NIRS end point scores with the new API lot ("new batch 70L-1") was outside the target NIRS end point region (over-granulated area), as labeled red "+"in Fig. 4. To achieve the target NIRS end point region, the total amount of water and the total batch granulation time were reduced to 34% and 16 minutes, respectively ("new batch 70L-2"). The predicted NIRS end point scores of the updated batch achieved the target NIRS end point region, as labeled by black "+" mark in Fig. 4. Both batches ("new batch 70L-1" and "new batch 70L-2") were performed to demonstrate the

effectiveness of the methodology. The results of these two large scale batches on NIRS-PC1 and NIRS-PC2 (observed vs. predicted) are shown in Fig. 2 and Fig. 4. The PLS model provided good prediction on both NIRS-PC1 and NIRS-PC2. As expected, the observed "new batch 70L-1" resulted was outside the target NIRS end point region, and the actual granules were slightly larger than desired from visual observations of appearance and particle size. The observed "new batch 70L-2" was inside the target NIRS end point region, and the resulting tablets were robust. These results indicate that the proposed methodology worked well and the models are useful and predictive in decreasing the risk during manufacture at the higher scale using a new API lot.

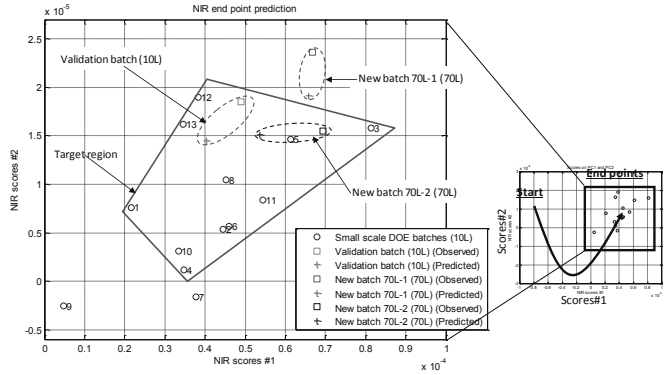


Fig. 4 Result of NIRS end point prediction of validation batch (10L) and two new batches (70L)

5. Conclusion

A scale-up methodology simultaneously accounting for both HSWG scale and API lot-to-lot variability has been successfully applied to de-risk the development of a drug product. The PLS model was built using small scale DOE batches, and provided good prediction on NIRS end points for not only the small scale DOE batches, but also small and large scale batches with a new API lot. This approach provides three advantages from an industrial perspective (1) No requirement of geometric similarity across scales and therefore, a more practical methodology unlike other scale-up models based on dimensionless analysis, and constant tip speed, Froude number, and shear stress. (2) Multiple large scale batches are not required and therefore, a more cost effective method. (3) Using small scale DOE batches to build a PLS model to predict a large scale operation reduces API usage and makes effective use of company assets (historic data), thus providing a useful Science of Scale tool for efficient scale-up in drug product development.

Performance Assessment and Benchmarking of Desalination Plants

N. Bhutani,[a] M. Srinivas,[a] Senthilmurugan S.,[b]

[a]*ABB Corporate Research, Bangalore, Karnataka, India*
[b]*ABB Water ISI, Bangalore, Karnataka, India*

Abstract

ABB has developed a generic "technology" based tool for Energy Assessment and Benchmarking of desalination plants. It facilitates systematic and quick opportunity identification of energy efficiency improvements along with cost-benefit estimation in typical Multi-Stage Flash (MSF) and Reverse Osmosis (RO) based desalination Plants. The tool (i) calculates energy flow distribution, efficiency, losses in equipments and various performance indices (ii) recommends measures/proposals to improve efficiency based on energy assessment and key performance indices (KPIs) based benchmarking (iii) recommends proposals with cost-benefit analysis and (iv) generates energy assessment report. As a test bed, the energy assessment study performed on MSF desalination plant with this tool is presented.

Keywords: Energy efficiency, energy assessment, desalination, reverse osmosis, multi-stage flash, cost-benefit estimation

1. Introduction

Desalination plants play an important role in producing potable water. Multi stage flash (MSF) and reverse osmosis (RO) desalination plants are two pre-dominant seawater desalting systems in the world, constituting more than half of the total desalination capacity. These plants present major opportunities to improve *energy efficiency,* plant *production* and *profitability* [1]. Many authors have applied concept of exergy analysis [2-4] to assess various industrial processes [5-7] but the industrial application of these concepts for energy assessment and benchmarking is very limited. To overcome above limitations, a generic, 'technology' based, graphic user interface (GUI) enabled tool for *"performance assessment and benchmarking"* of desalination systems is developed.

2. Energy Assessment and Benchmarking - Methodology

Conventionally, the energy assessment for industrial processes is performed by domain experts, based on their experience, by – recording, analysis, benchmarking, targeting, and reporting and control respectively. This onsite energy assessment exercise is quite tedious, prone to human errors and sometimes lacks thorough analysis. However, by means of automated energy assessment tool the overall procedure for energy assessment is simplified to these key functionalities: (i) Exergy analysis (ii) KPI calculations (iii) Cost-benefit estimation, explained by means of an application on MSF plant.

3. MSF Desalination Plant

3.1. Process

The schematic flow diagram of an MSF desalination process is shown in Figure 1. The system consists of Heat recovery section (HrecS), Heat reject section (HrejS), a brine

heater, vacuum system, and couple of pumps. The HrecS and HrejS consists 19 and 3 flashing units respectively. The seawater enters the condenser tubes of HrejS where its temperature is raised by absorption of the latent heat of the condensing water vapor on other side of tubes. Partly, the sea water is rejected back to the sea and the rest makes feed, which is chemically treated and then mixed to the brine pool of the last flashing stage of HrejS. The brine, partly extracted from HrejS, is introduced to HrecS (condenser tubes) where it first absorbs latent heat of condensing vapors, and then of the steam in brine heater. The heated brine is then introduced to HrecS first stage where it flashes off, in the subsequent flash columns and gets condensed to form the distillate product stream, which is extracted from the last stage of HrejS. The main thermal energy input to MSF results from use of LP steam in brine heater. Partly, excess steam is vented off or sent to dump condenser (if existing) for steam condensate recovery. MP steam, in small quantity compared to LP steam, is used in vacuum system (not shown in diagram) to remove non-condensable from Flash column. The electricity is consumed to run pumps for Sea water (SW) supply, brine recirculation (R/C pump), distillate product, condensate return (Cond pump) and brine blowdown (B/D pump) etc.

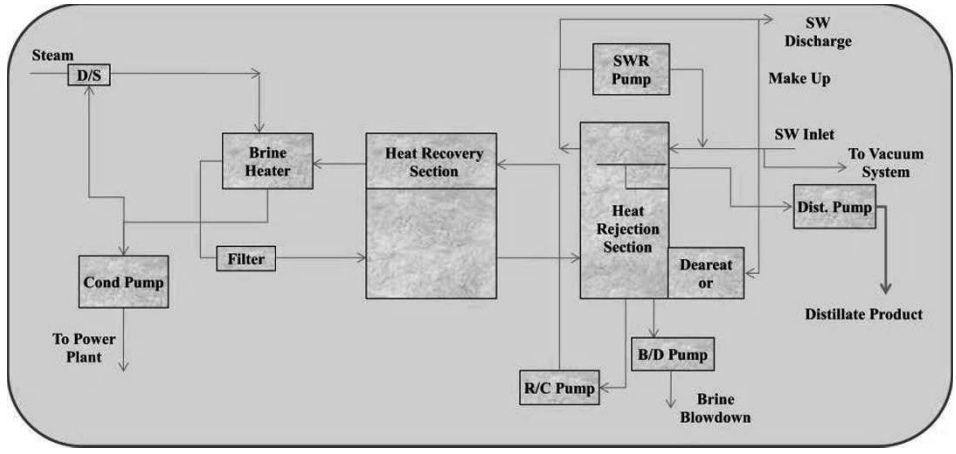

Figure 1 Simplified Process Flow Diagram for MSF desalination Plant

4. Case Study Results

As a pilot case study, the above industrial MSF desalination plant configuration was analyzed using this tool. The steady state operating data collected from the plant for a year of operation was preprocessed by data preprocessor and used for energy assessment in following steps.

4.1. Exergy Analysis

By exergy analysis, it was found that energy was mainly consumed in useful work, destroyed due to inefficiency (of mechanical or thermal process type) in process equipments like heat exchangers, pumps, flash stages, desuperheater or lost to environment with boundary streams (like brine blowdown, sea water reject) etc. The average distribution of exergy destruction in various equipments in the MSF desalination plant (Figure 2) reveals that almost 57% of the thermal energy is destroyed in MSF stages due to irreversible throttling and expansion in multiple flash stages,

followed by 20.7 % energy loss in desuperheater (D/S) due to mixing of superheated steam with condensate spray and 12.1 % loss in brine heater due to inefficiency. On an average 4 % of the energy is lost due to dumping of steam to dump condensers. Though the condensate is fully recovered from dump condensers, the latent heat of steam is still lost in the process. About 2.8 % of energy, in the form of electrical energy, is lost due to inefficiency of brine recirculation pumps. It is found that brine recirculation pump is the biggest pump in MSF desalination section and consumes more than 80% of total electrical input power to MSF section. About 1.8 % of the total energy is lost due to throttling in brine recirculation valve. Energy destruction in other equipments (like brine blowdown pump, distillate pump, condensate pumps etc) and direct losses to environment with brine blowdown stream, distillate product delivery, etc were negligible and therefore combined together into "Others" which makes 1.5 % of the total energy destruction/loss.

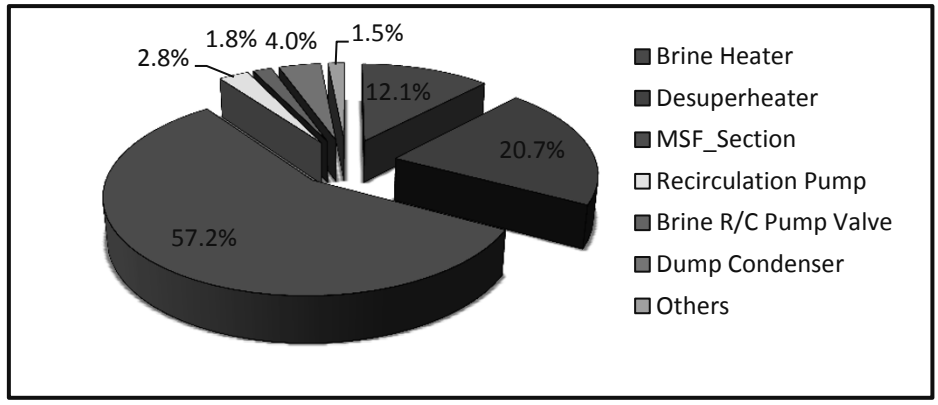

Figure 2 Exergy destruction in MSF desalination Plant

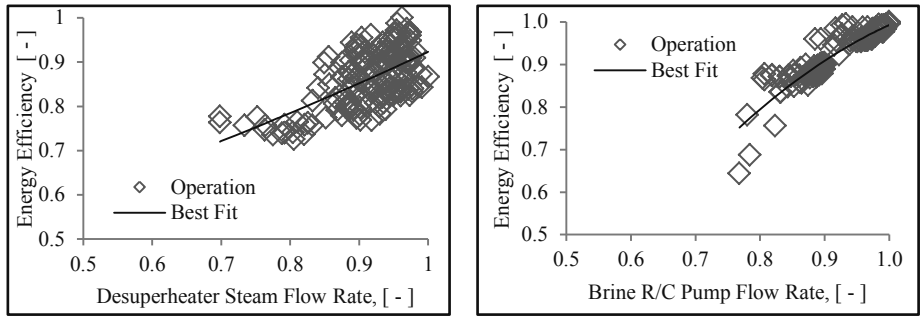

Figure 3 Energy efficiency of Desuperheater (left) and brine recirculation pump (right)

The dimensionless exergy efficiency of brine recirculation (R/C) pump and desuperheater are plotted in Figure 3. The exergy efficiency of desuperheater increases from 0.7 and 0.90 when the steam flow rate is increased from 0.7 to 1. Similarly, the exergy efficiency of brine recirculation pump increases from 0.8 to 1 when the flow is increased from 0.8 to 1, signifying opportunities for improvement in energy efficiency of both the equipments by increasing load on both the equipments. Also, for the fixed

flow conditions, the variations in efficiency are huge in case of desuperheater, signifying possible improvements in energy efficiency by reduced variations.

4.2. KPI Calculator

Various KPIs, defined in the tool, were configured to plant data and calculated for MSF desalination plant configuration. Trend plots were generated for these KPIs to evaluate their impact on plant performance. The specific steam consumption and specific electricity consumption in desalination plant can be reduced by increasing load factor (Figure 4). This would result in a maximum improvement in plant profit of ~ 0.2 kUSD/h (Figure 5, left). Note that a maximum total profit of 650 kUSD/year is possible based on the current plant production distribution profile. The specific steam consumption in plant can also be reduced by reducing the losses due to excessive dumping of steam to dump condenser (Figure 5, right). The mean values of some of the KPIs, defined in **Error! Reference source not found.**, were also compared against recommended values to identify improvements. As shown, by comparison in **Error! Reference source not found.**, a few KPIs are operating within permissible limits while others can be improved further to improve plant performance.

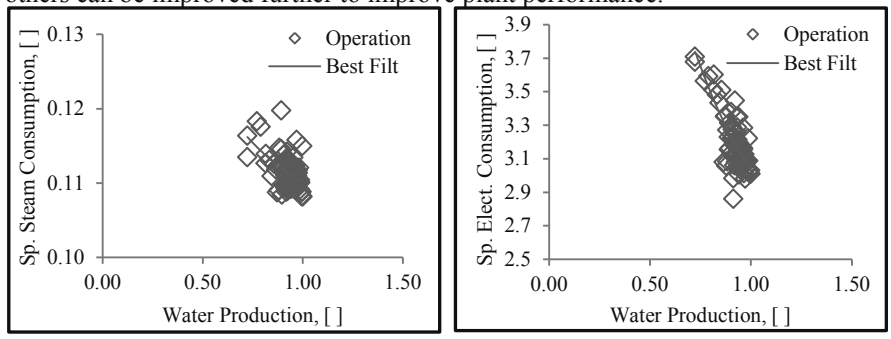

Figure 4 Specific steam consumption (left) and specific electricity consumption (right) with respect to water production.

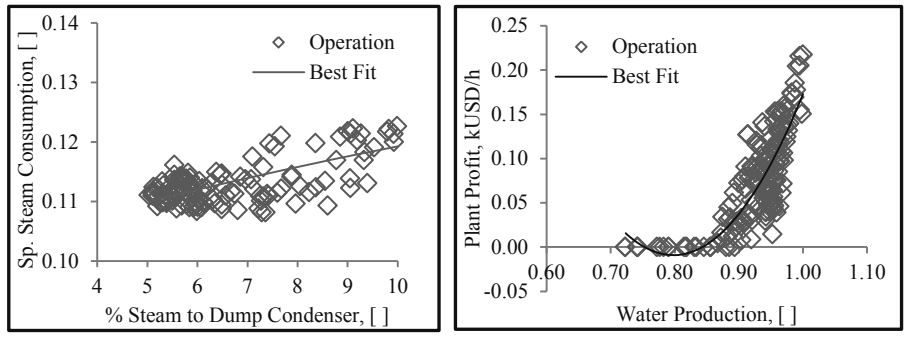

Figure 5 % Steam consumption vs. Specific steam consumption (left) and Water production vs. Plant profit (right) in an MSF desalination Plant.

4.3. Cost-Benefit estimation

In this section, the efficiency estimates of equipments from exergy analysis and improvements in KPIs were translated into cost savings. The estimated cost savings resulting from improved equipments efficiency of brine heater, desuperheater and brine

recirculation pump by improving load factor were 17, 21 and 30 kUSD/year, brine blowdown heat recovery was 19 kUSD and reduced steam losses by no dumping of steam to dump condenser was 104 kUSD respectively. Note that savings are tuned to current production of the pilot plant. Further, cost-benefit analysis is feasible with this tool for replacement of fixed drive with variable frequency drive (VFD) for pumps or other capital investments.

Table 1 Calculated KPI for MSF desalination Plant

KPI Definition	Mean Value	Recommended
Sp. Steam Consumption in major consumers, tons/m^3 water	0.12	Least Possible
Sp. Electricity Consumption in major consumers, kWh/m^3 water	3.22	Least Possible
% Brine Blowdown, %	62.56	Least Possible
Distillate To Makeup Ratio, [ ]	0.36	b/w 0.3-0.4
% Steam To Dump Condenser, %	8.18	Equal to 0 or Least Possible
Degree Superheat of LP steam, ^oC	30.12	Less than equal to 10-15 ^oC
Degree Superheat of Brine Heater steam, ^oC	10.64	Less than equal to 5 ^oC
Delta T Flash MSFSection, ^oC	57.20	Highest Possible
Delta T, SeaWater (Inlet – Reject), ^oC	7.87	Less than equal to 10 ^oC
Delta T BrineHeater (for Brine), ^oC	6.90	Less than equal to 5 ^oC

5. Conclusions

The energy assessment and benchmarking tool was used to identify opportunities for energy efficiency improvements and translate them into potential cost savings for the pilot customer. With a user-friendly graphic user interface (GUI), a wide range of industrial desalination plants/configurations (thermal, hybrid, membrane based) can be analyzed very quickly.

Abstract

We specified modeling requirements for biomass-derived production. An integrated modeling on interdisciplinary analysis across agriculture and engineering can become a key mechanism for enabling the clarification and fulfillment of the potential of biomass for sustainability. A modeling case study on sugarcane-derived ethanol production shows proposed integrated model can be used in the analysis of the environmental impacts associated with different conditions in agricultural and industrial process systems such as sugarcane cultivar and agricultural operation.

Keywords: sugarcane-derived ethanol, greenhouse gas, life cycle assessment, cultivar improvement, food production.

1. Introduction

Biomass resource and biotechnology have become key technologies for sustainable bioethanol production. In the previous studies, the environmental impacts of sugarcane-derived ethanol have been analyzed and its advantages on greenhouse gas emission have been confirmed (Macedo et al 2008; Sánchez and Cardona 2008). At that time, it was also confirmed that the composition of sugarcane have high sensitivities to the result of environmental assessments and process performance (Ohara et al 2009). Such detail features of sugarcane are strongly dependent on cultivars (Ohara et al 2009), the conditions of climate and soil, and the agricultural operations. To design a whole life cycle system of bioethanol appropriately, an integrated modeling from agriculture and engineering perspectives can be an effective approach.

Although modeling approaches for biomass-derived products have been discussed (Nguyen et al 2010; Kikuchi et al 2010), the process data of biomass cultivation was based on specific literature and biomass cultivar was not considered. Experimental results on yield and component of various cultivars of sugarcane planted in various types of soil have been cumulated as reports in agriculture (Okinawa Agricultural Experiment Station 1991; National Agriculture and Food Research Organization, National Agricultural Research Center for Kyushu Okinawa Region 2010).

In this study, we tackle with the integrated modeling of a whole production process of sugarcane-derived bioethanol. The modeling is based on the interdisciplinary approach to combine the knowledge from agriculture and engineering fields. The ethanol production system from sugarcane includes sugarcane cultivation, sugar and ethanol productions. The process parameters and conditions influencing on the environmental impacts due to the production of biomass-derived materials were specified and mathematical models were developed for such cradle-to-grave life cycle.

2. Specification of modeling requirement

To concretely identify the relationship among biomass related technologies and their impacts on social, economics, and environment, information-modeling approach based on unified modeling language (UML) (Objective Management Group 2011) was applied. UML has a large potential to visualize modeling requirements clearly for tools from design stages to maintenance and sustainment stages in agriculture and industrial processes. In UML class diagram, information categories are structured and characterized by specifying their properties and relationships. In addition to the static modeling by UML class diagram, dynamic information flows among stakeholders involved in agriculture and engineering processes can be discussed on UML activity diagram.

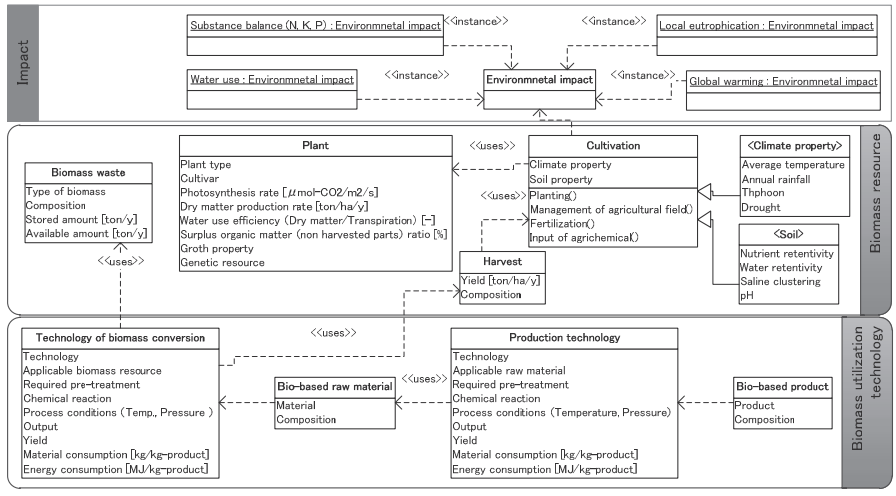

Figure 1.Overview of specified information relationships associated with agricultural and industrial processes

Figure 1 shows the overview of specified information relationships associated with agricultural and industrial processes by UML class diagram. In this diagram, the elements related with biomass resource and utilization technology. For example, biomass resources can be obtained as the result of cultivation. The composition of harvest is related with the properties of plant, agricultural operations, climate, and soil. It has also links to the biomass utilization technologies. Required pretreatment processes and available bio-based raw materials or products are strongly related with such resource conditions. Based on this diagram, we can systematically discuss the requirement on the modeling for designing agriculture and industrial processes in an integrated manner.

3. Case study: Sugarcane-derived ethanol production

3.1. Settings

Using developed modeling requirement as shown in Figure 1, an integrated model on sugarcane-derived bioethanol production was constructed as a case example. Data required for process modeling was based on the operation results of a pilot plant of sugar crystallization and ethanol fermentation constructed in Ie island in Okinawa prefecture, Japan (Ohara 2009). Heuristics and empirical data on biomass cultivation, sugar crystallization and ethanol fermentation were collected through investigations on existing literature and agricultural reports (Okinawa Agricultural Experiment Station 1991; National Agriculture and Food Research Organization, National Agricultural Research Center for Kyushu Okinawa Region 2010; Rein 2007; Okinawa Prefecture, Agriculture, Forestry and Fisheries Division 2010; Okinawa Prefecture 2006) and interviews to experts. In the development of an agricultural process model, the relationship among the process parameters on sugarcane cultivar, farm operation such as fertilization, and the conditions of cultivation area such as climate and soil was modeled on the basis of the results of the existing studies or cultivar evaluation. Depending on the composition of sugarcane such as sucrose, glucose, fiber, water-soluble materials, and water, the performance of sugar crystallization and ethanol fermentation processes are changed. For example, the sucrose and glucose are the raw material for ethanol fermentation, although glucose is an inhibitor of sugar crystallization. Fiber is not raw materials for sugar and ethanol production, but can be fuel for these processes and a green manure for agricultural field. Syrup is obtained after pretreatment of sugarcane, e.g., milling, fining and filtration treatments. Sugar crystallization is started by crystal seed, and crude sugar in massecuite is separated from molasses by centrifuge. 1st molasses includes about 70 %-sucrose in absolute dry mass. To increase sugar yield, sugar crystallization may be continued three times in Japan. The empirical relationships between sucrose purity and crude sugar yield were obtained from literature (Rein 2007) and operation results in Ie pilot plant. Molasses is the raw material for fermentation producing ethanol. Through interviews to experts and analysis on operation results of the Ie pilot plant, representative fermentation process was modeled.

In this case study, a life cycle assessment was performed by using developed integrated model. The settings of cases are organized in Table 1. The current situation of sugarcane cultivation and sugar crystallization in Japan is defined as the setting of base case. In case 1, the step number of sugar crystallization is decreased from 3 to 1. New cultivar of sugarcane is applied in case 2. Case 3 applies the new cultivar of sugarcane with one-step sugar crystallization. Based on these cases, the production amount of crude sugar and bioethanol, and greenhouse gas (GHG) emission due to their productions are evaluated with an assumption that produced bioethanol can be used as a fuel instead of gasoline.

Table 1. Case settings

	Base case	Case 1	Case 2	Case 3
Sugarcane cultivar	Current	Current	New	New
Crystallization step	3	1	3	1

3.2. Results and discussion

Table 2 organizes the results of agricultural processes. NiF8 is a cultivar of sugarcane widely planted in Japanese sugarcane field. KY01-2044 is called as “monster cane”,

which is a new cultivar of sugarcane developed in Japan. Slightly lower sugar-content than NiF8, but higher yielding is the characteristics of KY01-2044 as shown in Table 2.

Table 2. Results of agricultural processes

Cultivar	Yield	Composition [%]				
	[10^3 kg· $(10a)^{-1}$]	Sucrose	Glucose	Mineral	Fiber	Water
NiF8 (Current)	7.7	14.3	0.6	1.6	11.4	72.1
KY01-2044 (New)	10	13	0.7	2.4	14.7	69.2

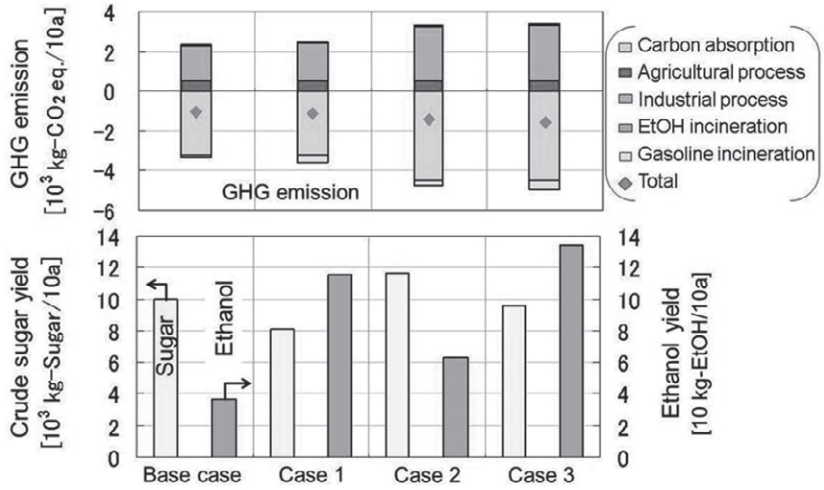

Figure 3. Total results of case study

Figure 3 shows the evaluation results of four cases. Comparing the results of base case and case 1, the decrease of crystallization step increases the production of bioethanol resulting in low GHG emission by applying bioethanol as a fuel. Case 2 demonstrates that new cultivar of sugarcane can increase sugar and bioethanol, because of its high-yielding characteristics. The new cultivar can produce nearly equal amount of sugar obtained in base case, as shown in the results of case 3.

The results of this case study reveals that new cultivar of sugarcane can increase the production amount of sugar and bioethanol in unit land area, simultaneously. It means that it may be able to increase sugarcane-derived bioethanol without the change in the production amount of food. In this regard, however, the results of agricultural process should be carefully checked, because they are highly sensitive to soil, climate conditions, and agricultural operations.

4. Discussion and conclusion

The developed model in case study on sugarcane-derived bioethanol can be used in the design of agriculture and industrial process systems to specify preferable sugarcane cultivars, agricultural operations, and production conditions for certain place under various constraints such as the demand or targeted amount of ethanol and sugar. Considering climate conditions and the prices of sugar and ethanol, the model can

propose alternatives on operations in cultivation and industrial processes. This kind of integrated agriculture and engineering model may become a strong tool for solving issues occurred in Asian countries, for example, the reduction in the land suitable for agriculture, the high frequency of abnormal weather, and the wild fluctuation of the prices of food and energy. Their conditions differ by year and counter measures must be planned constantly. The model can become a key mechanism for supporting analysis, alternative generation, and decision making on such issues. Note that the developed model is based on limited Japanese evidence. Further modeling on the relationships among impacts on environment, social and economics, amount and quality of biomass-derived products, and detail conditions on agricultural and industrial processes such as soil, climate, and so on are strongly needed.

Planning and Scheduling as a Part of a Control System – Implementation Aspects

Iiro Harjunkoski

ABB Corporate Research, Wallstadter Str. 59, 68526 Ladenburg, Germany

Abstract

This paper discusses some aspects that need to be taken into account when designing and implementing solutions for scheduling real industrial production processes. It highlights certain characteristics that may complicate the practical implementation and focuses on typical requirements stemming from everyday life at a production facility. The paper concludes with some necessary system development steps and reflects those using experiences from a few real-life implementation cases.

Keywords: Scheduling, industrial, integration, control system.

1. Introduction

The activity of scheduling results in a detailed and realistic production plan based on the production targets (orders) often provided by ERP systems. The detailed schedule is then dispatched to the plant floor, where automation and control systems ensure a smooth and efficient production. Scheduling of an industrial production process is complex due to several reasons, among others:

- The problem size may grow exponentially when scaled up to industrial size.
- There are often interruptions or disturbances in the process, which impact the goodness of an existing production plan.
- Normally, the underlying process is monitored, controlled and optimized by several systems, the targets of which may conflict with each other.
- The data available is mostly reflecting the past – access to up-to-date information is crucial as well as selecting which data to use and not to use for optimization.
- Manual interaction is often necessary. It must be clear which decisions need to be optimized and which ones should be made by the operator.

A proper level of integration is very important to any type of automation component. Even the most advanced and efficient planning and scheduling solution can never see the daylight in a real production environment, unless it can be tied into the real-world situation. Normally, the production schedule is generated on demand by composing a varying set of input data in a proper way. Scheduling is thus neither an isolated nor a one-off computational exercise.

The deployment topic was also discussed at the PSE2009 meeting e.g. by Henning (2009), also raising some challenges. For overcoming these, it is crucial that the method developers (often academics) and the implementers (industrial practitioners) collaborate seamlessly with a clearly defined common goal in mind. By using scalable methods where critical sets and parameters are easily configurable through user friendly interfaces, a well-balanced compromise between problem size, solution efficiency and solution quality may be found. Such approach may also help to balance various solution targets. Ensuring that the solution is capable of adapting to frequent changes (both at a model and SW-level) makes it functional in varying situations treating disturbances as

"everyday life". A well-defined relation between each model and solution component and their connection to the real process also contributes to increasing the overall understanding of a holistic system.

2. Production environment

A planning and scheduling (P&S) system needs a large number of data in order to work properly and fulfill its purpose. To access, monitor and analyze the relevant data in a useful way, Process Information Management Systems (PIMS), Manufacturing Execution Systems (MES) or Collaborative Production Management (CPM) systems exist to fill the gap between the process control systems and ERP systems. A planning and scheduling solution must have a well-defined role and work seamlessly within an existing production system in order to be able to support operations.

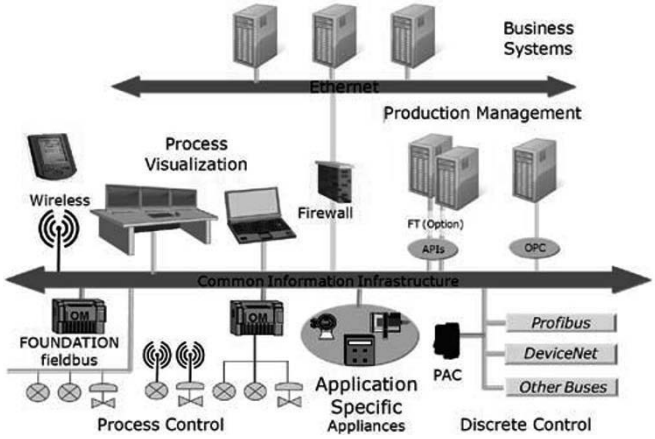

Figure 1. Logical view of a production system (Source: ARC, 2010)

Figure 1 shows a simplified view of a production system with the different hierarchical layers. Commonly a P&S solution is located in the production management layer and needs information both from the planning (ERP) as well as the process / distributed control systems (DCS) levels. Thus it is important to have a common information infrastructure that enables easy and efficient communication and management of data.

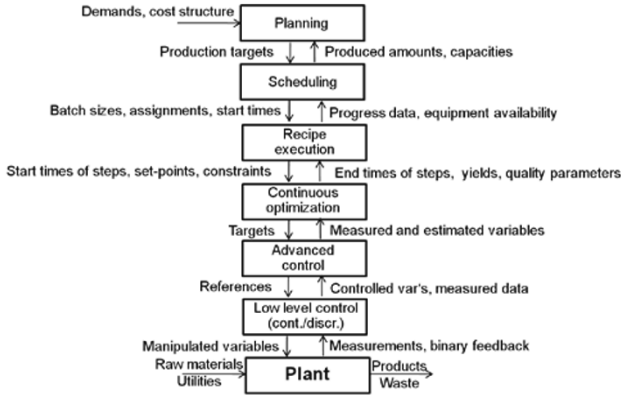

Figure 2. Functional hierarchy of batch production (Engell & Harjunkoski, 2012)

Another view on the decision landscape is seen in Fig. 2, which presents the functional hierarchy of a production system. It contains six main layers: A planning layer setting

the production targets, a scheduling layer generating the detailed schedule, a recipe execution layer governing the batch or production recipes, a continuous optimization layer optimizing the trajectories during the phases and an advanced control layer implementing the optimal trajectory e.g. through model-predictive control (MPC), and providing reference values to the low-level control layer, which is directly connected to the process.

A challenge is to ensure that information can be exchanged smoothly, e.g. information such as equipment availability is transmitted through this functional hierarchy up to the scheduling layer. This also puts more pressure on improving the interfaces and plug-ability of any kind of industrial scheduling solution. Standards such as ISA-88 and ISA-95 (ANSI/ISA, 2005) are often recommended as they can be expected to reduce problems in integrating different solutions. It is today physically possible to link every functional IT-component within a plant, as modern DCS also enable this. Nevertheless, because of the multitude of options it is very important to carefully investigate and analyze which factors can bring added value to the production process. Collaborative Process Automation Systems (CPAS, Hollender, 2009) expand the vision beyond the traditional DCS scope, and present an environment designed for agility and adaptability.

Main challenges for the implementation of P&S solutions are:

- Modeling. The cost and required time for modeling is often much too high, sometimes hindering even the exploration of potential benefits.
- Optimization algorithms. Solution times and robustness is crucial especially for online solutions.
- Interaction with the user / human operator. A solution that is not accepted by the operators will not be used in the long term, even if a benefit could be demonstrated.
- Automation systems and components. Integration of different software systems for different functions acting on a common open data structure is needed.
- Systems engineering. The design of integrated systems is a challenge for which no generic guidelines are available.

3. Example cases

Typical daily scheduling use cases that every P&S solution must be able to handle are:

- Rush customer orders (re-scheduling with priorities)
- Late deliveries or customer pickup (material & inventory considerations)
- Equipment breakdown or process delays (re-scheduling with possible re-routing)
- Scheduled maintenance (important to respect while maximizing productivity)
- Product quality problems (lower productivity, normally detected at the control level)

This also highlights the needs of good integration, user interfaces and rescheduling strategies. The core scheduling model or algorithm, often developed e.g. by a university or research laboratory, is only a part of the overall scheduling application. Production scheduling is a data intensive exercise and the success of an implementation relies on the quality of the data used by the model and on the effective transfer of data to and from the model. Before any implementation several issues must be confirmed:

- Separation of data and parameters from the model equations
- Full scalability of the models based on the provided data
- Ability of an advanced scheduling approach to solve the problem
- Availability of data needed for the advanced solution
- Possibility to integrate into the existing scheduling process and information system

In this paper we consider two concrete scenarios of integrating a P&S solution: One where the scheduling is added into an existing system and another one without a “host”.

3.1. Adding a P&S module into an existing CPM system

If the scheduling optimization solution needs to be embedded into an already existing and well-defined system, the integration effort is fairly low. The main focus on the implementation is to ensure that the solution works for all possible instances and has a way to react to unreasonable requests, i.e. fallback strategies or communication by failures. The hosting solution will be responsible for collecting all required input data (e.g. from databases, ERP and control system), converting it and providing it in a defined data format. It must be highlighted that often there are several programs involved, even written in different programming languages, so the responsibilities need to be clearly assigned to simplify the definition of roles within an integration team.

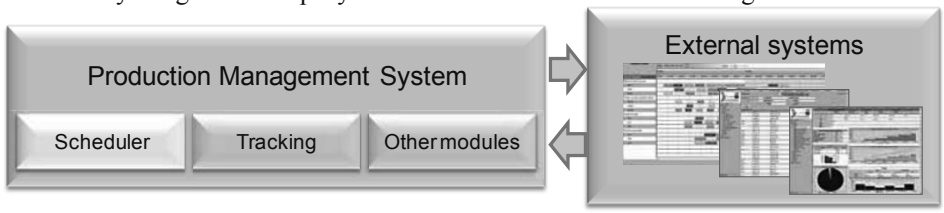

Figure 3. Scheduler as a part of an existing system

Although the integration is more or less trivial, the implementation work still requires lots of efforts, e.g.: Collection of requirements, modeling, constructing test cases, proof-of-concept in full scale, interface definition (data exchange format, how to actually invoke the solution), solution implementation (programming), comprehensive testing (never underestimate this) and finally detailed system documentation explaining the solution structure, use and possible enhancement. Through this strategy all existing connections to external systems (e.g. Gantt Chart) can be used without new efforts (see Fig. 3). It is still fairly realistic to say that the implementation easily takes about 5-10 times the amount spent on building a first prototype on for instance GAMS or AMPL, especially if these are not going to be part of the final system.

3.2. Implementing scheduling solution as a standalone module

In this scenario, the efforts of implementing a solution as a standalone module are huge: All data exchange, user interfaces, accessibility, security and backup policies must be defined separately. In this case applying standards can result in significant time savings at the implementation but also enable various future expansions, integrate-ability and it also makes it easier for a third person to work with further system development in the future. An example of such as solution is shown in Fig. 4, where the optimization models have been isolated in a modular structure and all data and parameter exchange is done using the ISA-95 standard with certain extensions.

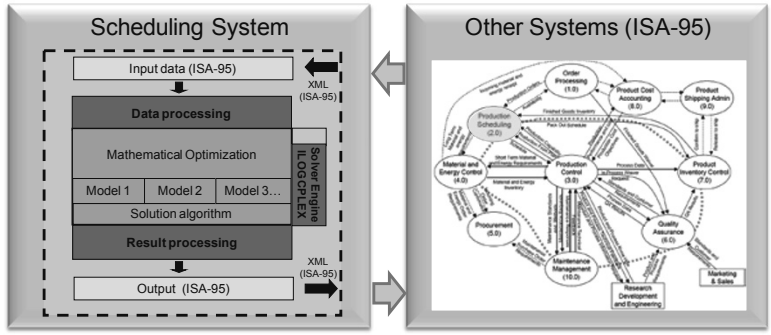

Figure 4. Modular solution and the ISA-95 Purdue Reference Model

The approach in Fig. 4 can be integrated in various ways, e.g. as a web-service (available through the internet), as a console or windows application or as a windows service. In all cases, the main system features remain the same and the data exchange is always based on the XML-file format.

4. Conclusions

The focus of this paper is on the integration and implementation, omitting the main mathematical challenges. Nevertheless, the original problem formulation must naturally comply with real requirements and be fully expandable through parameters. Along the proof-of-concept, models will continually be modified and enhanced also later as a more comprehensive understanding of the problem emerges through systematic testing and validation. Often the early use of a scheduling solution also tends to uncover necessary changes to account for unanticipated circumstances. Even when the model is robust and has been proven, it may need to be developed further due to possible changes in the production process or surrounding solution landscape as a scheduling solution must play a part in a complex IT-infrastructure. Thus, ideally the scheduling model should automatically adapt itself to most changes in the neighboring system, which may result in performance issues. Implementing a scheduling optimization solution in real life is challenging:

- In running production, every schedule is, in fact a re-schedule building upon a previous schedule. One important question is how to re-schedule in case of sudden disturbances?
- The solution should be maintainable for at least a 10-20 year time horizon (update models, adapt to major software updates).
- It should be possible to easily integrate the solution and link it to other applications.
- Implementing the solution should also ensure a good return-on-investment (ROI), which is directly affected by the related software license and development costs.
- Measuring the real performance or achieved improvement is not trivial as often the given schedule cannot be realized to 100% exactness.

Maintaining an industrial scheduling solution requires collaboration between various skills. Taking some steps towards integrated solutions already in the early model development phase may significantly reduce the required efforts (and costs) of implementing a theoretical method in practice. The ideal goal is that state-of-the-art academic models and algorithms could be tested in a plug-and-play manner on challenging industrial problems. This would speed up the development on both ends and enhance the success of optimization methodologies in the industry. But is this still a utopia? Not necessarily.

Advances in Procedural Automation in the Chemical Industry

Maurice Wilkins[a], Marcus Tennant[a]

[a]Yokogawa Corporation 2155 Chenault Dr. Carrollton TX, 75006 U.S.A.

Abstract

Over the past 20 years there has been significant advancement in automating batching processes in the Chemical industry. Many of the principles, models, and best practices outlined in the ISA-88 standard have lead to better control systems, more efficient designs, increased flexibility and safer operation of Batch processing plants.
Recently, ISA 106 was formed and now is working towards producing a standard for automating procedural operations in continuous processes. We review the concept of Modular Procedural Automation and a case study of how a company implemented procedural automation and the direct benefits they have achieved.

Keywords: Procedure, Safety, Operating Efficiency

The Chemical Industry- The tale of two business drivers and production systems.

The Chemical Industry is estimated to generate approximately three trillion US dollars a year in annual sales and supplies many markets with essential materials that are critical to making each a success through utilizing different processes, material, and operations. In classification of the chemical industry there are several ways of examining the sub segments. From a business perspective, it has been often been useful to analyze the chemical industry into two primary segments 1) Bulk Chemicals and 2) Specialty and Fine Chemicals.

Bulk chemicals produces material at the lowest cost with a focus on production innovation while specialty and fine chemicals focuses on product innovation and responding to rapid time to market product lifecycles. In general, the production process for manufacturing that supports the business driver in bulk chemicals is continuous process applications and with fine and specialty chemical, it has traditionally been batch process applications.

As global competition intensifies, the chemical industry is becoming more polarized along these two models. Material intermediates and their corresponding supply chains in the chemical industry are increasingly losing their margins at intermediate materials production. Every business segment in the Chemical industry must determine if their chemical product is either a commodity with a focus on a becoming a low cost producer and optimizing a production system that produces cost competitive material or if they

are a specialized materials solution provider maintaining a production system with maximum flexibly to meet rapidly changing market demands.

1. Advances in Procedural Operations in Specialty and Fine Chemicals

In the late 1980's specialty and fine chemical manufacturers faced a problem. In the previous decade, rapid advances in control technology from sensors, meters and distributed control systems had provided significant benefits to many process industries including the chemical industry. However, using these new technologies in automating batch processes often created problems and unintended consequences.

Due to non standard definition of terms that varied between companies and industries, it was often difficult to convey requirements to control vendors and system integrators. Terms like Procedure, Unit, and Recipe meant different things to different companies.

Improvements in automation and control often limited production flexibility. Many chemists, process engineers, and formulation scientists found it frustrating that when they had to make a procedural or formulation changes to their products they had to call in the control engineer to make the changes in the control system and often had to face significant delays. This directly impacted an important business driver in batch processing – production flexibility. Sometimes a plant would abandon the control system and revert to manual operations where they would make a change to a paper process sheet and hand it to the process operator

Lack of consistent programming methodology- Often a control engineer would build an Ad hoc batching program that would be initially well accepted by the operational staff. Eventually the control engineer would move on to a different job within the organization or leave the company altogether. The program would usually lack documentation and a consistent structure that a new control engineer could go in an easily make changes to meet the ever changing requirements of the process.

In light of these issues in 1988 the ISA (International Society of Automation) formed a standards and practices committee that focused on the automation of batch processes (ISA88). In 1995, the committee issued ISA 88 part 1- models and terminology for batch process applications. Since its issuance the ISA-88 standard has provided manufacturers in batch focused applications tremendous benefits, not only in Chemical but also in Pharmaceutical and Food & Beverage. Many papers have been written in the past 12 years that have highlighted the benefits of the standard and the business values such as: 1)Reduction in production cycle time. 2)Reduced Engineering Costs in initial implementation and in modifying systems. 3)Reduction in cost for Validation in cGMP applications. 4)Increased process plant throughput. 5)Improved Safety and risk reduction

2. Safety, Operational efficiency, and aging workforce – Bulk Chemicals emerging focus on procedural operations

As continuous process plants have taken advantage of the changes in process controls technology, it has helped make unprecedented gains in production efficiency. Most of

these benefits have occurred by optimizing steady state operations. All chemical plants spend a majority of their time at steady state but other conditions occur on a regular basis and require the most attention from the operational staff.

Startup & Shutdown-Safe and efficient startup of a continuous process unit or activity is critical to its overall operation. Startup frequency can vary, from once every day to once every five years. When startups occur often, they can occur on different shifts, and the time and skill of the operator on duty can determine the efficiency of the startup. If startups occur at longer intervals, companies run the risk of not having experienced personnel available to run and oversee the startup. Orderly and safe shutdown of a continuous process unit or operation is just as critical as a startup. One key item in the shutdown procedures is recognizing that a shutdown might not be scheduled. System problems, severe weather conditions, or power outages can require a shutdown of process operations at very short notice.

Feedstock and product output transitions- Many chemical processing units regularly operate at more than one optimum steady state. In refineries and petrochemical operations, for example, many facilities purchase feedstock of different properties from different sources and vendors. As the process runs out of one type of feedstock, operations must be adjusted to process correctly the next lot of feedstock. Similarly, in many chemical plants, it will often be a requirement to make a variety of products in a campaign fashion by changing operations to meet the new product specification.

Recovery from Abnormal Conditions- In the course of plant operations, process conditions from time to time enter abnormal operating regions where a plant is producing off spec or low quality material. Additionally, the process conditions may approach a critical condition that could cause a safety system shut down or worse a serious plant incident. This could be caused by a previous operational error or an equipment malfunction. Procedures are available for an operator execute to bring a process to normal operating conditions or to a safe state.

In most continuous process Chemical plants in the world these operations are performed by operators completing manual steps interfacing with a control system or instructing a field operator to manipulate a valve. Efficiency and accuracy in executing these operational procedures requires an experienced operational staff. Often through years of hands on experience the knowledge in a plant is no longer documented and resides in operators heads. One issue facing process plants worldwide is the loss of these knowledge based operational skills due to an aging workforce and retirements. This has already begun to affect many process manufacturers around the world.

Another issue is safety incidents caused by operational error. A study by J & H Marsh & McLennan that the shows that in an examination of major incidents by the average loss per incident indicates that operational error represents the largest average dollar loss[a]

3. The emergence of a procedural automation standard for the continuous process industries

Since the development of ISA 88, many practitioners of the standard have applied the model and principles to continuous process applications with various degrees of success, many process operations such as ethylene production, distillation, and polymer extrusion have had ISA 88 concepts applied, however there was never any whole scale adaptation of the standard to continuous process industries. Many Process manufactures have felt that ISA 88 was too rigid in its approach and did not take into account many other standards and practices that have emerged since ISA 88 was developed such as alarming, safety systems, security, and HMI interface design.

In view of the need for an industry standard to focus on continuous process operations, the International Society of Automation approved the formation of a new standards committee in April 2010, the committee, ISA106 adopted the title Procedural Automation for Continuous Process Operations. The purpose of the committee at its first meeting in June 2010 was to develop a standard, recommended practices and technical reports for the lifecycle of automated procedures for process operations in industries. So far, the standard has input and support from over 40 chemical manufacturers, refiners and suppliers. The initial goal is to publish a technical report based on the good practices that are used today, with a target release in 2012. Following that, the committee plans to refine the material and publish a standard

4. **Application of Procedural Automation & Case Example**

Yokogawa Corporation over many years has followed best practices in ISA-88, and often applied the lessons for the standard to continuous process applications. To capture the embedded knowledge and to convey to owner/operators the benefits, Yokogawa introduced an integrated solution concept called Modular Procedural Automation (MPA). MPA addresses industry needs to improve operating procedures and to apply a uniform approach to the standard using different technology tools. It is a consultative methodology whose purpose is to document and automate procedural operations in continuous processes. This approach optimizes user acceptance and reduces deployment costs by:

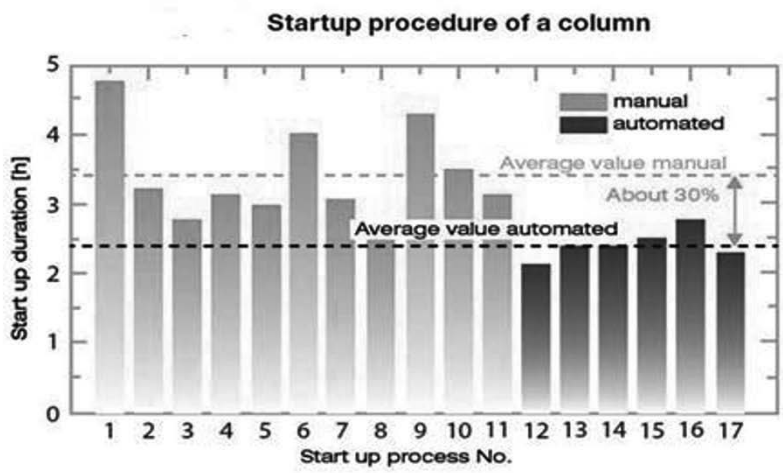
Establishing a hierarchy of Procedures: MPA breaks large and complex procedures into smaller modules and organizes them into a hierarchy. This modularization provides easier documentation, verification, and implementation of the discrete pieces of procedural logic and knowledge.

Re-use of Procedural Logic: Whether implemented with manual, prompted, or automated procedures, MPA can help re-use the same procedures and logic in different parts of the plant and with different products. When procedural logic (that is portions or modules of procedures) is re-used, the business gains repeatability, reliability, and it lowers the cost of developing duplicate procedures.
Use a Scalable Approach: MPA provides a flexible and scalable approach to automation; it avoids the “one size fits all” approach. Different types of procedure implementations contain scalability for manual, prompted, and automated control. The hierarchy of modular procedures is easily adjusted to fit the application requirements which can vary the level of complexity;

For example Evonik Industries operates an Acrylic Acid production facility in Germany that has integrated into the process two reactors, four distillation columns, and a

crystallizer for the manufacturing process. A regular system shutdown of the production of Acrylic Acid is required for cleaning and maintenance. The startup procedure for Acrylic Acid manufacturing requires the skills of experienced operators to bring the process up to steady state. Any additional time to bring the process to full production results in unnecessary rework and waste of production utilities.

Evonik developed their requirements and worked with Yokogawa engineers utilizing an MPA approach and determined the correct procedures and technology to automate the process. The results were
1) Process operators were able to start up their distillation columns 30% faster
2) Reactors were able to come on stream 70% faster
3) Process safety margins, of explosive conditions during startup, were increased significantly



5. Conclusion

Today many procedural operations in both continuous and batch processes are performed manually, often inefficiently and sometimes unsafely. With an aging workforce and business pressure to reduce cost, improve quality and reduce safety and environmental incidents, automating procedures offers the ability to preserve and manage a plant's and company's operational and procedural knowledge and improve safety performance. Modularizing the design and implementation also provides cost savings while allowing the flexibility to make changes without impacting production. The general need for procedural automation has been shown with the formation of the ISA106 standard committee and the strong industry support for it from both users and suppliers alike.

Retrofit design of a pharmaceutical batch process improving green process chemistry & engineering principles

Alireza Banimostafa*, Stavros Papadokonstantakis, Konrad Hungerbühler
Swiss federal institute of technology (ETH),Zurich 8093,Switzerland

Abstract

Rapid globalization during the last decades and increasing regulatory efforts from governments forced the chemical industry to meet up the rising concern about sustainability aspects of chemical process design. Besides these non-monetary issues, the economic performance is still a very crucial aspect of design. Therefore, considering the capital intensive nature of chemical industry, redesign of existing production plants has been recently regarded as a key strategic decision. This retrofitting task has been extensively performed in continuous processes for the production of bulk chemicals, however in the case of batch processes and specialty chemicals only few studies address the importance of retrofitting, especially including multi-criteria sustainability assessment.

The objective of this paper is to address retrofitting actions to enhance both monetary and non-monetary aspects of chemical process design. This is done using a systematic Path Flow Decomposition (PFD) method, multi-dimensional process assessment indicators, heuristics, and model based methodologies for generation of design alternatives. In this study a set of Environmental, Health, and Safety (EHS) hazard assessment and Life Cycle Impact Assessment (LCIA) indicators is newly introduced in the PFD method and evaluated in parallel with previously developed indicators. This set of indicators has been associated with a set of heuristics based on hazard and life cycle impact assessment rules and established principles of green chemistry and engineering.

The developed methodology is applied to an existent batch production plant from pharmaceutical industry by addressing three process flowsheet structural alternatives for waste solvent management, pressure swing distillation, extractive distillation, and extraction for the separation of the THF/Water azeotrope. It is found that the suggested structural alternatives result in improved EHS, LCIA, and cost metrics compared to the base case of solvent incineration.

1. Introduction

Referring to sustainability in process design, the first thing to take into account is the fact that sustainable development is a complex concept and today there is still ongoing effort to find common terms for describing it. In fact, as discussed in several approaches, one should not focus only on a single aspect (Jimenez-Gonzalez & Constable, 2011) without addressing aspects from all three main pillars of sustainability, i.e., economic, environmental and social ones. For pursuing sustainability in chemical industry it is advantageous to develop specific indicators for different sustainability aspects (Azapagic & Pedran, 2000). For instance, social aspects are partially captured by safety and health hazard indicators (Kletz & Amyotte, 2010). Moreover, the term sustainability comprises several different paradigms such as inherent safety, green chemistry, and green engineering to name the most relevant ones. Besides the non-monetary issues, considering the capital intensive nature of chemical industry, the economic performance remains a very crucial aspect of sustainable process design. As a result, redesign of existing production plants has been recently regarded as a key strategic decision in chemical industry. So far in the scientific literature and industrial practice several motivations have been considered for retrofitting tasks, the economic ones being the most prominent. However there has been little effort to systematically use green chemistry and engineering principles as an incentive. This study attempts to bridge this gap by combining an existing systematic retrofit framework based on PFD with a broad set of EHS and LCIA metrics and respective heuristics originated by green chemistry and engineering principles (Anastas & Zimmerman, 2003; Anastas & Eghbali, 2010).

2. Methodology

2.1. Path Flow Indicators (PFIs)

The original PFD method (Uerdingen et al., 2003) is based on a source-to-sink approach and includes a set of indicators focusing mainly on economic efficiency i.e. Material Value Added (*MVA*), Energy and Waste Cost (*EWC*), Reaction Quality (*RQ*), Accumulation Factor (*AF*) and Renting Cost (*RC*). In addition to these previously defined indicators, two new PFIs, namely *EHS* and *LCIA,* were newly introduced into the PFD methodology in order to consider more systematically green chemistry and engineering principles. *EHS* is appropriate for both open and cycle path flows and is defined by:

$$EHS_p = m_P . N_P . \sum_{dp=1}^{DP} \underset{u}{Max}(Ind_{p,dp}(T_u, P_u)) \quad \text{(Eq.1)}$$

where $Ind_{p,dp}(T_u, P_u)$ is the index value of path flow (p), calculated according to nine different dangerous properties (dp) , (i.e. Air effect, Water effect, Accumulation, Irritation, Acute toxicity, Chronic toxicity, Mobility, Fire/Explosion, Reaction/Decomposition) depending on temperature (T_u) and/or pressure (P_u) of the respective unit operation that affects the path flow, N_p is the number of unit operations that the path flow passes through, and m_p is the respective mass flow.

LCIA is only valid for open path flows and here is calculated based on Cumulative Energy Demand (CED), but in principle any LCIA metric could be used (e.g., Global Warming Potential, Eco-indicator, etc):

$$LCIA_{op,CED} = m_{op} . (CED_{op,pr} + CED_{op,tr}) \quad \text{(Eq.2)}$$

where *pr* and *tr* are the respective values for production and treatment (incineration or waste water treatment) of the open path respectively, and m_{op} is the respective mass flow. These two new indicators are used in combination with the existing ones in the framework of the PFD and are mainly related to four out of twelve principles of green chemistry, i.e., prevention of waste, design for energy efficiency, safer solvents and auxiliaries, and inherently safer chemistry for accident prevention. Additionally, four principles of green engineering are governed by the newly defined indicators namely, inherent rather than circumstantial, prevention instead of treatment, design for separation, and efficiency maximization.

2.2. Environment, Health, and Safety(EHS) hazard assessment

In this study, the original EHS hazard assessment framework (Koller et al., 2000) consisting of eleven Dangerous Properties (*DPs*) has been updated and condensed into nine *DPs* to provide a more versatile hazard assessment within chemical process design. Property parameters of the substances were the basis for an index calculation ranging between [0-1], 1 being the most hazardous. For each substance and each *dp* the most reliable data were selected from a variety of sources, such as databases and estimation tools.

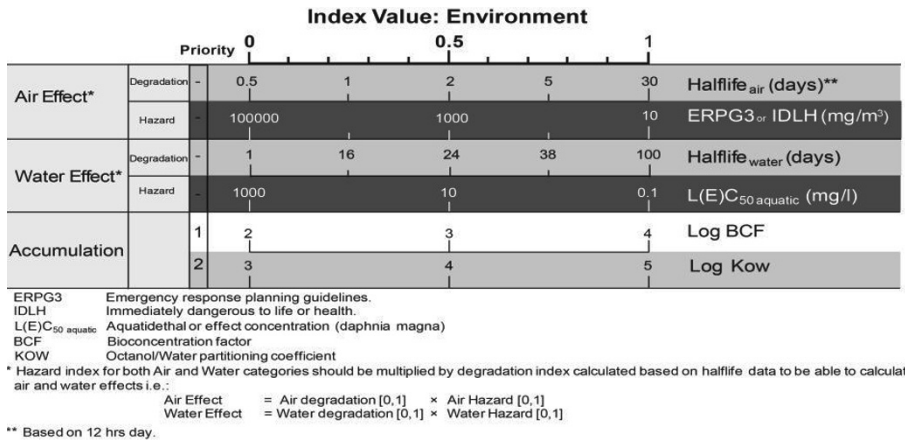

Figure 1: Dangerous properties of environmental category (E) within EHS framework

In addition, priorities were defined from the most available and reliable quantitative property to qualitative parameters such as risk phrases or generic material safety datasheets statements (MSDS). Fig.1 above depicts an example of an index calculation for the environmental (*E*) category. The air effect and water effect were based upon multiplication of the properties degradation and hazard in air and water respectively. For the index calculation of both degradation classes a probability distribution based on available data was considered. On the other hand, for the calculation of the accumulation index, only expert knowledge was considered and no statistical analysis was performed.

2.3. Life Cycle Impact Assessment (LCIA)

In order to measure if a retrofitted process is in fact green, it is crucial to determine the impacts of the process throughout its entire life cycle. There are several impact categories relevant for this kind of analysis, choosing the right impact category might be dependent on industry sector as well as company's interest. In this study, Cumulative

Energy Demand (CED) was chosen based on the industrial partner's interest in energy related impacts and the fact that typically waste management systems need to satisfy legal emission limits constraints, leaving energy consumption as the most important degree of freedom for the process design from LCIA perspective. Cradle-to-gate as well as gate-to-gate analysis were carried out for reactants, auxiliaries, and process utilities. For those streams which ended up in treatment facilities, i.e., incineration or waste water treatment , the impact categories were respectively calculated based on previously established studies(Seyler et al., 2005; Kohler et al., 2006).

3. Case study

A case study from Swiss pharmaceutical industry was performed to examine the application of the method on a batch production facility with a relatively high degree of complexity. Upstream process consisted of a semi-batch reactor with a first order reaction which was carried out in THF solution, and an extraction unit. Each batch represented approximately 100 kg of an essential intermediate in pharmaceutical production and the base case was defined based on 300 batches per year.

4. Results

The Highest Impact Potential Values (HIPVs) were chosen from the list of all calculated PFIs. Path flows with the highest number of occurrences (Highlighted column in Table 1) of HIPVs (Underlined values in Table 1) were chosen for retrofit actions. These HIPVs were connected to a table of EHS and LCIA generic heuristics. As an example by looking at separation specific heuristics, distillation with no entrainer is suggested for separation of path flows with a volatility ratio of a >1.1. However, by performing a sensitivity analysis regarding different process operating parameters and process layout settings, for separation of azeotropic mixtures, structural alternatives with no entrainer (e.g. pressure swing distillation) were not necessarily more efficient compared to those with an entrainer (e.g. extractive distillation).

Table 1: Example of normalized PFIs matrix with underlined HIPVs (Calculated based on modified PFIs ; OC refers to number of occurrences of HIPVs for each open path)

	MVA	EHS	LCIA	EI	AF	RQ	RC	OC	RANK
OP3	0.36	<u>0.73</u>	<u>1.00</u>	<u>0.87</u>	0.00	0.00	<u>0.82</u>	4	1
OP8	0.04	<u>1.00</u>	0.18	0.00	0.00	0.00	<u>1.00</u>	2	2
OP9	0.03	<u>0.64</u>	0.00	0.00	0.00	0.00	0.00	1	3

Therefore, sensitivity analysis facilitated the generation of meaningful Applicable Heuristics (AHs) to be able to suggest relevant retrofit actions. As mentioned earlier, for practicing green chemistry and engineering principles in chemical industry, it is essential to compare the generated alternatives in a multiobjective way. Therefore, all alternatives chosen by the PFD method were evaluated according to Pareto-front curves to highlight the trade-offs between different objectives along with those alternatives having the lowest objective values of LCIA , EHS, and cost.

Fig.2 illustrates an example of a structural alternative based on continuous extractive distillation using ethylene glycol as an entrainer. The base case represents the incineration option of a THF/Water azeotropic mixture currently performed in the plant. The respective values are normalized between [0, 1] and as depicted the base case represents the worse case in terms of all objectives. Two extreme points in Pareto-front 1 are cases with different recoveries (Similar THF purity). As depicted, the scenario

with higher recovery of THF is more profitable and needs less cumulative energy. On the other hand, higher recovery requires more amount of entrainer, which is the reason for higher column hold-up and EHS scores.

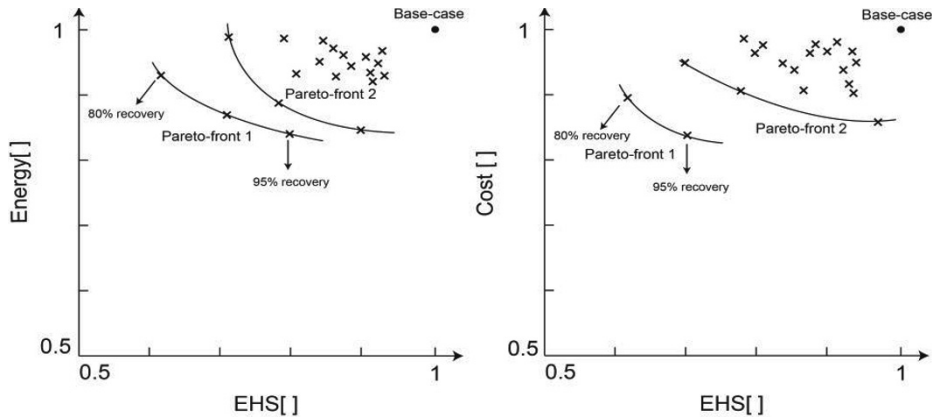

Figure 2: Multiobjective assessment of continuous extractive distillation with ethylene glycol as an entrainer compared to incineration (base case).

Furthermore, based on generic heuristics a sensitivity analysis was also performed regarding substitution of entrainers in case of extractive distillation. Finally, the results of different structural alternatives (Extractive distillation, pressure swing distillation, and extraction) were compared based on three objectives mentioned above. The comparison highlighted the fact that for downstream process, extractive distillation with ehtylene glycol was slightly advantageous compared to rest of alternatives.

Abstract

The use of detailed pharmacokinetic (PK) and pharmacodynamic (PD) models in order to investigate drug resistance and the susceptibility breakthrough by means of *in-vivo* or *in-vitro* trials is a widespread practice in the preliminary stages of drug development. However, complex PK-PD models are usually affected by identifiability issues typically related to their specific model structure and to the strong correlation among the model parameters. Model-based design of experiments (MBDoE) techniques can be successfully adopted to design multiple experiments to be executed simultaneously, detecting a proper set of experimental settings improving the identifiability of the model parameters. The preliminary results presented in this paper show that designing experiments in parallel, rather than sequentially, can substantially decrease the time and effort required by the model identification task for a microbial growth model.

Keywords: model-based design of experiments, time-kill study, parallel experiments.

1. Introduction

Pharmacokinetics (PK) and pharmacodynamics (PD) experiments are required for the development of new antimicrobial therapies and the preclinical assessment of antibacterial agents in the preliminary stages of drug development [1]. Pharmacokinetics is concerned with the time course of antimicrobial concentrations in the body, while pharmacodyamics is concerned with the relationship between those concentrations and the antimicrobial effect. Thanks to *in-vivo* and *in-vitro* trials, allowing for the definition of the dose and the proper selection of the dosing interval, it is possible to study the susceptibility breakthrough and the antimicrobial resistance of a single individual, as well as of an entire population [2]. Antibiotic resistance observed in nosocomial infection is strictly related to the treatment strategies: when the resistance to antibiotics appears, PK-PD models may provide needful indications to correct the therapy by means of time-kill studies (bacterial burden variation with time and antimicrobic concentration). In the clinical practice, trials are usually performed to determine the antibiogram of an infective pathogen, which is identified by several heuristic indicators (area under the curve, minimum inhibitory concentration, minimum bactericidal concentration) on which the therapy is currently based. The adoption of such indicators gives only descriptive and semi-quantitative information on the system and it cannot exactly predict the effects of antibiotic concentration in time. A PK-PD modeling effort is thus required to improve the ability of prediction of time-kill phenomena, and several models have been proposed in the literature to describe the dose-response to antibiotic agents [3-4]. However, structural complexity and high

correlation among model parameters may expose these models to severe identifiability issues [5], such that unplanned or ill-conceived experiments may not allow estimating the entire set of model parameters in a statistically sound way, prolonging the time and effort required by the model identification task. Structural identifiability can be assessed *a priori* for relatively simple PK-PD models at given experimental conditions [6], but its assessment is related to the level of excitation provided by the identification experiments. Furthermore, the possibility to detect a subspace of experimental conditions yielding local identifiability is strictly related to the way in which experiments are executed in time, e.g., in case multiple equipment is available and parallel experimentation is thus possible [7]. Model-based design of experiments (MBDoE) techniques represent a valuable tool to design optimally informative experiments, providing a set of experimental conditions ensuring the local identifiability of the system. Multiple experiments can be designed according to different experimental configurations, adopting parallel or sequential MBDoE techniques, and exploiting conventional and advanced design criteria [8]. In this paper, experiments are designed by MBDoE with the purpose to identify the set of parameters of a PD model of *in-vitro* bacterial growth [4]. Identifiability issues are tackled through the design of parallel experiments allowing for a progressive reduction of the initial uncertainty affecting model parameters. The resulting design permits to exploit the total duration of the experimental campaign in a more efficient way, improving the accuracy and precision of obtained parameters providing easier experimental protocols to be implemented.

2. The methodology

Conventional MBDoE techniques for parameter identification usually involve a sequential procedure: 1) the design of the experiment (based on current knowledge on model structure and parameters); 2) the execution of the designed experiment, where new data are collected; 3) the estimation and statistical assessment of model parameters. Iteration of steps 1 to 3 generally leads to a progressive reduction of the uncertainty region of model parameters. Complex PD models are usually described by systems of differential and algebraic equations in the form

$$\begin{cases} \mathbf{f}\left(\dot{\mathbf{x}}(t), \mathbf{x}(t), \mathbf{u}(t), \mathbf{w}, \boldsymbol{\theta}, t\right) = 0 \\ \hat{\mathbf{y}}(t) = \mathbf{g}\left(\mathbf{x}(t)\right) \end{cases} \tag{1}$$

where $\mathbf{x}(t)$ is the N_x-dimensional vector of time dependent state variables, $\mathbf{u}(t)$ and $\mathbf{w}$ are, respectively, the model time dependent and time invariant control variables (manipulated inputs), $\boldsymbol{\theta}$ is the set of N_θ unknown model parameters to be estimated, and t is the time. The symbol ^ is used to indicate the estimate of a variable (or a set of variables): $\mathbf{y}(t)$ is the M-dimensional vector of measured values of the outputs, while $\hat{\mathbf{y}}(t)$ is the vector of the corresponding values estimated by the model. MBDoE procedures aim at decreasing the model parameter uncertainty region by acting on the experiment design vector $\boldsymbol{\varphi}$:

$$\boldsymbol{\varphi} = \left[\mathbf{y}_0, \mathbf{u}(t), \mathbf{w}, \mathbf{t}^{sp}, \boldsymbol{\tau}\right]^T \tag{2}$$

The design vector $\boldsymbol{\varphi}$ in the most general form may contain a N_y-dimensional set of initial conditions for the measured variables ($\mathbf{y}_0$), the manipulated input variables ($\mathbf{u}$ and $\mathbf{w}$), the duration of the single experiment ($\boldsymbol{\tau}$) and the N_{sp}-set of time instants at which the output variables are sampled $\mathbf{t}^{sp}$. Usually the variables that can be optimized for design purposes in PK-PD experiments ($\boldsymbol{\varphi}$ elements) are: the allocation of samples, the initial

bacterial/antibiotic concentration, (possibly) the procedure for the administration of antimicrobial agents in time, and the duration of each single experiment. Conventional MBDoE procedures aim at decreasing the model parameter uncertainty region predicted *a priori* by the model by acting on the n_φ-dimensional experiment design vector $\boldsymbol{\varphi}$ and solving the following NLP optimization problem:

$$\boldsymbol{\varphi}^{\text{opt}} = \arg\min_{\boldsymbol{\varphi}} \left\{ \psi\left[\mathbf{V}_\theta(\boldsymbol{\theta}, \boldsymbol{\varphi}) \right] \right\} = \arg\min_{\boldsymbol{\varphi}} \left\{ \psi\left[\mathbf{H}_\theta^{-1}(\boldsymbol{\theta}, \boldsymbol{\varphi}) \right] \right\} \tag{3}$$

subject to the set of model equations (1) and to a set of constraint equations in the form

$$\mathbf{F}(\mathbf{x}) - \mathbf{G}(t) \le 0 \tag{4}$$

$$\mathbf{H}(\hat{\mathbf{y}}) - \mathbf{D}(t) \le 0 \tag{5}$$

given the set of initial conditions $\mathbf{x}(0) = \mathbf{x}_0$. In (3), $\mathbf{V}_\theta$ and $\mathbf{H}_\theta$ are the variance-covariance matrix of model parameters and the dynamic information matrix, respectively (usually evaluated from discrete forms of the Fisher information matrix), while ψ is an assigned measurement function of the variance-covariance matrix representing the chosen design criterion [9]. Among the set of constraint conditions (4-5) a distinction is made between constraints involving unmeasurable states (4) and estimated outputs (5). The formulations are expressed through a set of (possibly time-varying) constraints $\mathbf{G}(t)$ and $\mathbf{D}(t)$ on the state variables, while $\mathbf{F}$ and $\mathbf{H}$ are two sets of selection functions, allowing to choose the variables being actually constrained.

2.1. Sequential Vs Parallel design of experiments

If a sequential MBDoE approach is considered, the information matrix is defined as:

$$\mathbf{H}_\theta = \sum_{k=1}^{N_{exp}-1} \mathbf{H}^*_{\theta|k} + \mathbf{H}^*_{\theta|N_{exp}}(\boldsymbol{\theta}, \boldsymbol{\varphi}) = \mathbf{K} + \mathbf{H}^*_{\theta|N_{exp}}(\boldsymbol{\theta}, \boldsymbol{\varphi}) \quad , \tag{6}$$

where $\mathbf{K}$ is a constant matrix defined by the previously performed (N_{exp}–1) experiments. In the above information matrix, only the vector $\boldsymbol{\varphi}$ of the experimental conditions for the new experiment (N_{exp}) is available for optimization. If multiple equipment is available, as it frequently happens when time-kill experiments are carried out *in vitro*, N_{exp} new experiments can be designed simultaneously adopting a parallel design approach [8]. In this case, the information matrix becomes:

$$\mathbf{H}_\theta = \sum_{k=1}^{N_{exp}} \mathbf{H}^*_{\theta,k}(\boldsymbol{\theta}, \boldsymbol{\varphi}_k) \quad . \tag{7}$$

Here, all vectors $\boldsymbol{\varphi}_k$ (one for each experiment k) are optimized simultaneously, adopting classical alphabetic design criteria [9] or advanced criteria based on singular value decomposition of $\mathbf{V}_\theta$ [8], where each single experiment is designed so as to optimize a specific component of the overall predicted information. The $\mathbf{V}_\theta$ thus obtained will not be the same as the sum of the variance-covariance matrices obtained by optimizing each individual experiment N_{exp} times in a sequential way, and the N_{exp} new optimal experiments will normally be distinct.

3. Case study

The case study presented in this study concerns the identification of the model proposed by Tam and coworkers [4] to investigate the relationship between microbial burden and antimicrobial agent concentrations by means of *in-vitro* time-kill experimentation:

$$\frac{dN}{dt} = G\big(N(t)\big) - K\big(C(t), N(t), t\big) \qquad G\big(N(t)\big) = K_g\left[1 - \frac{N(t)}{N_{\max}}\right]N(t) \tag{8}$$

$$K\big(C(t), N(t)\big) = \left[\frac{K_k \cdot C(t)^H}{C(t)^H + \big(\alpha\big(C(t), t\big)C_{50k}\big)^H}\right]N(t) \qquad \alpha = 1 + \beta\left(1 - e^{-C(t)\cdot t\cdot\tau}\right) \quad .$$

In the model, $N(t)$ is the concentration of bacterial population over time, $C(t)$ is the concentration of meropenem (the antibiotic agent) over time, $G(t)$ is the intrinsic growth rate and $K(C(t), N(t),t)$ is the kill rate by antimicrobial agent. The purpose of the study is to design an experimental session lasting at maximum $\tau = 24$ h in order to identify the set of parameters $\boldsymbol{\theta} = [C_{50k}\ K_g\ K_k\ H\ N_{\max}\ \beta\ \tau]^T$ in the most precise and accurate way. It is supposed that a maximum number of 3 experiments can be executed simultaneously in distinct bacteria cultures. There is only one measured response, namely the concentration of bacterial population over time ($x_1 = y = N$). Measurements are possible only if taken above a detectability threshold of $D = 500$ cfu/mL, which represents a design constraint in the (5) form.

Three distinct design configurations have been compared:

- SD1: D-optimal design of a single experiment ($N_{sp} = 21$);
- PD3: parallel D-optimal design of $N_{exp} = 3$ experiments ($N_{sp} = 7$ for each experiment).

The variables being optimised by design are: the allocation of samples, the initial concentration of meropenem ($C_0 = C(0)$) and the administration of meropenem in time (SD1 configuration only). Measurements are obtained by simulation of the model with $\boldsymbol{\theta} = [0.888\ \ 1.848\ \ 3.744\ \ 1.336\ \ 7.2E9\ \ 3.580\ \ 0.0083]^T$ as the "true" parametric set and by adding Gaussian noise with zero mean and relative deviation of $\omega = 0.05$. The initial guess on model parameters is $\boldsymbol{\theta}^0 = [0.739\ \ 2.310\ \ 3.119\ \ 1.670\ \ 9.0E9\ \ 4.475\ \ 0.0069]^T$.

3.1 Results and comments

Parameter estimation results in terms of estimate values (normalized with respect to $\boldsymbol{\theta}$) and *a-posteriori* statistics (*t*-values and confidence intervals) are given in Table 1.

Table 1 Comparison of different experiment design configurations. Superscript * indicates *t*-values failing the *t*-test ($t < t_{ref}$).

Design	Parameter Estimate	Conf. Int. (95%)	*t*-values	t_{ref}
SD1	[1.03 1.04 1.04 0.90 0.99 0.95 0.91]^T	[4. 36 7.13 4.63 4.05 5.35 2.94 3.40]^T	[0.23* 0.15* 0.23* 0.22* 0.18* 0.32* 0.27*]	1.78
PD3	[1.01 1.00 0.99 1.06 0.98 1.17 0.80]^T	[0.15 0.02 0.05 0.29 0.05 5.88 4.59]	[6.75 40.13 19.01 6.63 19.86 0.20* 0.17*]	1.86

SD1 shows a poor estimation of model parameters in terms of precision on the estimate (low *t*-values) even if a higher excitation level is realized during this experimental protocol (Figure 1a) by managing the antibiotic administration in time. Even if not shown here for the sake of conciseness, it has been verified that, independently of the number of samples, the structural identifiability of the model cannot be achieved if a single experiment is executed and no antibiotic administration is undertaken, because the phases of bacterial growth, death and re-growth cannot be observed in the same trial. Conversely, PD3 allows managing the initial meropenem concentration ($\mathbf{C}_0 = [0.00\ 2.12\ 7.16]$) in such a way as to observe these phases in separate experiments executed simultaneously (Figure 1b), with great improvement in terms of precision and accuracy of the estimate for C_{50k}, K_g, K_k, H, $N_{\max}$. In fact, it can be verified that one key advantage of parallel experiment design is that it is possible to plan experiments building up the

information in a complementary way, i.e. each experiment is capable of maximizing the information specific to a subset of parameters. Notwithstanding this, the sound estimation of parameters β and τ require an additional (sequential) set of parallel experiments (adding more parallel experiments was proved to be insufficient for satisfactory estimation). Note how a specific advantage of parallel configurations is their ease of implementation, since they do not require the management of antibiotic administration in time.

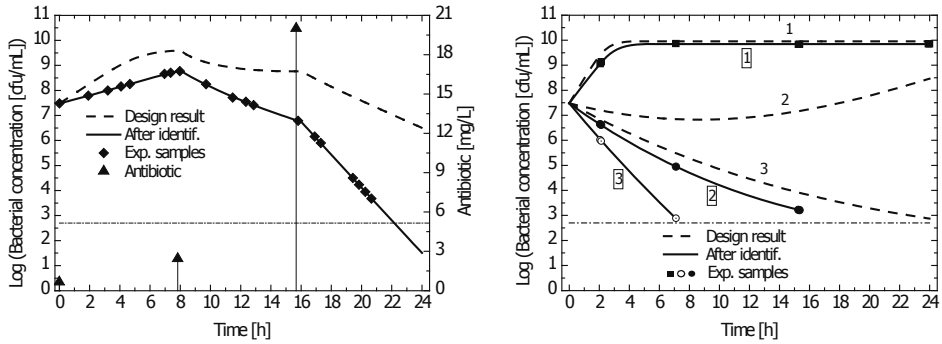

Figure 1. Bacterial concentration profiles before and after identification as obtained by (a) SD1 and (b) PD3 design configurations. The antibiotic administration for SD1 is indicated by triangles.

4. Final remarks

A parallel design approach for the optimal design of pharmacodynamic experiments has been presented in this paper. Preliminary results show the capability of the technique to improve the information content of the trials, exploiting in a more efficient way the available experimental time, designing experiments that can be optimally informative for parameter estimation purposes and easy to be implemented in the experimental practice. Future work is required to extend the applicability of parallel design techniques to larger systems by exploiting advanced design criteria.

Abstract

The integral formulation of the nonlinear continuous Smoluchowski coagulation equation (CSCE) using the CQMOM presents a hierarchical method to couple the QMOM and the physically evolving particle size distribution. This hierarchical nature of the CQMOM can be utilized in process system engineering and at individual unit operation as well. Here, not only the cumulative particle size distribution is reconstructed, but also its low-order cumulative moments. Numerical analysis shows two desirable properties of the CQMOM: First, it can be considered as a mesh-free method, since the solution of each integral equation at the current grid point does not depend on the other ones. Second, the accuracy of the targeted low-order cumulative moments depend only on the nodes and weights of the continuous Gauss-Christoffel quadrature, and not on sampling the continuous low-order cumulative moments. Moreover, at the upper particle size limit, the QMOM is imbedded as a limiting case.

Keywords: Integral Population Balance, CQMOM, Numerical Solution.

1. Introduction

The continuous Smoluchowski coagulation equation (CSCE), which is known also as the population balance equation for particle coagulation, is a nonlinear integro-partial differential equation with no general analytical solution, especially when coupled with complex CFD solvers or process system simulation at the flowsheet level. Fluid phases which are discrete either at the molecular or particle levels can be described by a statistical Boltzmann-type equation or the CSCE as a special case [4, 5]. The CSCE finds many scientific and engineering applications with mono and multivariate number density functions. Such applications include multiphase flows and turbulence modelling, aerosol science and kinetic theory [1,3-7]. The general CSCE is a hyperbolic integro-partial differential equation, which is characterized by a nonlinear integral source term. This source term accounts for interactions with which particles of a specific state can either form or disappear from the system [6]. These interactions can describe the system behavior up to any degree of detail. Thus, the CSCE is suitable for understanding and investigating many single processing units such as crystallizers, turbulent flame reactors, polymerization reactors, bubble phase reactors, and extraction columns [5, 7, 9]. However; due to its complexity and the lack of general robust numerical solution, the CSCE is hard to be used in flowsheeting programs to simulate whole plants made up of many interacting units or CFD simulations using complex

equipment geometry [3, 4, 6-8]. Therefore, there is a need to have a simple reduced model for discrete phases, without losing the detailed description of single phenomena inherently embedded in the CSCE. One of the popular model formulations is the transformation of the CSCE into a set of self-contained integral equations that describe the moments' evolution of the particle size distribution. In general, these methods belong to the moment transformation of the CSCE at the expense of destroying the distribution itself [2-4]. In contrast to the classical method of moments, where closure problem is overcome by a priori assumed distribution or simplified kernel functions [10], the Quadrature Method Of Moments (QMOM) provides not only an efficient closure to the moment problem, but also an extremely efficient Gauss-like integration quadrature [2-4]. The QMOM is based on the global low-order moments of the weight function and requires only a few nodes (two or three) to converge. However; the major drawback of the moment methods in general and the QMOM in particular is their inability to reconstruct the particle size distribution (PSD). The PSD plays a decisive role in the determination of the physicochemical and mechanical product properties made of particulate systems [6, 9, 10]. Recent advances and development in online measurements and control provide real-time access to system parameters, which are estimated, based on the whole size distribution [1, 6]. John et al. [9] investigated rigorously the PSD reconstruction from its low-order moments, where they addressed the theoretical and practical difficulties in solving the ill-posed inverse moment problem. This ill-posedness and uniqueness of the PSD are still open problems and are recently addressed by Mnatsakanov and Hakobyan [11]. This work presents a method, which obviously overcomes the above shortcomings. The present method uses a hierarchical novel formulation of the CSCE, in which the *r*th (with respect to particle property space) cumulative distribution is reconstructed at given arbitrary grid points. Here, the *r*th cumulative moment is function of the particle internal property and evolves in time and physical space. Since the *r*th cumulative moment at any grid point along the particle property space is not expected to affect the global moments, the number and structure of the grid points are not going to affect the accuracy of the cumulative integration quadrature. The present method provides a continuous Gauss-Christoffel quadrature for which a two-node quadrature with equal and unequal weights is derived analytically. For the *n*th-node quadrature, the standard Product Difference Algorithm (PDA) is used [3].

2. The Cumulative Quadrature Method Of Moments (CQMOM)

Let $\omega(x;z,t)$ be a nonnegative integrable function on the interval $[a,b]$ and all its cumulative moments exist. This function can be expanded at any given point x as a sum of Dirac delta functions (with weights $\lambda_j(x;.)$ and nodes $\zeta_j(x;.) \in [0,x]$). Now, let the cumulative moments of $w(x;.)$ be defined as:

$$\mu_r(x;.) = \int_{a=0}^{x} \zeta^r w(\zeta;.)d\zeta, \quad r = 0,1,2...2N_q - 1 \tag{1}$$

and substitute $w(x;t) = \sum_{j=1}^{N_q} \lambda_j(x;t)\delta(\zeta - \zeta_j(x;t))$ in Eq.(1) to get:

$$\mu_r(x;.) = \sum_{j=1}^{N_q} \lambda_j(x;.)\left[\zeta_j(x;.)\right]^r \tag{2}$$

The above continuous cumulative integration quadrature is exact for integrands that are polynomials of degree at most $2N_q-1$. Note that in contrast to the QMOM, the CQMOM is formulated using nodes and weights that are functions of the particle property space. This quadrature has continuous nodes and weights as long as the cumulative moments are also continuous. The global Gauss-Christoffel quadrature can be viewed as a special case when the limits of integration given by Eq.(1) are from zero to infinity. Note that $\mu_0(x) = W(x)$, which is the cumulative distribution of $w(x)$ and the other cumulative moments (for $r = 1, 2, \ldots 2N_q-1$) are all monotone and at least right continuous functions. These functions satisfy two important properties: they tend to zero as the particle property (x) tends to zero and their change with respect (x) tends to zero as (x) goes to infinity. These properties help in eliminating the so called finite domain error during the solution of the CSCE and force the numerical schemes to be conservative (with respect to x). Eq.(2) can be inverted analytically for a two-node quadrature and using the PDA For the nth-node quadrature.

3. Integral formulation of the Continuous Smoluchowski Equation

The CQMOM described in section 2, when applied to the CSCE with particle growth provides not only the cumulative number distribution, but also the required cumulative moments of higher order:

$$\frac{\partial \mu_r(x;t)}{\partial t} + G(x;c)\frac{\partial(\mu_r(x;))}{\partial x} = r\int_0^x \zeta^{r-1} G(\zeta;c)w(\zeta;t)d\zeta + S_{c,r}(x) \tag{3}$$

Where G is the particle growth rate and $S_{c,\mathrm{r}}$ is the nonlinear integral source term of Smoluchowski equation. In the above equation as the limit of the particle size tends to infinity $\partial\mu_r/\partial x \to 0$. This leaves the CSCE divergence free with respect to particle size. Using the CQMOM (Eqs.(1) & (2)), the integral source term of Eq.(3) is written as:

$$\begin{aligned} S_{c,r}(x) = \frac{1}{2}\int_0^x w(\zeta;t)d\zeta \int_0^{\eta(x,\zeta)} \psi(\zeta,u,\varphi)\left(u^3 + \zeta^3\right)^{r/3} w(u;t)du \\ - \int_0^x \zeta^r w(\zeta;t)d\zeta \int_0^{\infty} \psi(\zeta,u,\varphi)w(u;t)du \end{aligned} \tag{4}$$

Where $\eta^3(x,u) = x^3 - u^3$ and ψ is the aggregation frequency. Now by formal substitution of the $w(x)$ expansion given in section 2 and making use of the Dirac delta function properties, one gets the following semi-discrete closed source term for Eq.(3):

$$\begin{aligned} S_{c,r}(x) = r\sum_{j=1}^{N_q} \zeta_j^{r-1}(x;t)G(\zeta_j(x;t);c)\lambda_j(x;t) \\ + \frac{1}{2}\sum_{j=1}^{N_q}\sum_{n=1}^{N_q} \lambda_j(x;t)\lambda_n(\eta(x,\zeta_j);t)\Psi_{j,n,r}(x;t) \\ - \sum_{j=1}^{N_q} \zeta_j^r(x)\lambda_j(x)\sum_{n=1}^{N_q} \lambda_n(x_\infty)\psi(\zeta_n(x),\zeta_n(x_\infty),\varphi) \end{aligned} \tag{5}$$

Where Ψ is an aggregation frequency matrix to conserve the rth population moment. The source term in Eq.(5) is closed since ζ and λ are found by inverting Eq.(2). Note that the closure used above does not depend on particular values of x. So, the

cumulative moments can be reconstructed by sampling arbitrary the particle size x. This makes the CQMOM a mesh-free method and the mesh can be easily refined in the regions of sharp cumulative moments.

4. Numerical Results and Discussion

In this section numerical results are presented and analyzed to illustrate the implementation of the CQMOM using the CSCE for the homogenous case to isolate the interaction of complex flow field numerical algorithms with the CQMOM solver.

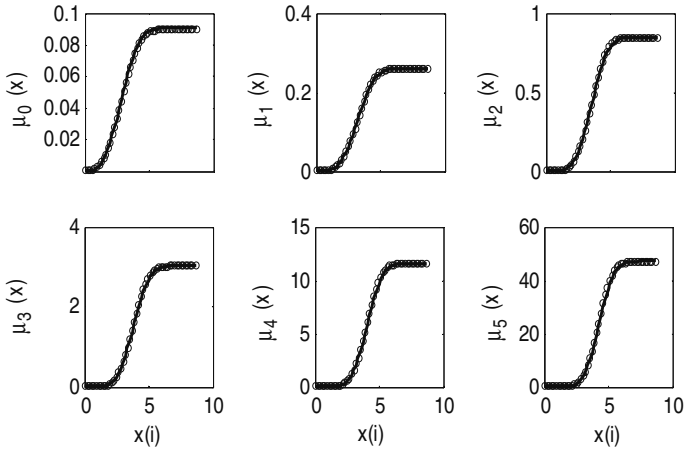

Figure (1): Comparison between analytical [12] (solid line) and numerical (open circles) solutions for the case of simultaneous particle aggregation and growth in batch vessel.

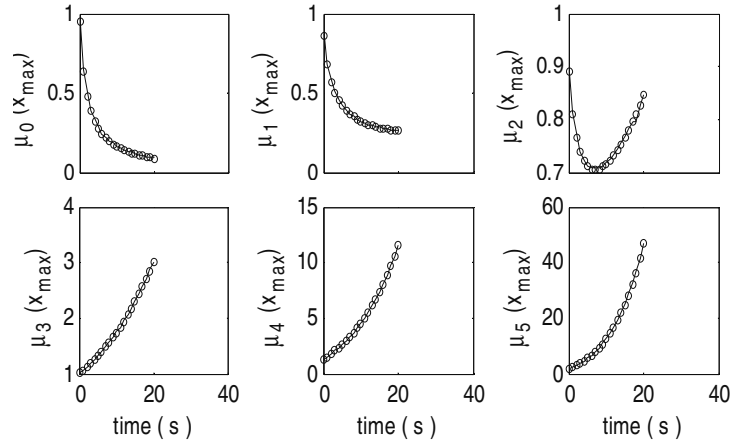

Figure (2): Simultaneous particle coagulation and growth in batch vessel (τ = 20 & number of grid points = 50) with solid line is analytical [12] solution and open circles is numerical one.

Fig.(1) compares the analytical [12] and numerical solutions using the CQMOM of three quadrature nodes for simultaneous particle coagulation and growth in a homogeneous batch vessel ($\psi = \psi_0$, G= G_0x/3 and $w_0 = exp(- x^3)$). As can be seen, Not only the PSD (cumulative number of particles) is reproduced correctly as function of particle size, but also all the other low-order cumulative moments, which are involved

in the inverse moment problem given by Eq.(2). For this case the Product Difference Algorithm (PDA) [3] is used to construct the weights and abscissa to close the source term of Eq.(5). It is clear that Eq.(3) is in the standard Lagrangian form, which is Hyperbolic PDE with a source term given by Eq.(5). It is solved using a Lagrangian moving grid with a velocity equals to the particle growth rate $G(x)$. The solution on the moving grid is projected back after each time step using polynomial interpolation on an Eulerian fixed grid. It is worthwhile to mention that the solution accuracy does not depend on the number of grid points, but only on the number of quadrature points (here $N_q = 3$). This reflects one of the important properties of the CQMOM, which is the free-mesh property. The global moments as predicted by the CQMOM are also compared to the analytical ones as can be seen from Fig.(2). These are obtained by setting the particle size to a largely enough value ($x_\infty = x_{\max} = 10$) such that $\partial \mu_r / \partial x \to 0$. For this special case the classical QMOM and the CQMOM are identical. More interestingly, the inflection point (third panel in the first row of Fig.(2)) in the surface area of the particles due to simultaneous particle coagulation and growth is predicted correctly at $\tau \approx 8$ units. This inflection point represents the balance between particle area decrease due to particle coagulation and particle area increase due to growth process. Therefore, particle coagulation is dominant for $\tau < 8$. Concerning implementation complexity, when compared to sectional methods (e.g. SQMOM [2]), the CQMOM is easier in implementation and coding and it offers a sequential solution of the ODEs, thanks to the mesh-free property. The CPU time is found also less than that of the SQMOM [2], in particular for number of grid points less than four. Consequently, since large increase in the number of grid points is decoupled from the prediction of global quantities, using small number of grid points is sufficient to infer about the shape of the distribution.

5. Conclusions

The derivation of the cumulative Gauss-Christoffel quadrature as a continuous closure rule makes it possible to derive and solve the CSCE. This continuous formulation is used to reproduce consistently any finite number of low-order cumulative moments. In contrast to the QMOM, which destroys the number density function, the present CQMOM reproduces not only the cumulative number density function, but also its low-order cumulative moments. The CQMOM can be considered as a mesh-free method since the grid structure is independent of the integration quadrature. The CQMOM is reduced simply to the standard QMOM when only one grid point is placed at infinity.

Abstract

In this work, we develop an integrated optimization under uncertainty framework to address the problem of capacity planning in pharmaceutical supply chains that employ novel integrated continuous production schemes. Since the outcomes of clinical trials are uncertain, the problem naturally leads to a stochastic programming problem, which is formulated as a scenario-based multi-period mixed-integer linear programming (MILP) model. The number of scenarios grows exponentially with the number of potential products, resulting in large-scale MILP models that are intractable with standard solvers. We propose a novel solution method to solve the above industrial-scale problems that contain up to 10 potential products and nearly 60,000 scenarios.

Keywords: Capacity Planning, Pharmaceutical, Decomposition Algorithm.

1. Introduction

The single most important driver in the pharmaceutical industry is the time-to-market since the large players of the industry have relied on so-called "blockbuster" drugs for their sustained growth (Shah, 2004). Since new products must be introduced into the market as early as possible, strategic decisions such as the building of new facilities and/or expansion of existing facilities must be made when the new products are still in the development stage. Thus, one of the key challenges that decision makers routinely encounter is to ensure the availability of enough production capacity to meet the demands of products through efficient capacity planning.

Traditionally, production in the pharmaceutical industry takes place in two major steps: i) primary production, and ii) secondary production (see Figure 1a). In primary production, the raw materials are converted into active pharmaceutical ingredients (APIs) through multiple intermediate production stages, while in secondary production, the APIs are formulated into different final drug products. The above traditional two-echelon production scheme leads to inefficient supply chain operations. In addition, the pharmaceutical industry has embraced the batch mode of operation for decades, which potentially contributes to inefficiencies in the supply chain.

Recently, the Novartis-MIT Center for Continuous Manufacturing has embarked on an innovative project to develop technology for a shift from the batch mode of operation to the continuous mode, where raw materials through the APIs to the drug products are produced seamlessly in an integrated facility (see Figure 1b). Such an integrated end-to-end production scheme is more promising for several reasons: a) low costs of inventory, logistics, and production, b) short supply-chain cycle times, and c) resilient supply chain. In a recent work, Schaber et al. (2011) performed an economic comparison of

integrated continuous and batch pharmaceutical manufacturing, where the authors quantified the cost savings achieved through integrated continuous manufacturing.

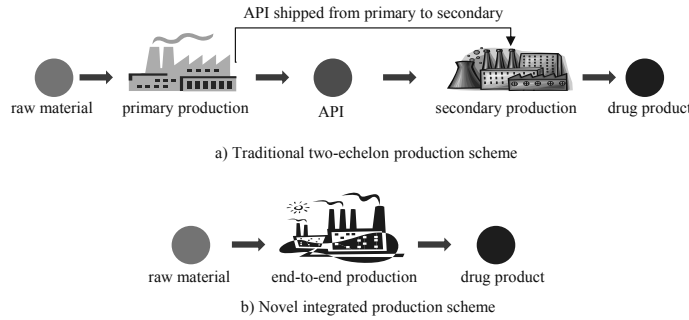

Figure 1. Traditional vs. integrated production schemes in the pharmaceutical industry.

Variants of capacity planning and drug development problems for pharmaceutical manufacturing have been addressed by several researchers in the past. For a review of various existing methods, see the work of Colvin and Maravelias (2008). The novel integrated end-to-end production scheme based on continuous manufacturing brings in additional challenges and opportunities towards better investment strategy. The aim of this work is to develop a framework for capacity planning that addresses the above challenges and exploits the benefits of novel integrated production schemes while taking into account the uncertainty in the outcome of clinical trials.

2. Problem Description

The formal statement of the problem is: given, i) a planning horizon which is divided into a number of time periods, T, defined by a set of time points $t \in \mathbf{T} = \{0,1,2,\ldots,T\}$, ii) a set of potential products $i \in \mathbf{I}$ that have passed Phase I clinical trials (PI), iii) a set of potential greenfield integrated facilities $p \in \mathbf{P}$ that are either dedicated or multipurpose, iv) success probabilities of trials Phase II (PII) and Phase III (PIII), and v) demand, price and cost details, the goal of the capacity planning problem is to decide: i) when to build a new facility and/or to expand an existing facility, ii) how much capacity to build/expand, iii) which product(s) to produce in which facilities, and iv) how much to produce and store at different time periods.

We consider potential products that have already passed trial PI, and thus we are only interested in the outcomes of trials PII and PIII. Thus, if ξ_i denotes the discrete random variable associated with the clinical trial outcome of product i, then the sample space Ω_i = {IIF, IIIF, IIIP}, where IIF corresponds to trial PII failure, IIIF to trial PIII failure, and IIIP to trial PIII success. Furthermore, if $s \in \mathbf{S}$ denotes a set of scenarios corresponding to the Cartesian product of the sample spaces, then the total number of scenarios $|\mathbf{S}| = 3^{|\mathbf{I}|}$.

To address the above problem, we propose a two-stage stochastic programming (TSSP) approach in which the first-stage decisions are when to build a new facility and/or to expand the existing facility, while the second-stage decisions are the sizes of facilities, assignment of products to facilities, and production and inventory levels at different time periods from the product launch to the peak demand. We assume that the sum of the durations of clinical trials PII and PIII is the same for all the potential products. In addition, we also assume that there are no resource constraints at the development stage. Therefore, the clinical trials are carried out simultaneously, and the uncertainties in the outcomes of clinical trials are realized for all the products by the launch period.

3. Mathematical Formulation

The proposed formulation contains the following optimization decisions: i) building new facility: W_{pt} = 1 if construction of new facility p is started in period t, ii) capacity expansion: V_{pt} = 1 if capacity expansion of existing facility p is started in period t, iii) assignment: X_{ipts} = 1 if product i is assigned to facility p in period t in scenario s, iv) production rate: R_{pts} denotes the production rate in facility p in period t in scenario s, v) incremental production rate: ΔR^N_{pts} / ΔR^E_{pts} denotes the incremental production rate installed due to new/existing facility p in period t in scenario s, vi) production amount: Q_{ipts} denotes the production amount of product i in facility p in period t in scenario s, vii) inventory: H_{ipts} denotes the inventory amount of product i in facility p in period t in scenario s, viii) order delivery: F_{ipts} denotes the supply of product i from facility p in period t in scenario s, ix) backlog: B_{its} denotes the backlog amount of product i in period t in scenario s.

The MILP model contains the following constraints:

$$\sum_t W_{pt} \le 1, \quad \forall p, \tag{1}$$

$$V_{pt} \le \sum_{t' \le (t-\theta^N)} W_{pt'}, \quad \forall p,t, \tag{2}$$

$$\sum_{t'=t-\theta^E+1}^{t} V_{pt'} \le 1, \quad \forall p,t, \tag{3}$$

$$\sum_t V_{pt} \le \sigma_p, \quad \forall p. \tag{4}$$

$$R_{pts} = R_{p(t-1)s} + \Delta R^N_{pts} + \Delta R^E_{pts}, \quad \forall p,t,s, \tag{5}$$

$$\lambda_p^{\min} W_{p(t-\theta^N)} \le \Delta R^N_{pts} \le \lambda_p^{\max} W_{p(t-\theta^N)}, \quad \forall p,t,s, \tag{6}$$

$$\varphi_p^{\min} V_{p(t-\theta^E)} \le \Delta R^E_{pts} \le \varphi_p^{\max} V_{p(t-\theta^E)}, \quad \forall p,t,s, \tag{7}$$

$$\rho_p^{\min} X_{ipts} \le Q_{ipts} \le \rho_p^{\max} X_{ipts}, \quad \forall p, i \in \mathbf{I}_p, t,s, \tag{8}$$

$$\sum_{i \in \mathbf{I}_p} Q_{ipts} \eta_{is} \le R_{pts} \Delta t, \quad \forall p,t,s, \tag{9}$$

$$H_{ipts} = H_{ip(t-1)s} + Q_{ipts} - F_{ipts}, \quad \forall p, i \in \mathbf{I}_p, t,s, \tag{10}$$

$$B_{its} = B_{i(t-1)s} + \eta_{is}\omega_{it} - \sum_{\{p: i \in \mathbf{I}_p\}} F_{ipts}, \quad \forall i,t,s, \tag{11}$$

$$H_{ipts} \le \upsilon_{ip}, \quad \forall p, i \in \mathbf{I}_p, t,s, \tag{12}$$

where $\mathbf{I}_p$ is the set of products that can be assigned to facility p. Eqs. (1-4) are capacity related constraints, where θ^N/ θ^E is the construction lead time for a new/existing facility, and σ_p is the maximum number of expansions on an existing facility. While (5)-(7) are

constraints that correspond to the production rates and amounts subject to some upper and lower limits, (8) and (9) are the capacity utilization constraints. Furthermore, the inventory, supply, and backlog constraints are given by (10)-(12). Finally, the objective is to maximize the expected net present value (ENPV), which is given by the sales revenue in each scenario RV_s, total operating cost in each scenario OC_s, fixed investment cost FIC, and variable investment cost per scenario VIC_s:

$$\max ENPV = \sum_s \kappa_s RV_s - \sum_s \kappa_s OC_s - FIC - \sum_s VIC_s. \quad (13)$$

4. Solution Method

The special structures of TSSP with recourse are well-exploited by duality-based decomposition methods (Birge and Louveaux, 1997). In Benders decomposition, or its extension to nonlinear problems, generalized Benders decomposition (GBD), the original problem is projected onto the space of first-stage variables and then reformulated into a dual problem (Geoffrion, 1972). Because the dual problem contains an infinite number of constraints, it is relaxed into a lower bounding problem with a finite subset of these constraints.

Li et al. [2011] extended the GBD framework to a more general framework, called nonconvex generalized Benders decomposition (NGBD), to handle nonconvex recourse problems in TSSP rigorously. In NGBD, nonconvexity in the form of nonlinear functions participating in the objective and/or constraints are effectively handled using McCormick's relaxation technique (McCormick, 1976; Scott et al., 2011).

In this work, we extend the NGBD framework to address TSSP with integer recourse, where the nonconvexity in recourse problems arises from binary variables. We employ continuous relaxation of the second-stage binary variables by treating them as [0,1] continuous variables. While the sequence of lower bounds on the original problem solution value is generated by a sequence of solutions of lower bounding problems, the sequence of upper bounds on the original problem solution value is obtained by a sequence of solutions of upper bounding problems, which are generated by fixing the first-stage decisions to the solutions of the lower bounding problems. When the sequences of upper and lower bounds converge, we obtain an optimal solution to the original problem. It should be noted that when the first-stage decisions are fixed, the upper bounding problem can be decomposed into smaller subproblems for each of the scenarios, which can then be solved in parallel, thus making this method computationally very attractive.

5. Results and Discussion

Consider a pharmaceutical company that has a portfolio of new products in the beginning of the PII trial. The expected launch date of these products is five years from now, and the planning horizon is 15 years, which is divided into 30 time periods of six months each. The company would like to consider building of two greenfield continuous facilities (F1 and F2) and their possible expansions in the future. We are given the probability of the outcome of PII and PIII trials for each product. The decisions of interest to the company are when to build the greenfield facilities and when to expand them, and in each scenario, how much capacity, which product to produce in which facility, and in what amounts to produce, store, etc.

We consider nine different examples, which varied in terms of the number of products in the portfolio and thus the number of scenarios addressed. For the largest example, we

consider 10 products and nearly 60,000 scenarios. We used GAMS 23.7/CPLEX 12.3 on a 3.2GHz Intel Xeon CPU with 12GB RAM on a Windows platform. The full-space model was solved within a time limit of 10,000 CPU s for examples containing up to six products (< 1000 scenarios). However, when the number of products is increased to more than six, the full-space model was not solved due to a time limit and/or memory limit. The NGBD algorithm, on the other hand, solved all the examples within the time limit. Furthermore, with the NGBD algorithm, the solver time scales linearly with the number of scenarios, and thus the largest 10-product example with nearly 60,000 scenarios comprising about 212 million variables (36 million binary and 176 million continuous variables) and over 150 million contraints was solved in less than 3 hr of solver time.

6. Conclusion

In this work, we addressed an important strategic problem faced by major pharmaceutical companies. We developed a mathematical framework for capacity planning problem under clinical trials uncertainty based on TSSP. Since the proposed formulation resulted in a large-scale MILP model, whose size increases exponentially with the number of products, the existing state-of-the-art commercial solvers are not sufficient to solve such massive problems. This motivated us to develop an efficient decomposition algorithm, which efficiently solved problems with up to 10 products and nearly 60,000 scenarios in less than 3 hr of solver time. The solution time of the NGBD algorithm scales linearly with the number of scenarios in the problem, which makes it attractive to solve industrial-scale problems. Furthermore, one can achieve an increased speedup using the NGBD algorithm by employing massively parallel computing since the subproblems can be solved in parallel.

Multivariate Analysis of API Particle Size Distribution Variation in a Manufacturing Environment

Keeley Stepney,[a] Elaine Martin,[a] Gary Montague[a]

[a]*Biopharmaceutical and Bioprocessing Technology Centre, Newcastle Univesity, Newcastle-Upon-Tyne, NE1 7RU*

Abstract

The particle size distribution (PSD) of an active pharmaceutical ingredient (API) can influence important properties of the final product, such as the content uniformity of tablets and the dissolution rate of the drug to the patient. The purpose of this study is to characterise the PSD of a particular API product using laser diffraction measurements and then assess how multivariate data analysis methods can be applied to PSD data. Results show that a similar PSD is produced from the main and product recovery process, but there are differences between samples that are collected on two different plants. These findings are emphasised by applying principal component analysis to the PSD: clusters of samples are seen for each plant and the loadings show areas of the PSD where the differences materialise. By reducing the dimensionality of the PSD data through principal component analysis, the data can be summarised in a scores plot enabling the trends in the data to be more easily identifiable.

Keywords: Particle size distribution, multivariate analysis, active pharmaceutical ingredient

1. Introduction

When an active pharmaceutical ingredient (API) is manufactured it may be in the form of a solid powder. The particle size distribution (PSD) of the API will affect a number of important properties of the product, both during the formulation of the API into tablets and the quality of the final product that is taken by the patient [1]. For example, smaller particles may produce a greater uniformity of the drug content within tablets [2]. A greater overall surface area of the API particles will lead to more rapid dissolution and a higher release rate of the drug [3].

Laser diffraction (LD) is a commonly used method of particle size measurement in the pharmaceutical industry [1]. To take a measurement on a sample of powder, laser light is scattered by the particles and the angle of the light scatter is measured and interpreted to give a particle size distribution. Data is produced of the frequency densities of a number of size measurements. The frequencies will be correlated for similar size measurements and hence the data is appropriate for multivariate data analysis.

To compare the PSDs of several samples, the distributions can be overlaid onto a line graph. An example is shown in Figure 1. Additionally, a set of percentiles, such as the 10^{th}, 50^{th} and 90^{th}, can be found for each sample, to summarise the information contained within the PSD. However percentiles are coarse measures of PSD information content and do not capture the detail contained within the distribution. An alternative

approach is the application of multivariate data analysis techniques to analyse the complete distribution and compare the PSDs of a number of samples.

1.1. Multivariate Data Analysis

Principal component analysis is a technique of reducing the dimensionality of a dataset comprising of many variables to a smaller set of principal components that represent the majority of the variation in the data [4]. A principal component is a linear combination of the original variables that represents some of the variation within the data. Principal component analysis (PCA) summarises the data into scores and loadings that represent the trends in the observations and variables respectively.

Multivariate data analysis techniques have been widely applied in process analysis. For example in spectroscopic data, which contains many highly correlated variables (wavenumbers), PCA can be used to identify the important trends by summarising the data into a small number of principal components. This allows the data to be analysed more efficiently without losing information that is contained in the data. For example, Gabrielsson et al [5] applied PCA to a combination of process and ultra-violet spectroscopy data and by monitoring the scores, the evolution of a hydrogenation reaction could be followed. Brülls et al [6] applied PCA to near infrared spectroscopy data from a freeze drying process. They showed that the scores from the first PC indicated the rate of the drying process and step changes between drying phases.

Multivariate analysis has previously been applied to data generated from particle size distribution measurements. Typically when laser diffraction measurements are made, several repeats are taken and the data are averaged to give the PSD. Ma et al [7] applied PCA to the raw data from laser diffraction measurements, to detect small quantities of large particles that were only detected in a small number of repeats. Furthermore Mattila et al [8] applied PCA to online laser diffraction data from a mineral processing plant to detect disturbances in the process.

1.2. Aims and Objectives

The aim of this study is to characterise the PSD of the API for Rosuvastatin Calcium, manufactured by AstraZeneca and to understand the causes of the variation of the PSD. More specifically the goal was to assess the effect of different manufacturing plants and process streams on the PSD. Understanding more about the particle size distribution of the product enables the manufacturer to determine the range of particle sizes that are acceptable for the API that is to be formulated into tablets. Therefore when changes are to be made to improve the process, the PSD of new batches can be compared to that of the baseline set of samples to determine whether the change has impacted on the PSD.

Furthermore this study presents an opportunity to apply multivariate data analysis techniques to PSD data, to assess the effectiveness of using principal component analysis to compare PSD profiles through summarising the data into score and loadings.

1.3. Overview of the Industrial Process

The data forming the basis of the paper are taken from the industrial manufacturing process that produces the API. A solid powder is formed from a precipitation reaction and is isolated on a filter dryer. The powder is then milled to reduce and homogenise the particle size distribution. The API manufacture is a batch process that takes place in one

of two processing plants. Plant 1 is primarily used for the manufacture of the API, but a second plant is brought into operation when greater capacity is required. Product can be recovered from the liquors from the filter dryers and reprocessed in the recovery process, through acidification, extraction into solvent and basification and precipitation. This process can be run in either manufacturing plant.

2. PSD Baseline Study

Samples were taken from a number of batches after the product was milled to analyse the particle size distribution of the product. Each sample was analysed by laser diffraction to create a baseline dataset of the current PSD distribution. Most of the samples were taken from the main process on plant 1, but batches from plant 2 and the recovery process were also analysed. The particle size distribution measurements were taken with a Sympatec Dry Dispersion Laser Diffractor.

The study was carried out in two stages as two different particle size analysers were used. Firstly study A was run with batches from the main processes on plants 1 and 2. Subsequently study B was run with a new set of batches, including both the main and recovery processes from both plants. The two machines have been shown to produce differences in the PSD measurements, so results from the two studies cannot be compared. Each study includes one sample from each of 41 batches.

2.1. Plant 1 and Plant 2

The batches analysed in study A include a number of main batches from each plant. Figure 1 shows that after milling there are differences in the PSD of the material from the two plants, in particular the material from plant 2 has a higher level of fine particles than the material from plant 1. Although the stages of the manufacturing processes are the same for each plant, the batch sizes are different, so the precipitation vessels are not identical. The speed of the agitator in the vessel varies across the two plants, causing the rate of the precipitation reaction to differ and leading to differences in the particle sizes. Although they differ, in both cases the PSDs are within the specification limits for the product.

2.2. Main and Recovery Processes

Study B includes three batches from the plant 1 recovery process. The main and recovery processes differ at the start of the process, since different starting material is used, but the same steps are followed from the precipitation stage, as described in 1.3. The PSD profiles appear to be similar for samples from the two contrasting processes (Figure 2). This suggests that although there are differences between the main and recovery processes, this does not materialise in a difference in the particle size distribution of the final product.

3. Principal Component Analysis

An alternative approach to comparing the particle size distribution data is through the use of principal component analysis. Strong correlations exist within the data so principal component analysis can be used to summarise the data into a small number of principal components, to assess the underlying trends and identify potential outliers or unusual behaviour.

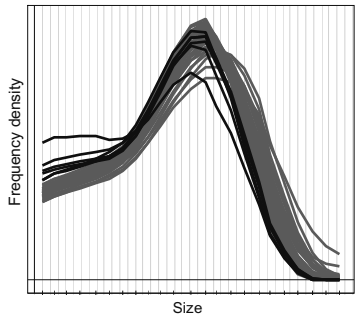

Figure 1: Plant 1 (grey) and plant 2 (black) main batches analysed from study A

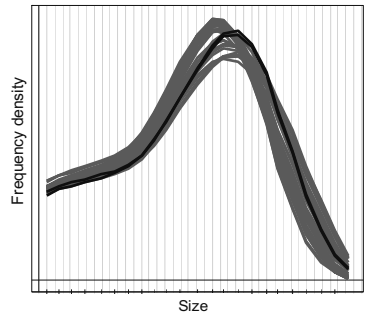

Figure 2: PSD of plant 1 main (grey) and recovery (black) process batches from study B

From the dataset for study B, the batches from the plant 1 main process were used to create a PCA model. Three principal components were retained, explaining 99% of the variability in the data. Batches from the plant 1 recovery process and both processes on the second plant were introduced as a prediction set to the PCA model. All of the data was from study B. The scores from the plant 1 recovery batches fit fairly closely with the plant 1 main batches that were used to build the model, although they do form a cluster to one side (Figure 3). However the plant 2 batches from both product streams have low scores for PC2, which corresponds to a high level of fine particles (Figure 4), agreeing with the trend observed in Figure 2.

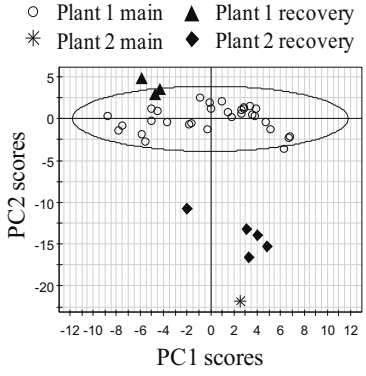

Figure 3: Scores for PC2 vs. PC1, with plant 2 and recovery batches as a prediction set

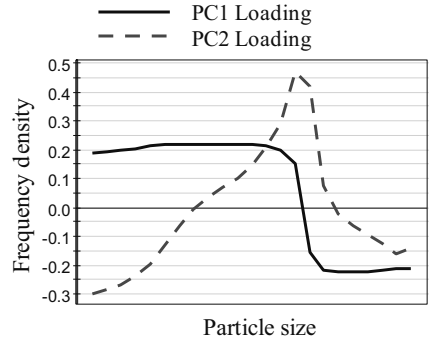

Figure 4: Loadings for PC1 and PC2

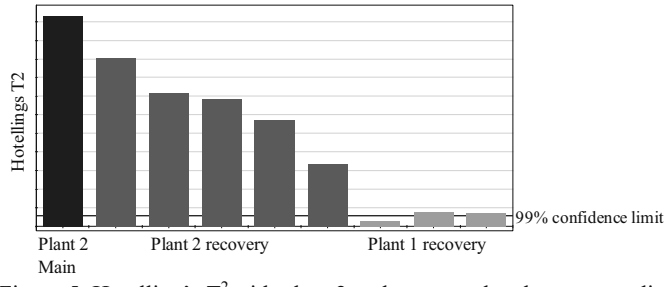

Figure 5: Hotelling's T^2 with plant 2 and recovery batches as a prediction set. Process representation built from plant 1 main process batches

From Hotellings T^2 it is evident that the plant 2 batches are significantly different to the plant 1 main batches. The baseline model was constructed from the plant 1 main batches. The benefit of this representation is that the information from the three retained principal components is presented in one representation, clearly illustrating the differences between both the plants and the recovery processes.

4. Conclusions

An assessment has been made of the particle size distribution of an API and how the PSD varies across two plants and processes. Differences have been found in the particle size of material produced on two different plants, but not between the main and recovery processes. This suggests that it is the plant where the particles are formed and the size of the batch that affects the PSD, rather than the process that is used before the precipitation stage. It is important to state that the PSD always remained within product specification, and all of the batches were successfully formulated, showing the range of particle size that is acceptable.

Principal component analysis of the PSD data was able to capture 99% of the variation in three principal components and emphasises the differences between the batches manufactured on the two plants using a scores plot. PCA is potentially an effective method for comparing the distributional behaviour of PSD data.

When the information for each batch can be compressed into a principal component representation, the batch-to-batch variation can be compared on a scores plot. The plot shows clusters of similar batches that were manufactured on the same plant, and also allows unusual batch behaviour to be detected. When several batches are to be compared, it is more efficient to compare batches on a scores plot rather than overlaying several PSD curves onto a line graph. The loadings allow the differences in the scores to be explained, for example they show that batches produced on plant 2 have a higher level of fine particles. Since 99% of the variation is explained by the principal component representation, very little information of the PSD will be lost.

Long-term Scheduling of a Multi-stage Multi-product Bio-pharmaceutical Process

Shaurya Kabra, Munawar A. Shaik, Anurag S. Rathore

Department of Chemical Engineering, Indian Institute of Technology Delhi, Hauz Khas, New Delhi – 110016, India. E-mail: munawar@iitd.ac.in

Abstract

There have been several works in the literature for scheduling of multi-product continuous processes with significant attention laid on short-term scheduling. This work presents a continuous-time model for long-term scheduling of a multi-stage multi-product process from bio-pharmaceutical industry. The overall model is a mixed-integer linear programming (MILP) formulation based on State-Task-Network (STN) representation of the process using unit-specific event-based continuous-time representation. The proposed model is an extension of model by Shaik and Floudas (Ind. Eng. Chem. Res., 2007, 46, 1764-1779) with several new constraints to deal with additional features such as unit and sequence dependent changeovers, multiple intermediate due dates, handling overproduction, shelf-life and waste disposal, and penalties on backlogs and delayed order fulfillment. Improved tightening and sequencing constraints have been presented leading to better relaxed objective values. The validity of the proposed model has been illustrated through an example from the literature.

Keywords: Long-term Scheduling, Multi-stage, Multiproduct Plants, Optimization, Bio-pharmaceutical Process.

1. Introduction

Scheduling in the industrial context deals with optimal allocation of limited resources in a plant comprising multiple stages to maximize the performance (generally profit) in terms of efficiently meeting the demands of multiple products with several due dates. There has been lot of attention in the literature for scheduling of batch processes compared to semi-continuous/continuous processes. While short-term scheduling typically deals with shorter time horizons of the order of several hours to days, medium-term scheduling deals with time horizons of the order of several days to weeks, and long-term scheduling (or mid-term planning) deals with longer time horizons ranging from several weeks to months. Finding optimal solutions to scheduling problems with longer time horizons has been generally found to be difficult compared to short-term scheduling problems. Therefore, in the literature either heuristic based or decomposition based approaches have been reported for solving medium-term and long-term scheduling problems. Dogan & Grossmann (2006, 2008) presented bilevel decomposition algorithm for solving simultaneous planning and scheduling of single-stage multi-product continuous plants. Lima *et al*. (2011) proposed rolling horizon algorithms for long-term scheduling of single-unit multi-product continuous process to manufaure high performance glass.

2. Problem Statement

The problem in this study may be defined as follows: the objective is to develop a production schedule that maximizes profit, given a multi-stage processing plant with several parallel units at each stage with the following information: (i) unit/stage dependent production rates, (ii) minimum processing times, (iii) sequence dependent transition times for product changeovers, (iv) finite dedicated storage capacities, (v) shelf-life of intermediates or products, (vi) selling price of finished products, (vii) costs of manufacturing, inventory, transitions, backlogs for late deliveries and waste disposal, and (viii) multiple intermediate due dates and demands for each product for each customer. It is assumed that overproduction is not allowed and backlogs are penalized. Product selling is feasible only at the demand date. There are specific constraints that are often encountered in scheduling of bio-pharmaceutical processes to monitor the processing of a product before its expiry as governed by its shelf-life and also to effect any waste disposals due to rejections during any clinical trials and/or other product wastage.

3. Mathematical Model

The proposed model is an extension of the short-term scheduling model for continuous processes developed by Shaik and Floudas (2007) to cater to long/medium-term scheduling problems. Additional constraints are formulated by introducing binary variables for handling sequence-dependent changeovers and to keep track of total number of changeovers taking place within each unit, based on similar equations presented in Shaik *et al.* (2009). New constraints are written to monitor and track the demands at intermediate due dates using the production and time variables. Within each time period several sub-events are postulated and the above constraints are checked only at sub-events. This way there is no need to use slack variables, as employed in Shaik *et al.* (2009) to monitor the inequalities at the time of intermediate demands, hence there are fewer number of variables. New constraints are also written to deal with specific needs of shelf-life expiry and waste product management for the case of scheduling of bio-pharmaceutical processes. If a product is within its shelf-life it can be either stored or processed, else it is considered as waste product and disposed off. The objective is maximization of profit that includes various costs for manufacturing, storage, changeovers, waste disposal, and penalties for late deliveries. The objective function also includes penalty on the total number of binary variables used in the model. The proposed constraints are not given here due to space limitations.

The following are the enhancements and improvements in the proposed model as compared to the earlier works. The proposed constraints effectively handle sequence-dependent changeovers. New constraints are written to meet multiple intermediate due dates effectively for both the cases of overproduction being allowed or not, without the use of any slack variables. Additional tightening constraints on processing duration and changeovers have been incorporated to make the overall model tighter and give improved RMILP solution. These tightening constraints are more efficient as they make use of exact transition times in a unit compared to previous works. The sequencing constraints are also improved by removing the big-M terms. The proposed model is demonstrated on a two-stage example from a bio-pharmaceutical industry with two fermentation and two purification suites at each stage, to produce three products with multiple orders of each product during a year-long time horizon.

4. Example

The proposed model is applied to a scheduling problem taken from Lakhdar *et al.* (2005). This example caters to a general problem in bio-pharmaceutical industry that includes most common features of long-term scheduling/mid-term planning. The problem consists of a two-stage facility, with two fermentation (J1, J2) and two purification suites (J3, J4) at each stage, to produce three products (P1, P2, and P3) with multiple orders of each product during a year-long production time horizon. The STN represenation is shown in Fig. 1. Data for production rates, lead times, different costs, production and storage related parameters are taken from Lakhdar *et al.* (2005). Lakhdar *et al*. (2005) used prefixed time periods of 60 days and employed a discrete-time model to solve this problem. In their model the demands were not met on time although there were few unutilized days in different time periods.

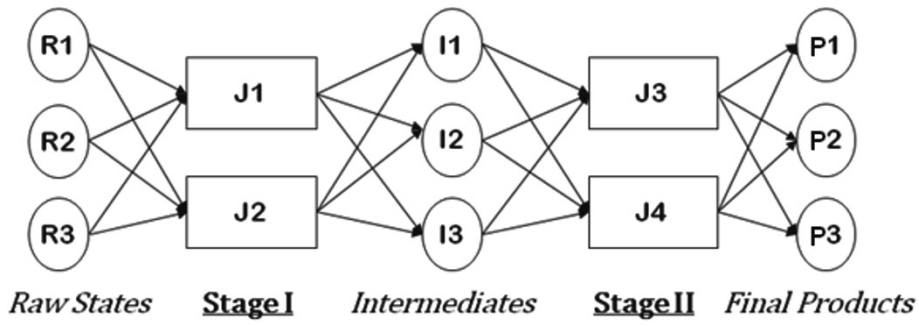

Figure 1. State-Task-Network for example

The proposed model is impelmented using GAMS 23.5/CPLEX 12.2 on 2.66 GHz Intel Core 2 Duo Processor with 3 GB RAM running on windows operating system. The model statistics such as number of binary and coninuous variables, constraints, CPU time and so on are shown in Table 1. The proposed model is solved to zero optimality gap and results in a better objective function of 517 compared to 487 reported by Lakhdar *et al.* (2005). Further, there is zero wastage and all the demands are met and were on time leading to zero backlogs and zero late deliveries. The resulting Gantt chart is shown in Fig. 2 and the demand-supply profile is shown in Fig. 3.

Table 1. Results and Model Statistics using Proposed Model

Statistics	Proposed model
Binary variables	255
Continuous variables	760
Constraints	2416
CPU time (s)	85.5
MILP solution	517

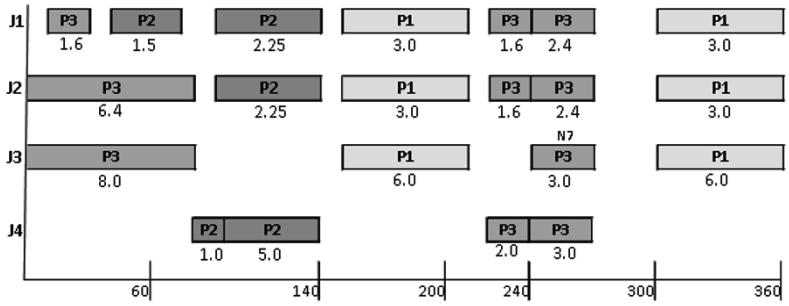

Figure 2. Gantt Chart using the Proposed Model

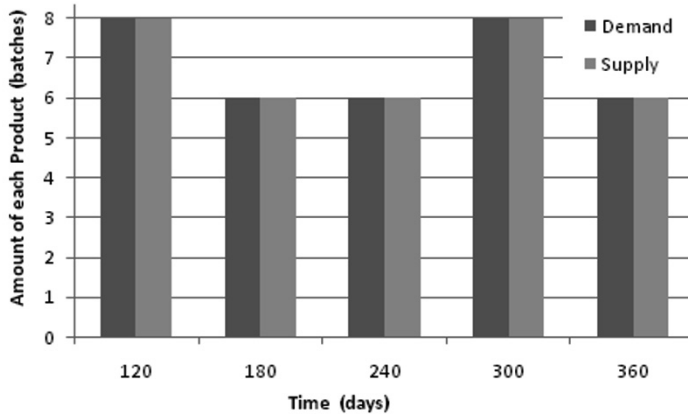

Figure 3. Demand-supply Profile using the Proposed Model

5. Conclusion

In this work, an MILP model has been proposed for solving long-term scheduling problem of a multistage multiproduct facility from bio-pharmaceutical industry. The proposed model is based on STN representation using unit-specific event-based continuous-time representation. It has been demonstrated on a literature example involving two stages with parallel units for producing three products over a year-long time horizon giving better objective values compared with results reported in the literature.

An advanced model for controlled oral drug delivery

Naresh Pavurala,[a] Luke E.K. Achenie,[b]

Department of Chemical Engineering, Virginia Polytechnic Institute and State University, Blacksburg, Virginia 24060

Abstract

A drug release mechanism is combined with the Compartmental Absorption and Transit (CAT) model to develop a complete pharmaco-kinetic model for predicting orally administered drug release profile. Within an optimization framework, the developed model has been used for evaluating optimal values for key parameters including the size of the tablet and pharmacokinetic parameters like peak plasma concentration (C_{max}), area under the curve (AUC) and bioavailability needed to obtain plasma concentration profiles within the therapeutically required range.

Keywords: oral drug delivery, ACAT model, dissolution model, pharmaco-kinetic simulation, optimization

1. Introduction

The oral administration route is by far the most common way of administering pharmacological substances. It is estimated that 90% of all medicines are oral formulations and oral drug delivery systems comprise more than half the drug delivery market. In 2008, the oral drug delivery market was a USD 35 billion industry and was expected to grow as much as 10% per year until at least 2012 (Gabor, Fillafer et al. 2010). Oral drug products are also profitable for the pharmaceutical industry. With recent developments in manufacturing technology, large quantities of oral formulations are produced with short production times. By following good manufacturing practices (GMP regulations), high quality oral delivery products are prepared in a reliable and reproducible manner.

Among liquid and semi-solid formulations, the tablet is still the preferred drug product for oral administration, offering several advantages. It is also a given fact that oral administration is the most comfortable mode of therapy for patients (Gabor, Fillafer et al. 2010). However, biopharmaceutical issues such as physicochemical requirements of the drug and physiological conditions make oral delivery one of the most challenging routes.

The delivery of drugs, peptides or proteins, occurs through a process of continuous swelling of the polymer carrier that is associated with simultaneous or subsequent dissolution of the polymer carrier. The drug is usually molecularly dispersed or dissolved in a polymer matrix at low or high concentrations. As water penetrates the polymer, swelling occurs and the drug is released to the external environment (Narasimhan and Peppas 1997).

Dissolution and absorption of drugs from the gastrointestinal (GI) tract is a very complex process, influenced by many factors that not only vary among drugs but also between different regions in the GI tract. However, since, nearly one third of the blood from cardiac output flows through the gastrointestinal organs, it serves a good absorption surface for the drug into the system (Gabor, Fillafer et al. 2010).

Mechanistic models try to represent the physiological and pharmacological processes as accurately as possible. Mechanism-based models help in testing hypothesis of suggested mechanisms and for learning about system processes which are not easy to test experimentally (Marshall, Macintyre et al. 2006). An effective mathematical model, which can predict the drug release profile and the optimal blood plasma concentration, helps in reducing the expense, time and effort involved in drug design.

There are dispersion models that define the GI tract as a single tube with spatially varying properties (pH, surface area, etc.) along the tube (Ni, Ho et al. 1980). The movement of drugs through the intestine was described by Willmann and co-workers (Willmann, Edginton et al. 2007) by introducing an intestinal transit function. However, assumptions such as negligible first-pass effect and passive intestinal permeability do not appear justified.

A typical CAT model (Yu and Amidon 1999) divides the GI tract into three segments namely, stomach, small intestine and colon, while the transit flow in the small intestine is separated into seven compartments. The model considers simultaneous small intestinal transit flow and drug absorption. The model assumes instantaneous dissolution and equal transit times in all the compartments. It also does not account for the first-pass effect.

The Grass Model (Huang, Lee et al. 2009) is a physiologically based compartmental model. It describes the gastric emptying, transit in the GI tract based mainly on solubility, permeability, and tissue surface area and calculates the drug absorption in each compartment.

2. ACAT Model

In this work, an Advanced Compartmental and Transit (ACAT) model (Agoram, Woltosz et al. 2001) was used as a basis for developing the pharmacokinetic model. It includes linear transfer kinetics, six plausible states of the drug component (unreleased, undissolved, dissolved, degraded, metabolized and absorbed), nine compartments (stomach, seven segments of the small intestine, and colon), and three states of the excreted material (unreleased, undissolved and dissolved). Physiological factors such as gastric emptying, intestinal transit rate, first-pass metabolism, luminal transport and physicochemical factors (e.g. pKa, solubility, particle size, particle density, permeability) and dosage factors including dosage form and dose are taken into account in predicting the oral drug absorption (Huang, Lee et al. 2009).

In the ACAT model, the drug passing through the small intestine has transit times specific to each compartment. The rate of drug transit is determined by a transfer rate constant, k_t, which is a reciprocal of the mean transit time between each compartment. The dissolution process is defined by a simple rate constant, k_d, which is calculated from the solubility of the drug (C_S) (as a function of pH), lumen concentration (C_L), its effective particle size (r_0), particle density (ρ), molecular diffusion coefficient (γ) and diffusion layer thickness (T) (Equation 1.1). Hence it does not account for the process of dissolution as in (Narasimhan and Peppas 1997) where the disentanglement of the polymer is also taken into account along with the drug dissolution, clearly explaining the dissolution process. The time scale for the absorption process is set by a rate constant, k_a, which is expressed in terms of the effective permeability (Peff) of the drug and absorption scale factor (α) for each compartment (Equation 1.2).

$$k_{(i)d} = 3\gamma \frac{C_{(i)S} - C_{(i)L}}{\rho r_0 T} \qquad (1.1) \qquad k_{(i)a} = \alpha_i P_{eff(i)} \qquad (1.2)$$

Here, 'i' is the compartment number, which in our case varies from 1 to 9.

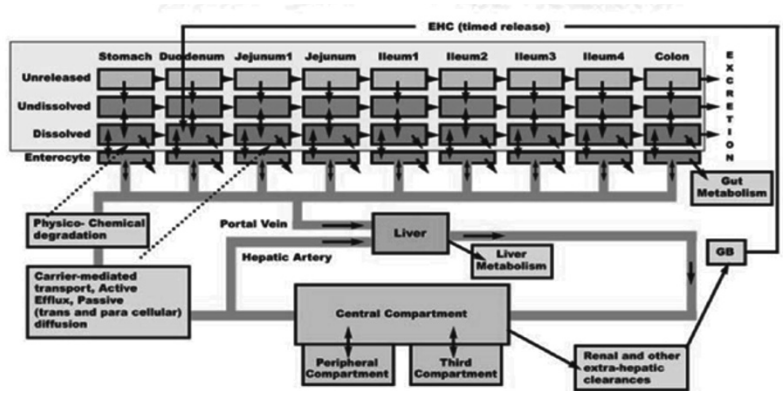

Figure 1:ACAT model schematic (Huang, Lee et al. 2009).

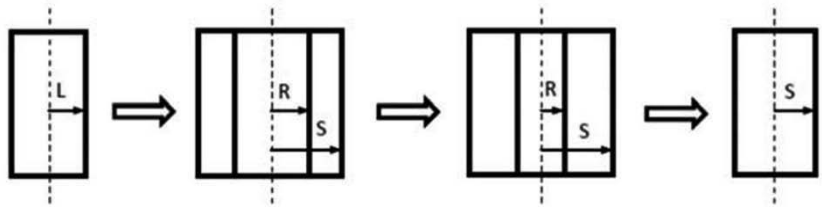
3. Dissolution Model

The Dissolution Model (Narasimhan and Peppas 1997) explains the release of a water soluble, crystalline drug enclosed within a swellable, hydrophilic glassy polymer, placed in contact with water or a biological fluid. It is a moving boundary problem formulated using a system of partial differential equations (pde's) and ordinary differential equations (odes) which describe the diffusion of (i) water into the system; (ii) drug out of the system; (iii) polymer chain disentanglement through the boundary layer; (iv) the left and right moving boundaries.



a b c d

Fig. 2: One-dimensional solvent diffusion and polymer dissolution process(Narasimhan and Peppas 1997).

In this model, when water comes in contact with the glassy polymer of initial diameter 2L (Figure 2a), the polymer starts to swell and two distinct fronts are formed: the swelling interface at position R, and the polymer-water interface at position S (Figure 2b). Initially, front R moves inwards since the drug starts moving out of the gel layer, and front S moves outwards till the polymer keeps swelling. When the concentration of water inside the polymer gel layer exceeds a critical value, v_1^*, polymer disentanglement begins and both R and S diminish. Hence, during the latter stage of dissolution process, both R and S move towards the center of the tablet (Figure 2c). The process continues, till the glassy core disappears and only front S exists, which continues to diminish till the entire polymer is dissolved (Figure 2d).

The developed pharmaco-kinetic model employs linear transfer kinetics with two plausible states of the drug component (dissolved and absorbed). The first two layers in the ACAT model (Figure 1) representing the unreleased, released states of the drug component are replaced by input from the dissolution model. The basic approach is that,

the amount of dissolved drug, which enters into each of the compartments in the ACAT model, is evaluated using the dissolution model. The latter uses the initial radius of the tablet as input to evaluate the radius of the tablet at the beginning of each compartment of the ACAT model. Hence, the drug feed into each of the compartments is evaluated using the density of the drug and the thickness of the tablet. The drug feed determines the plasma concentration profile of the drug. An optimization model is also employed into the pharmaco-kinetic model, in order to evaluate the optimal thickness of the tablet by minimizing the error between the predicted plasma concentration and the desired plasma concentration profiles.

In this paper, Cimetidine is used as a model drug to test the pharmaco-kinetic model. Cimetidine is an antagonist of the Histamine H_2-receptor that inhibits the secretion of gastric glands. The drug is available in a variety of oral dosage forms for the treatment of duodenal and gastric ulcers (Somogyi and Gugler 1983). Plasma concentration-time profiles of Cimetidine in 12 healthy patients following oral administration of a commercially available immediate release formulation (Tagamet) as well as three extended release formulations was presented in Jantratid *et al*(Jantratid, Prakongpan et al. 2006). Bioavailability and pharmacokinetics of cimetidine in 10 healthy volunteers after administration of oral doses (100,400, and 800 mg) is studied in Grahnen *et al* (Grahnén, Bahr et al. 1979).

4. Results and Discussions

A desired plasma concentration profile for cimetidine was obtained from Jantratid *et al* (Jantratid, Prakongpan et al. 2006) in which, a 400 mg cimetidine tablet was used as the initial dosage in the experiment which contained 40% of drug and 7.5% of polymer. A plasma profile with peak plasma concentration (C_{max}) of 2100 ng/ml and a bioavailability of 64% (well within the range of experimental results) was considered for the model. The optimization was started with an initial dosage of 190 mg (considering just the mass of drug and polymer). The density of cimetidine is taken as 1.4 g/cc and the effective human permeability as 0.287×10^{-4} cm/s. The total time of simulation is taken as 12 hours. The transit times, volumes and radii of each compartment were taken from (Table I) in (Bolger 2009). The radius of the tablet was fixed at 7.00 mm and the thickness of the tablet was varied during the optimization.

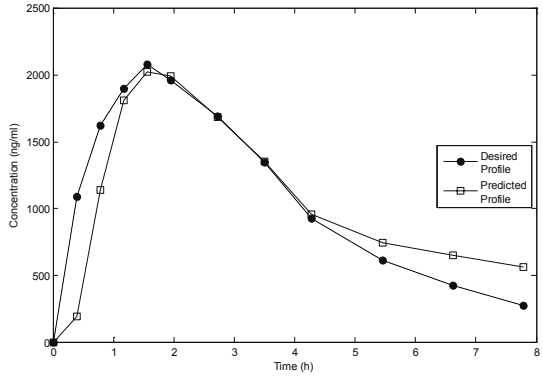


Fig. 3: Predicted and desired plasma concentration profiles of cimetidine oral dose. The dotted line represents the desired plasma concentration profile obtained from literature and the solid line represents the predicted plasma concentration profile using the pharmaco-kinetic model.

The optimal thickness of the tablet was obtained as 1.37 mm. The value of Cmax was obtained as 2024.8 ng/ml, which is comparable to the experimental value. The area under the curve (AUC) values obtained for the desired and predicted profiles in Fig. 3 are 8399.4 ng.hr/ml and 8435.4 ng.hr/ml respectively. In both profiles, the peak plasma

concentration (C_{max}) was achieved within 1.5 – 2 hours. The initial dosage (just the drug and polymer) calculated after obtaining the optimal thickness was 292 mg, which gives a bioavailability of 41%.

5. Conclusions

This paper presents effective models for drug release, drug absorption and transit. Coupling ideas from the ACAT model and the dissolution model, we have developed a complete pharmacokinetic model. The values of the pharmacokinetic parameters such as C_{max}, AUC calculated from the model are comparable to experimental results. The value of initial dosage calculated from the obtained optimal tablet thickness is slightly higher than the experimental values, which in turn results in a lower bioavailability. The advantage of the suggested approach is that it can be used to test hypothesis about the mechanism involved in drug delivery into the blood circulatory system; these are included in the next stages of our research. The model also evaluates the optimal thickness for the drug tablet in order to obtain the required plasma concentration profile. We are currently employing the composite model to hypothesize the optimal diffusion coefficient (and other physico-chemical properties) that a new drug needs in order to obtain a desired drug release profile. This is expected to be useful for drug design.

Model and analysis of pharmaceutical manufacturing system with government intervention and emergency supply

Chen Wang[a], Michael Pishko[a], and Carl Laird[a]

[a]*Texas A&M University, 3122 TAMU, College Station, TX 77845, USA*

Abstract

Recurring drug shortages continue to be a significant problem, and one major cause is the desire for manufacturers to leave the business due to the high-risk associated with uncertain demand. Guaranteed orders from government and the existence of flexible-by-design rapid manufacturing facilities can decrease manufacturing risk and ensure production of necessary products. In this paper, we model the production choices of a pharmaceutical manufacturer, assuming that the manufacturer attempts to maximize its expected profit with conditional-value-at-risk constraints on the loss. The resulting linear programming problem is analyzed to determine the optimal production level as a function of the government order amount. Including the possibility of emergency production allows for increased manufacturing flexibility and reduces the required government order costs.

Keywords: rapid therapeutics manufacturing, conditional-value-at-risk, optimization.

1. Introduction

Recurring drug shortages remain a significant problem, demonstrating limitations in the current pharmaceutical manufacturing infrastructure. In December of 2000, a single manufacturer of tetanus and diphtheria (Td) vaccine ceased production, causing a severe shortage that disrupted the routine immunization program until June of 2002. Again in 2004, the closure of a single production facility caused a shortage of influenza vaccine, and the US supply of influenza vaccine was nearly half of the desired doses. One of the major causes of these drug shortages is the desire for pharmaceutical manufacturers to avoid high-risk products with uncertain demands. Such risks can be reduced by government intervention, including for example, contract orders and guaranteed inventory buy-back (Nevel *et al.*, 2005). By doing this, the financial risk to the manufacturer is reduced, and a certain amount of a steady production is maintained.

There has also been significant interest in the development of a national infrastructure for rapid pharmaceutical manufacturing in the form of emergency production facilities, such as the National Center for Therapeutics Manufacturing (NCTM) in Texas. The NCTM is a flexible-by-design prototype of multi-product, multi-technology, flexible pharmaceutical manufacturing facility. An emergency rapid manufacturing capability provides the possibility for production recourse when demand is higher than expected.

In this paper, we consider a planning problem where the government wants to determine the appropriate guaranteed order amount to ensure continued production of a particular therapeutic. The manufacturer is assumed to be risk-averse and it attempts to maximize its expected profit while satisfying constraints on financial return and risk. A popular

financial risk measure, the Conditional Value-at-Risk (CVaR), is used to quantify the manufacturer's risk. The loss function is a convex piecewise linear function of the planned production amount, and the decision-making process of the manufacturer can be formulated as a linear programming problem. Using this model, government entities can evaluate the minimum fixed order amount that is required to ensure that a particular demand will be met. We further quantify the savings possible with the existence of an emergency rapid production facility.

2. System model

A detailed description of each entity in the model is as follows.

Manufacturer: The pharmaceutical manufacturer has to plan and schedule its manufacturing resources among multiple products at a general level. In this model, we assume that the manufacturer attempts to maximize its expected profit subject to constraints on its financial risk to determine general-level plans and therefore some "risky" products may be underproduced and lead to shortage problems in the future. The associated parameters and variable are as follows.

x_H – output of high-risk product
x_L – output of low-risk product
C_H^F – fixed cost of high-risk product
C_L^F – fixed cost of low-risk product
C_H – unit cost of high-risk product
C_L – unit cost of low-risk product
R_p – ratio of profit to investment
R_r – ratio of risk to investment

Market: Each product of the manufacturer has a known and fixed price and an unrealized demand. The underlying distribution of the demand is assumed available.

P_H – price of high-risk product
P_L – price of low-risk product
$\tilde{d}_H$ – demand of high-risk product
$\tilde{d}_L$ – demand of low-risk product

Emergency supply: The emergency suppliers such as the NCTM can take orders when drug shortages occur or are expected. The emergency supplier has its own production capacity and a reasonably higher production cost.

P_E – emergency supply price
Cap_E – emergency supply capacity

Government authorities: Government authorities can affect the manufacturers' decision in two ways. One is contract order at a price equivalent to or lower than the market price. The other is through inventory buy-back, i.e. the government authorities buy back a portion or all of the manufacturers' unsold inventory at a price lower than the manufacturing cost.

P_B – government buy-back price
γ_B – government buy-back ratio
O_G – government contract order amount of the high-risk product

According to the proposed model, the profit of the high-risk product is composed of three parts: 1) profit due to regular selling, 2) profit due to government buy-back, 3) profit due to emergency selling with the support of emergency supply. Using the above notations, the total profit can be expressed as follows.

$$Profit_H := min\{x_H, \hat{d}_H\} P_H + P_B \gamma_B \left(x_H - \hat{d}_H\right)^+ + (P_H - P_E) S_E - (C_H^F + C_H x_H) \quad (1)$$

where for any $\alpha \in \mathbb{R}, \alpha^+ := \max\{\alpha, 0\}, \alpha^- := \max\{-\alpha, 0\}$, and $\hat{d}_H := \max\{O_G, \tilde{d}_H\}$ is the order that the manufacturer finally take and

$$S_E \coloneqq min\{(x_H - \hat{d})^-, Cap_E\} \tag{2}$$

is the amount that is to be ordered from the emergency supplier. As S_E is neither a convex nor a concave function of x_H, $Profit_H$ in (1) is not directly convex or concave in x_H. However, its reformulation for computational purpose is given later. Similar to the profit of the high-risk product, the profit of the low-risk product without government interventions and emergency supplies is

$$Profit_L \coloneqq min\{x_L, \tilde{d}_L\} P_L - (C_L \cdot x_L + C_L^F) \tag{3}$$

which is concave piecewise linear function of x_L.

3. Risk measure

The conditional value-at-risk (CVaR) of the manufacturer's loss is used to measure the risk of its production plan. In this section, the loss function of the manufacturer and its convex formulation is given followed by a brief review of CVaR.

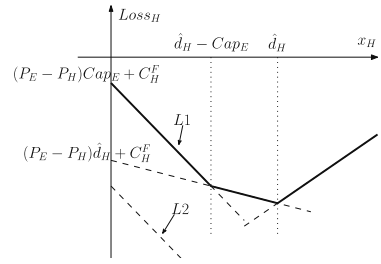

Figure 1: Loss function

3.1. Loss function and its convex formulation

As a function of the decision variable $x_H(x_L)$ and the stochastic demand $\tilde{d}_H(\tilde{d}_L)$, the associated profit is also a random variable and the loss of a product is defined as the opposite of profit, i.e.

$$Loss_H = -Profit_H,\ Loss_L = -Profit_L \tag{4}$$

As mentioned in section 2, $Loss_H$ is not directly convex. However, it can be reformulated as a convex piecewise linear function and this result is given in the following theorem.

Theorem 1: The loss function of high-risk product defined in (1) is equivalent to

$$Loss_H = max\begin{Bmatrix} (C_H - P_H)x_H + (P_E - P_H)Cap_E + C_H^F \\ (C_H - P_H)x_H + (P_E - P_H)\hat{d}_H + C_H^F \\ (C_H - P_B \cdot \gamma_B)x_H + (P_B \cdot \gamma_B - P_H)\hat{d}_H + C_H^F \end{Bmatrix} \tag{5}$$

under the condition $P_H \geq P_E \geq C_H \geq P_B \cdot \gamma_B$.

Proof: 1) Consider the case $Cap_E \leq \hat{d}_H$: i) when $x_H \leq \hat{d}_H - Cap_E$, $Loss_H = (C_H - P_H)x_H + (P_E - P_H)Cap_E + C_H^F$; ii) when $\hat{d}_H - Cap_E < x_H \leq \hat{d}\_H$, $Loss_H = (C_H - P_E)x_H + (P_E - P_H)\,\hat{d}_H + C_H^F$; iii) when $x_H \geq \hat{d}_H$, $Loss_H = (C_H - P_B \cdot \gamma_B)x_H - (P_H - P_B \cdot \gamma_B)\hat{d}_H + C_H^F$. Note that $P_H \geq P_E \geq C_H \geq P_B \cdot \gamma_B$, $Loss_H$ in case i)-iii) is roughly shown in Figure 1 and clearly equivalent to (5).

2) Consider the case $Cap_E > \hat{d}_H$: i) when $x_H \leq \hat{d}_H$, $Loss_H = (C_H - P_E)x_H + (P_E - P_H)\,\hat{d}_H + C_H^F$; ii) when $x_H > \hat{d}_H$, $Loss_H = (C_H - P_B \cdot \gamma_B)x_H - (P_H - P_B \cdot \gamma_B)\hat{d}_H + C_H^F$. Note that in case 2) $f(x_H) = (C_H - P_H)x_H + (P_E - P_H)Cap_E + C_H^F$ shifts from *L1* to *L2* in Figure 1 and $(C_H - P_H)x_H + (P_E - P_H)Cap_E < (C_H - P_E)x_H + (P_E - P_H)\,\hat{d}_H$ for all $x_H \geq 0$, hence $Loss_H$ in case 2) can also be expressed by (5). Combination of case 1) and 2) completes the proof. □

The requirement that $P_H \geq P_E \geq C_H \geq P_B \cdot \gamma_B$ is quite reasonable. If the condition is not satisfied, the optimization problem becomes trivial and the solution can be determined simply by observation. With (4), the total loss is

$$Loss\left(x_L, x_H, \tilde{d}_L, \tilde{d}_H\right) \coloneqq Loss_H\left(x_H, \tilde{d}_H\right) + Loss_L\left(x_L, \tilde{d}_L\right). \tag{6}$$

3.2. Risk measure and the whole formulation

In this work, the CVaR of the loss function (6) is used to measure the risk associated with the manufacturer's production plan. CVaR is a coherent risk measure (Artzner *et al.*, 1999) and hence yields nice properties such as subadditivity and convexity. Additionally, the associated computation is also straightforward The definition and properties of CVaR is briefly reviewed below. For more results and detailed proofs, refer to (Rockafellar & Uryasev, 2002). Given $\alpha \in (0,1)$ and a loss $L(x, \tilde{d})$ as a function of the decision variable x and the random variable $\tilde{d}$, CVaR is defined as

$$CVaR_\alpha(x) \coloneqq (1-\alpha)^{-1} \int_{L(x,\tilde{d}) \geq VaR_\alpha(x)} L\left(x, \tilde{d}\right) p\left(\tilde{d}\right) d\,\tilde{d}, \tag{7}$$

where $VaR_\alpha(x) \coloneqq \min\{\xi \in \mathbb{R}: \int_{L(x,\tilde{d}) \leq \xi} p\left(\tilde{d}\right) \mathrm{d}\tilde{d} \geq \alpha\}$ is the Value-at-Risk of the loss. It has been proven that,

$$CVaR_\alpha(x) = min_{\beta \in \mathbb{R}}\, F_\alpha(x,\beta) \coloneqq \min_{\beta \in \mathbb{R}} \{\beta + (1-\alpha)^{-1} \int \left[L\left(x, \tilde{d}\right) - \beta\right]^+ p\left(\tilde{d}\right) d\tilde{d}\}. \tag{8}$$

If enough samples $d_1, \cdots, d_k$ of $\tilde{d}$ are available, $F_\alpha(x,\beta)$ can be approximated by

$$\hat{F}_\alpha(x,\beta) \coloneqq \beta + [k(1-\alpha)]^{-1} \sum_{i=1}^{k} [L(x, d_i) - \beta]^+ \tag{9}$$

4. Simulation results and analysis

The final optimization problem is given by,

$$\begin{aligned} \max_{x_H, x_L, \beta} \quad & \mathrm{E}[Profit_H + Profit_L] \\ \text{s.t.} \quad & \mathrm{E}[Profit_H + Profit_L] \geq R_p(C_H^F + C_H x_H + C_L^F + C_L x_L) \\ & \mathrm{CVaR}_\alpha\left\{Loss\left(x_L, x_H, \tilde{d}_L, \tilde{d}_H\right)\right\} \leq R_r(C_H^F + C_H x_H + C_L^F + C_L x_L) \end{aligned} \tag{10}$$

where the first constraint is on the expected return of the initial investment which can be approximated using sampling approach, the second constraint restricts the financial risk of the initial investment. *CVaR* can be approximated using (9).

Based on (10), two simulations are done on an example system to analyze the impact of the government order amount. Demand $\tilde{d}_H$ is assumed to be truncated normally distributed on the interval [20 150] and the original normal distribution has mean $\mu_H = 100$ (million) and variance $\sigma_H^2 = 25^2$. Other parameters include $C_H^F = 120$, $C_H = 10$, $P_H = 15$, $\gamma_B = 1$, $Cap_E = 20$, $P_E = 12$, $R_p = 1.2$, $R_r = -0.2$ and $\alpha = 0.95$. The simulation results are shown in Figure 2. With no government order amount, the problem is infeasible (i.e. the manufacturer will not plan to produce any of the high risk production). The left hand chart in Figure 2 quantifies the increase in the feasible range for production as the government order increases. The existence of an emergency supply facility increases the flexibility of the system. The right hand chart in Figure 2

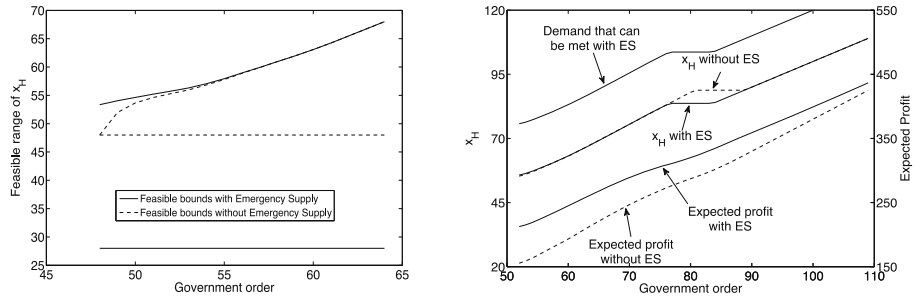

Figure 2: Simulation results

quantifies the optimal production level for the manufacturer as a function of the government order amount. This figure provides the necessary information for government planners to determine the necessary order amount. Furthermore, it quantifies the possible reduction in government costs that are possible because of the availability of an emergency rapid manufacturing facility.

5. Conclusions

Drug shortages continue to be a recurring problem. One of the major reasons for drug shortages is the exit of key manufacturers from the business due to the high-risk associated with uncertain demand. Assuming that therapeutics manufacturers is risk averse and operates according to some optimization formulation, continued production of a high-risk product can be ensured by reducing the manufacturers risk through guaranteed government orders. The existence of an emergency rapid therapeutics manufacturing facility further increases the demand that can be met for a given government order amount. In this paper, we have proposed a simple optimization formulation that represents the manufacturers' decision-making process. The manufacturer is assumed to maximize profit with conditional value-at-risk constraints on the loss. We show that the loss function is convex under reasonable conditions for the problem parameters. Sampling the demand, the CVaR condition is approximated, producing a linear programming problem. For a given set of system parameters, simulations show that the government intervention and the emergency supply can both reduce the manufacturer's risk while keeping a steady drug supply. Including an emergency rapid therapeutics facility in the system provides a much better solution since the facility allows for recourse after the demand is realized, resulting in a lower government order cost for a particular guaranteed demand.

Optimization and Control of Crystal Shape and Size in Protein Crystallisation Process

Jing J. Liu[a,b], Yang D. Hu[b] and Xue Z. Wang[a*]
[a] Institute of Particle Science and Engineering, School of Process, Environmental and Materials Engineering, University of Leeds, Leeds LS2 9JT, UK
[b] School of Chemical Engineering, Ocean University of China, Qingdao, China, 266001

Abstract

The purpose of the current work is to develop optimization techniques for protein crystallisation processes for controlled manufacture of protein crystals with desired shape. Based on a newly developed morphological population balance model for protein crystallisation that can simulate the multidimensional size distributions of a population of crystals, known as shape distribution, an optimisation technique is applied to investigate and control the growth of individual faces with the aim of obtaining desired crystal shape. Using a target shape distribution as the objective function, optimal temperature and supersaturation profiles leading to the desired crystal shape were derived. Genetic algorithm was investigated and found to be an effective optimisation technique for the current application.

Keywords: Multidimensional and morphological population balance model; Crystal shape distribution； Hen-Egg-White lysozyme crystallisation； Protein crystallisation control.

1. Introduction

Large molecule protein crystals have shown significant benefits in the delivery of biopharmaceuticals to achieve high stability, high concentration of active pharmaceutical ingredients (API), and controlled release of API. However, among the about 150 biopharmaceuticals on the market by 2004, only insulin has been marketed in crystalline form (Basu. et al, 2004). A technical challenge is that protein crystallisation has a very complicated environment and is affected by many factors. There is currently a lack of knowledge on commercial scale production of protein crystals. Therefore, in contrast to the majority of previous work on experimental and computational studies of protein crystallisation that was centered on single crystal scale, the focus of the research reported in this paper is placed on computational study of protein crystallisation at process scale, investigating the growth behavior of the population of crystals in a crystallizer.

The morphology and size distribution of protein crystals are key measures in quality control. However, research on population balance modelling of protein crystallisation processes is still very limited and restricted to simulation of crystal size distribution (Shi et al, 2005), ignoring crystal shape information because the size of a crystal is simply defined as the diameter of a sphere having the same volume as the crystal. A new morphological population balance model was proposed for modelling protein crystallisation processes (Liu et al, 2009; Liu et al, 2010a; Liu et al, 2010b). In the model, the shape of a crystal is quantitatively defined by the distances of all crystal faces to the geometric centre of the crystal. For all the crystals in the crystalliser, a

* Correspondence author, x.z.wang@leeds.ac.uk

concept of multi-dimensional size distributions, which we call shape distribution for the crystal population, was proposed. In principle, the morphological population balance model for protein crystallisation can be applied to control of the growth of individual faces with the aim of obtaining desired crystal shape and size. Therefore in this paper, process optimisation is introduced to the model for optimising the product crystal shape distribution. Optimal temperature and supersaturation profiles leading to the desired crystal shape distribution is derived. Genetic algorithm was investigated for optimisation. Since tracking an optimum temperature or supersaturation trajectory can be easily implemented by manipulating the coolant flowrate, the methodology provides a feasible closed-loop mechanism for protein crystal shape tailoring and control.
The case study protein is Hen-Egg-White (HEW) lysozyme for which the thermodynamics and kinetics of crystallisation were discussed in previous publications (Liu et al, 2009; Liu et al, 2010a; Liu et al, 2010b). The focus here is on optimisation in order to obtain desired shape for a population of protein crystals.

2. Morphological PB model and the optimisation problem

2.1. Morphological PB model for crystallisation of HEW Lysozyme

The morphological PB model of HEW Lysozyme has been presented in literature (Liu et al, 2009; Liu et al, 2010a; Liu et al, 2010b), so it is only briefly introduced here. In the current study, seeded crystallisation at a given operating condition, i.e. fixed buffer, fixed pH value and salt concentration, is considered. Supersaturation is created by reducing the temperature at constant cooling rates. As indicated in previous publications (Liu et al, 2009; Liu et al, 2010a; Liu et al, 2010b), crystal shape is modelled in two size dimensions x and y, which are the distances from the geometric crystal centre to the identified independent faces. The mathematical formulation for two-dimensional PB modelling is given in eq.(1).

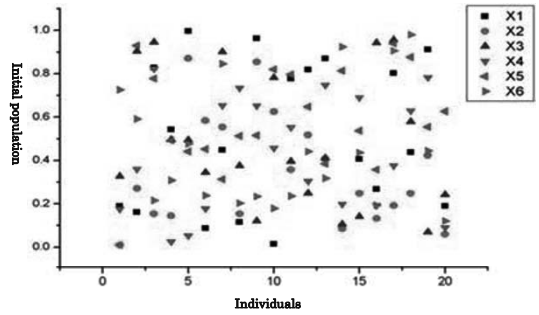

Figure 1 The initial 20 populations, each represented by six linear cooling rates, x1 ~ x6.

$$\frac{\partial f(x,y,t)}{\partial t} + \frac{\partial [G_{101}(x,t) f(x,y,t)]}{\partial x} + \frac{\partial [G_{110}(y,t) f(x,y,t)]}{\partial y} = 0 \tag{1}$$

The mass balance equation and facet growth rates are given in equations (2) and (3)

$$\frac{dC}{dt} = -\rho_c K_V \int_0^\infty \int_0^\infty f(x,y,t)\left(G_{101}(8\sqrt{2}y^2) + G_{110}(16\sqrt{2}xy - 12\sqrt{2}y^2)\right)dxdy \tag{2}$$

$$G_{101} = k_{101}\left(\frac{C - C_{sat}}{C_{sat}}\right)^{n_{101}} = k_{101}\sigma^{n_{101}} \quad G_{110} = k_{110}\left(\frac{C - C_{sat}}{C_{sat}}\right)^{n_{110}} = k_{110}\sigma^{n_{110}} \tag{3}$$

$$\sigma = \frac{C - C_{sat}}{C_{sat}} \tag{4}$$

where C is the solute concentration, *kg/l*, C_{sat} is the saturated solute concentration, *kg/l*, σ is the relative supersaturation, defined by equation (4), and k_{101}, k_{110}, *m/s*, n_{101}, n_{110} are facet kinetic parameters (Liu et al, 2009; Liu et al, 2010a; Liu et al, 2010b).

2.2. The optimization problem and genetic algorithm

For a population of HEW Lysozyme crystals, in here, the shape is described in equation (5) as a ratio of two distances, where x and y are the distances from the crystal geometric centre to the two independent faces, (101) and (110).

$$\mathrm{x} / y = ds \tag{5}$$

ds is identified as the objective function for optimising the shape of the crystal population. If the objective is to get plate shaped crystals, then the objective is to make *ds* approach 1. So the optimization function considering HEW Lysozyme crystal shape can be defined as:

$$\min_{CR(\mathrm{t})} \sum_{\mathrm{x},y} (\psi(\mathrm{x}, y, \mathrm{t})[(\mathrm{x} / y - ds)^2]) / \sum_{\mathrm{x},y} \psi(\mathrm{x}, y, \mathrm{t}) \tag{6}$$

$$\text{Contraints:} \quad CR_L \le CR(t) \le CR_U \tag{7}$$

where CR_L and CR_U are the lower and upper boundaries of the cooling rate during crystallization; $\psi(\mathrm{x}, \mathrm{y}, \mathrm{t})$ is the number population density function at the moment 't' based on population balance model; $\sum_{x,y} \psi(\mathrm{x}, \mathrm{y}, \mathrm{t})$ denotes summary of all particles density function in discrete space which can be derived from PB models. In this work, genetic algorithm (GA) is investigated since GA has features (Chiu & So, 2003) that fit the current problem well. Details of its application are described below.

3. Results and discussion

Suppose crystals with plate shape are desired, that is $x/y = ds = 1$. Cooling rates considered are CR_L= 0.01 °C/day and CR_U=8 °C/day. Five segments with six cooling rates: $x_1, x_2, x_3, x_4, x_5 x_6$, are divided within the whole process. Initial population (20 individuals) distribution is plotted in Figure 1, different colours mean different cooling rates. Morphological population balance is applied to simulate the process and scores fitness function for each individual. The maximum generation is 250 because it was found that the fitness function no longer decreases after 250 generations. The initial condition for the simulation is listed in Table 1.

Table 1 Initial condition for Lysozyme crystallization

pH	Precipitate	Concentration of precipitate	Concentration of solution	Temperature initial
4.5	NaCl	2.5% (w/v)	40 (mg/ml)	25°C

Individuals in the final generation are shown in figure 2, each variable (cooling rate) with the same colour in different individuals are quite close to each other, meaning all approaching the same solution. Figure 3 shows the change of fitness function vs. generations, clearly showing a quickly decreasing trend.

The optimal temperature and supersaturation profiles are shown in Figure 4. The shape of a typical crystal varies following the optimal temperature curve as shown in Figure 5. It can be seen that the crystal shape changed clearly from the beginning to the end of crystallization, and the crystals grow gradually from needle-like to plate-like. The value of the shape objective function $(x/y-1)^2$ decreases gradually to zero. However, facet $\{110\}$ of HEW Lysozyme is becoming diamond, shape changed totally if the value of objective function $(x/y-1)^2$ decreased to be zero. So the point should be avoided in the process of simulation and shape control. Gaussian-type distribution is kept as initially but the peak value of the distribution has dropped a little within the whole evolution, as shown in Figure 6. The changes of peak value are caused by the coefficient of variation,

which can be described as the full width at half maximum (FWHM), however, the full width at half maximum of the initial size distribution is given smaller, the increase of FWHM is not obvious compared to the decrease of peak value after optimisation.

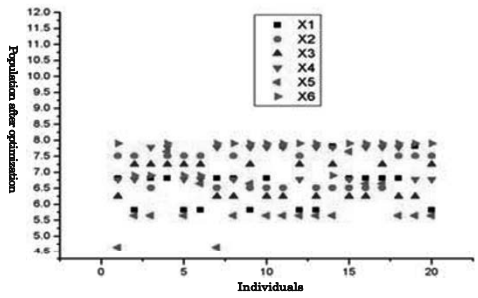

Figure 2 Final populations

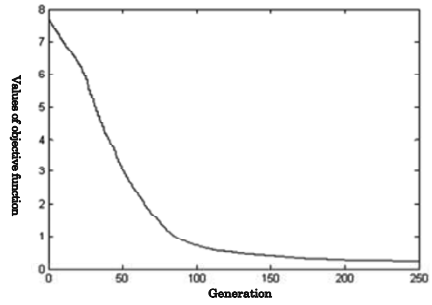

Figure 3 Objective function vs. generations

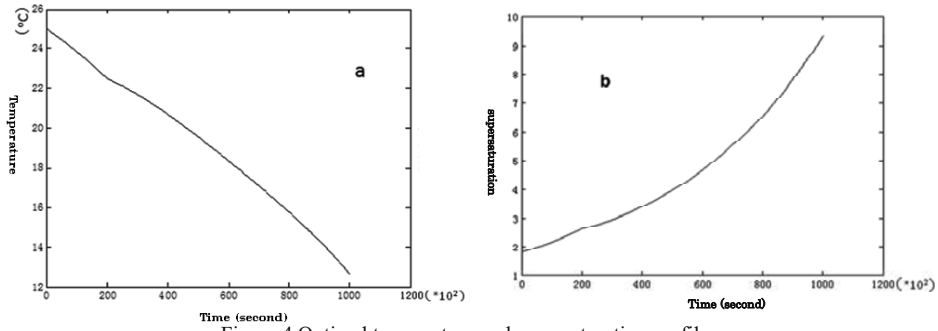

Figure 4 Optimal temperature and supersaturation profiles

4. Concluding remarks

Optimisation is applied to a morphological PB model for HEW Lysozyme crystallisation with the aim of obtaining operating conditions that lead to desired shape of crystals. Genetic algorithm proves to be an effective method for the optimization. The results demonstrated that by tracking the optimal temperature or supersaturation profile, crystals of desired shape can be obtained. The current work only represents a small step forward towards the ultimate goal of successfully manufacturing high quality protein crystals in large scale. Test of the optimization control techniques on real laboratory and industrial crystallizers should be discussed in the future work.

Intelligent Decision-Support Tools for Effective and Integrated Operational Planning in Pharmaceutical Plants

Naresh Susarla and I A Karimi

Department of Chemical and Biomolecular Engineering, National University of Singapore, 4 Engineering Drive 4, Singapore 117576

Abstract

Fierce market competition, peaking patent cliffs, mounting R&D costs, shrinking product pipelines and stringent regulatory protocols have brought a complete paradigm shift in the way pharmaceutical enterprises are operated. Motivated by an immediate need of efficient decision–support aids in pharmaceutical companies, we have devised 2 smart tools: PlanPerfect and DRplan. These tools are designed in association with Singapore based plants of multi-national pharmaceutical companies to find their application for production planning at manufacturing facilities and for requirement planning at distribution hubs. Our tools aid decisions pertinent to (i) campaign lengths with number of batches in each campaign, (ii) campaign sequencing and sequence-dependent cleaning and setups, (iii) plant maintenance, (iv) NCEs testing and production, (v) material outsourcing, (vi) resource allocation, (vii) manpower handling, (viii) inventory management, (ix) plant utilization, (x) waste generation, (xi) generate optimal size and numbers of material orders, (xii) forecast management, and (xiii) requirement planning.

Keywords: Integrated production planning, pharmaceutical plants, resource allocation, decision-support tools.

1. Introduction

The global pharmaceutical industry is now facing unprecedented challenges. Fierce market competition, peaking patent cliffs, mounting R&D costs, shrinking product pipelines and stringent regulatory protocols have brought a complete paradigm shift in the way pharmaceutical enterprises are operated. In addition, the management of global supply chains for such multinational pharmaceutical enterprises is highly complex and vital. Thus, companies are now grappling with an intensive need to optimize their manufacturing operations and improve sustainability by reducing operational costs, optimizing operations, and conserving resources. To remain competitive and economically sustainable, companies seek new and innovative technologies to reduce costs and improve profit margins. In this regard, several studies[1-3] estimated that the possible savings in the manufacturing of pharmaceutical products are in the range of $20 to $50 billion every year.

Unique characteristics of pharmaceutical plants and criticality of effective decision making demands sophisticated support tools for efficient resource allocation and production planning to achieve an optimal plan. The existing software applications such as – advanced planning and scheduling (APS), manufacture resource planning (MRP 2), or the literature models tend to be too generic to satisfy the specific needs and constraints of the pharmaceutical plants. Also, the existing tools and technologies for

the aforementioned planning problem often fall short in evaluating different scenarios and their effect on the overall profit of the plant. In addition, such commercially available tools are difficult to use and require special trainings. They offer less freedom to the planners in altering process parameters or plant configurations. As a result of this, planners in most companies either make ad hoc decisions or tend to use simple spreadsheets[9] for planning that are time consuming (usually, 2 to 3 days for a scenario) and often yield solutions with ample room for improvement.

In this paper, we present a blueprint for a smart production planning and resource allocation tool that addresses the specific needs and constraints of planners and other stakeholders in a pharmaceutical plant. We then present our decision-support tools PlanPerfect and DRplan. Our tools are specifically customized for their application in pharmaceutical plants. PlanPerfect aids decisions pertinent to (i) campaign lengths with number of batches in each campaign, (ii) campaign sequencing and sequence-dependent cleaning and setups, (iii) plant maintenance, (iv) NCEs testing and production, (v) material outsourcing, (vi) resource allocation, (vii) manpower handling, (viii) inventory management, (ix) plant utilization, and (x) waste generation. Also, PlanPerfect allows a planner to choose (add) an appropriate mode (e.g. slow/high throughput mode, vacation mode, etc.) of operation from (to) an in-built list of modes. DRplan facilitates decision making in generating optimal size and numbers of material orders, inventories, forecast management, and requirement planning. In addition to gross profit and minimum cost, which are the most comprehensive planning objective, our tools also allow the planners to choose other planning objectives such as minimum waste, maximum plant utilization, minimum production time, and maximum order fulfillment. Furthermore, they permit the user to explore and evaluate different combinations of variations in plant or process configurations, parameters, demand profiles, and operational constraints using a 'what-if' approach. Specifically, our tools embody a uniquely designed GUI keeping in view the needs of its users and stakeholders, manage a specially structured database, and employ a customized mathematical model to optimize production plans.

2. Motivation and Challenges

The procurement, manufacturing, and distribution process in a global pharmaceutical company is extremely complex. It involves a number of manufacturing stages (active pharmaceutical ingredients, drug formulation and packaging) and distribution configurations. Now, the production stages and configurations require multiple raw materials and a number of other resources (e.g. manpower, utilities, electricity, and equipments), to produce different intermediates / products or to distribute them to the consumers. Usually, the resources involved in the production and the distribution process are both limited and expensive. Thus, an efficient manufacturing / distribution process requires an effective allocation and usage of resources to meet desired targets. For this, the plant management regularly plans resource allocations and schedules process operations in the best interest of the company. The planning of operations and material requirements in a pharmaceutical plant or a distribution house involve a plethora of decisions, usually, for a period of 2 or 3 years. This primarily consists of determining campaign lengths and their sequences, cleaning and set-up times, resource allocation, inventory management, material procurement, maintenance plan, new product introductions (NPIs), waste generation, plant utilization, requirement planning, forecast management, and size and number of orders. Also, the planning activity demands collaboration with different departments[4] (process, maintenance, laboratory, sales, and suppliers) for various inputs such as demands, supplies, resource availability,

and maintenance (Figure 1). As most of the decisions and the related inputs are estimates or forecasts, their values keep changing with time. This requires regular changes and modifications to the existing plan. Given the importance of the planning problem and non-suitability of existing methods to address the specific characteristics, development of effective tools and technologies is critical.

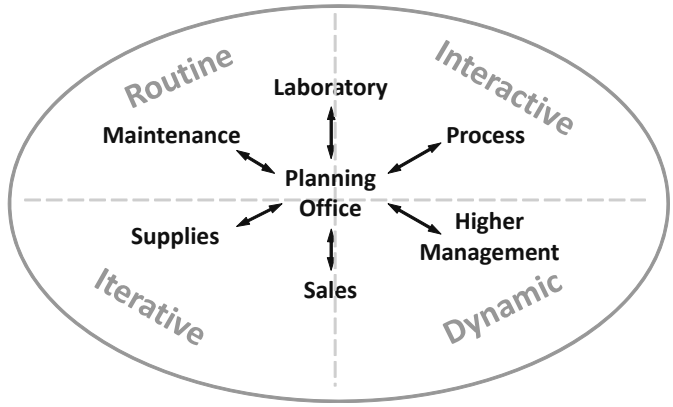

Figure 1. Schematic of collaboratove planning in pharmaceutical plants

3. Decision Support Framework

The key idea here is that the availability and allocation of the limited resources directly affects the productivity of a plant. For instance, as pharmaceutical plant operations are human intense, a limited availability of operators directly affects the number of batches that can be processed. Also, under the limited availability of operators, production of some products can be expedited by allocating sufficient operators at the cost of impeding the production of other products. Clearly, without the consideration of resource allocation and availability, a given plan may either underestimate or overestimate the total production. Typically, plant managers deal with limited resources by making ad-hoc and *in-prompt* decisions. The plant is then operated in a mode different from normal. A mode of operation can then be defined as the plant operating procedure under the limitation of one more resources with a specific resource allocation and usage profile. There can be m (m = 1, 2, …, M) such modes, e.g. low/high throughput mode, vacation mode, lab constrained mode, etc. In the normal mode of operation all resources are assumed to be available in sufficient quantities. Each mode differs from the other because the plant's productivity (number of batches processed/produced in a week/month) is a function of its mode of operation. Clearly, planning models must consider this variation in productivity for generating realistic targets.

$$\text{Plant productivity} = f(\text{mode of production, m}) \quad \text{(a)}$$

To capture the variation in productivity, we consider the knowledge and experience of the planners in modeling productivity for different modes of operation. Stake holders of a plan (planners, process engineers, laboratory officials, maintenance engineers and technicians, etc.) provide important insights of the entire process. Figure 2 represents the framework used to construct our tools.

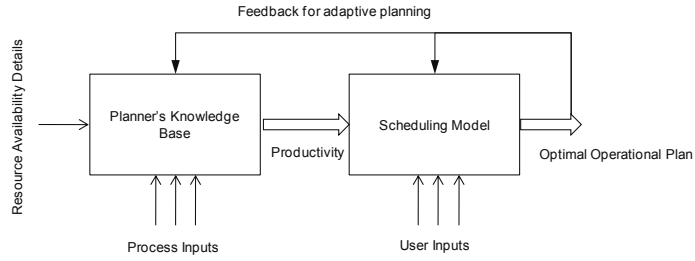

Figure 2. Framework used to construct our tools

Another important aspect is an effective adaptive planning framework to absorb any change in the planning scenario (with respect to resource availability or user inputs), as soon as a new information is available. Thus, a feedback mechanism that evaluates the current plan against the revised scenario and communicates useful information back to the scheduling model is critical.

4. Principal Features: PlanPerfect

The main feature of PlanPerfect is that it is specifically tailored for application to the pharmaceutical plants. Our copyrighted tool is developed in association with a Singapore-based plant of a multi-national pharmaceutical company and has a competitive advantage on intelligence, speed, versatility, cost, and ease-of-use. Given the plant configuration data and planning scenario data, PlanPerfect aides decisions such as campaign scheduling, inventory management, material procurement, cleaning and set-ups, waste generation, and plant utilization. The tool features constraints regarding maintenance planning, new product testing, different modes of operation, and resource allocations that are specific to the pharmaceutical companies. While gross profit may be the most comprehensive planning objective, the tool also allows the planner to specify other planning objectives such as minimum waste, maximum plant utilization, minimum production time, minimum cost, maximum order fulfilment, etc. A key feature of PlanPerfect is its smart GUI (Figure 3), which is based on popular MS Excel spreadsheet. This makes it very easy to use and so, does not require any prior training for its use. The user has a complete freedom in changing various plant parameters and configurations, to generate various scenarios for scenario planning. In addition, the tool embodies a state-of-the-art interactive help feature for quick reference and troubleshooting.

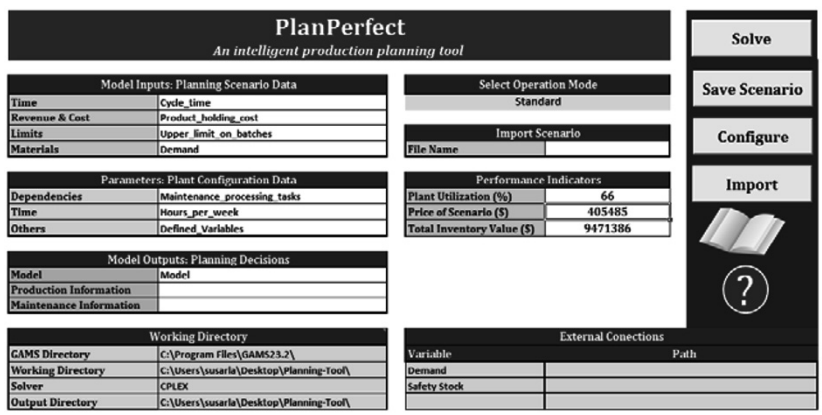

Figure 3. GUI for PlanPerfect

5. Performance Demonstration: PlanPerfect

Here, we consider an active pharmaceutical ingredient manufacturing (API) plant F, involving 10 products with up to 6 stages each and handling around 48 materials. F tests 6 new chemical entities (NCEs), consists 4 shared resources, and incorporates a given maintenance plan. For a planning horizon of 3 years, PlanPerfect gives an optimal plan with an objective value (gross profit) of $405485 and total inventory value of $9471386 within 15 minutes of CPU time. The optimal plan is represented as a gantt chart on a calendar and inventory profiles are generated for each product. Figure 4 shows a part of this solution. We then evaluate 3 different scenarios with limited resources at different mode if operations.

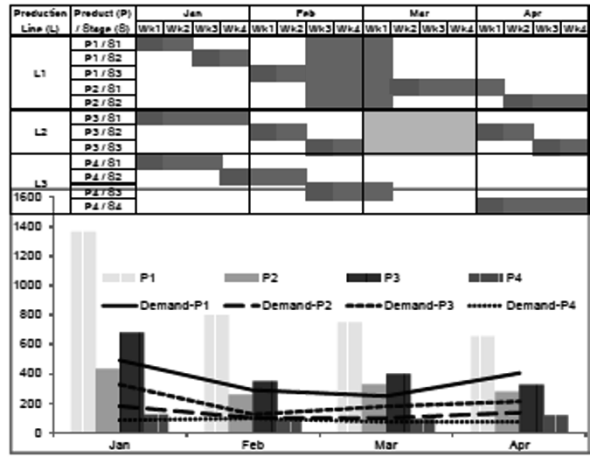

Figure 4 Gantt chart and inventory profiles obtained from PlanPerfect for the optimal solution

6. Conclusion

Resource allocation and operational planning (manufacturing and distribution) are critical for efficient operations of pharmaceutical plants. We successfully presented an intelligent framework for effective and efficient planning tools. Also we explained and demonstrated a smart, holistic, realistic, and use-friendly decision support tool (PlanPerfect) based on such a framework. PlanPerfect is specially designed for application in pharmaceutical plants.

Abstract

Non-incremental reductions in process plant size, cost reduction, safety, environment, and energy are some of the major objectives that currently drive the process industry towards intensifying the existing and future installations. In the present study, direct coupling of methane steam reformer and methanol reactor has been proposed. The synthesis gas produced in reformer was directly fed to methanol reactor skipping secondary reformer and shift convertors. A heterogeneous steam reformer model was developed and embedded with heterogeneous methanol reactor model. The set of differential algebraic equations was solved in MATLAB. Steady state and dynamic simulation results were validated against real plant data. The results showed gradual increase in the methanol mole fraction along the reactor length with a simultaneous decrease in CO and CO_2 levels. Although, the methanol yield achieved through this new reactor scheme remained unchanged, but the reduction in number of equipment and heat integration may help lower operational and capital cost and overall energy demand of the plant.
Keywords: Energy, Methanol, Modeling, Reactor Coupling, Synthesis gas

1. Introduction

Methanol is among few renewables which have the potential to replace or at least minimize dependency on fossil fuels. Commercially, methanol is produced in a three step process; Steam reforming, Methanol conversion, and Product separation. Like every other alternative fuel, the major constraint is end user product cost or market competency in terms of economic benefits. Basini [1] estimated that in most applications of synthesis gas such as methanol, about 60-70% of the cost of the overall process is associated with syngas generation, 20-25% for liquid fuel production and the rest of 5-15% for final product upgrading and purification.

Environmentally benign technical solutions, sustainability, efficient plant design, optimization of process schemes and development of new technologies are only few of the methods that may be adopted to hold decrease in the capital cost of any process in general [2; 3] and methanol in particular McGuire et al. [4]. In the present study, a new scheme is proposed that has the potential to not only save energy but can also help to considerably reduce capital investment. The main objective of this research is to model the novel idea of merging steam reformer and methanol convertor in a way to save on energy and capital investment.

2. Hybrid Reactor Concept

Multifunctional reactors integrate one or more transport processes and reaction systems in a single vessel resulting savings in capital and operational costs. Khademi et al. [5] applied differential evolution method for optimization of methanol synthesis reaction and cyclohexane dehydrogenation in a thermally coupled reactor. Methane Steam Reformer (MSR) was modeled in a parallel plate micro-reactor with alternating channels carrying out reforming and catalytic combustion [6]. Mahajan and Goland [7] integrated methanol synthesis and CO_2 sequestration for application in integrated gasification combined cycle plants. But no work on the integration of steam reformer and methanol reactor is available.

In this study, coupling of MSR and methanol reactor is proposed. The syngas generated from MSR was directly fed to methanol reactor. The difference in temperature of both reactors (~700 K) and the heat content are used to raise high-pressure steam separately. The same may partly be used to preheat reformer feed thus making process more integrated and energy efficient. Secondary reformer and shift convertors that are used to maintain CO to CO_2 ratio were skipped. There can be a number of combinations but as a first step we considered a series arrangement similar to one proposed byHasar [8] for operating two membrane processes. Fig. 1 portrays the concept outlined above. The present work shall be novel in the sense that work of this scope has not been part of any previous study.

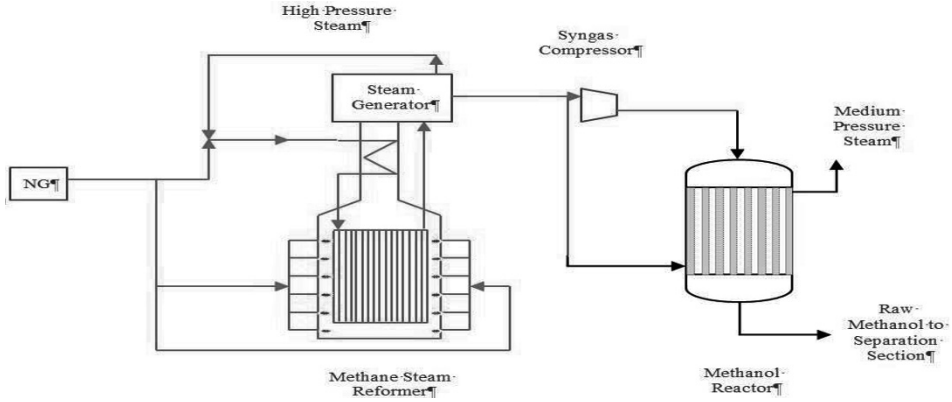

Fig. 1 Schematic of Proposed Reactor

3. Model Development

The following model considers process side of MSR but accounts for outside heat transfer effects. One dimensional plug flow was considered. Axial dispersion of heat, external mass and heat transfer resistances, radial concentration and temperature gradients were neglected.

For fluid phase:

$$\varepsilon_b c_t \frac{\partial y_i}{\partial t} = -c_t \frac{\partial (u y_i)}{\partial z} - K_{g_i} a_V c_t \left(y_i - y_{is}\right) \quad i = 1, 2, ..., N-1 \tag{1}$$

$$\varepsilon_b C_{p_g} c_t \frac{\partial T}{\partial t} = -C_{p_g} c_t \frac{\partial T}{\partial Z} - h a_V \left(T - T_s\right) + \frac{4\pi U_{tube}}{D_{in}} \left(T_{tube} - T\right) \tag{2}$$

For the solid phase:

$$\varepsilon_s c_t \left(1-\varepsilon_b\right)\frac{\partial y_{is}}{\partial t} = K_{g_i} a_V c_t \left(y_i - y_{is}\right) - a\, r_i \eta_i \rho_b \tag{3}$$

$$C_{p_s}\rho_b \frac{\partial T_s}{\partial t} = h a_V \left(T - T_s\right) + \sum_{i=1}^{3}(-\Delta H_r) a\, r_i \eta_i \rho_b \tag{4}$$

Where y_{is} and T_s are the mole fraction and temperature of the catalyst surface; and y_i and T are the mole fraction and temperature of gas phase respectively

The boundary conditions and initial conditions are as follows:

$$\text{At } z = 0\ ;\quad y_i = y_{i_o} \text{ and } T = T_o \tag{5}$$

$$\text{At } t = 0;\ y_i = y_i^s,\ y_{i_s} = y_{i_s}^s,\ T = T^s,\ T_s = T_s^s,\ a=1 \tag{6}$$

Where y_i^s, y_{is}^s are steady state mole fractions, and T_s, T_s^s is temperature of fluid phase and solid phase, respectively.

The kinetic model of Xu and Froment [9] and Catalyst deactivation model presented by Fuentes and Gamas [10] were employed. The output of syngas model comprises of gas composition and temperature both in the fluid and solid phase.

A one-dimensional heterogeneous dynamic model for methanol synthesis was simulated by Zahedi et al. [11] and is used for linking with the developed MSR model. For details of methanol model, reference may please be made to PhD work of Zahedi [12]. The techniques currently in practice for sub model routines in a single program have been adopted and the composition of syngas from MSR was exported to methanol program.

3.1. Numerical Solution

Various expressions used and the model assumptions form a system of differential algebraic equations for the two heterogeneous models. In order to avoid numerical instability [13], the reactor was divided into 50 separate sections and the discrete nonlinear algebraic equations at each section were solved. Partial differential equations were discretized by means of backward finite difference to algebraic and ordinary differential equations for each node of reactor. All of the model equations were implemented in MATLAB (R2010b).

4. Results And Discussions

Composition of natural gas used for the process is obtained from [14] and given in Table 1. Feed enters the reactor at 893 K temperature, 24 barg pressure and steam to carbon ratio 2.78 [15].

Table 1. Natural gas composition

Sr. No.	Component	Composition (mol %)	
		Dry basis	Wet basis
1.	Methane, CH_4	90.00	25.01
2.	Carbon dioxide, CO_2	2.69	0.75
3.	Carbon monoxide, CO	0.80	0.22
4.	Water, H_2O	0.00	72.21
5.	Hydrogen, H_2	3.00	0.83
6.	Nitrogen, N_2	3.51	0.98

Fig. 2 shows a gradual but exponential increase in the concentration of methanol and water in early part of the reactor but show a steady behaviour in the later sections. It was observed that CO conversion to methanol is the major reaction near the exit section of the reactor as it continues to show a decreasing trend. The contributors of carbon show a slow, steady and smooth decline in concentration owing probably to the low reaction rate and that both CO_2 and CO are tied up by shift reaction. The exothermic nature of methanol synthesis reactions causes an increase in temperature in the initial part of the reactor. The sharp rise is then compensated in the later sections of the reactor owing to endothermic nature of shift reaction. The catalyst deactivates at a faster rate during the initial phases of operation. After the fast deactivation phase, the process tends to stabilize itself and the less steep slopes are supportive of this fact.

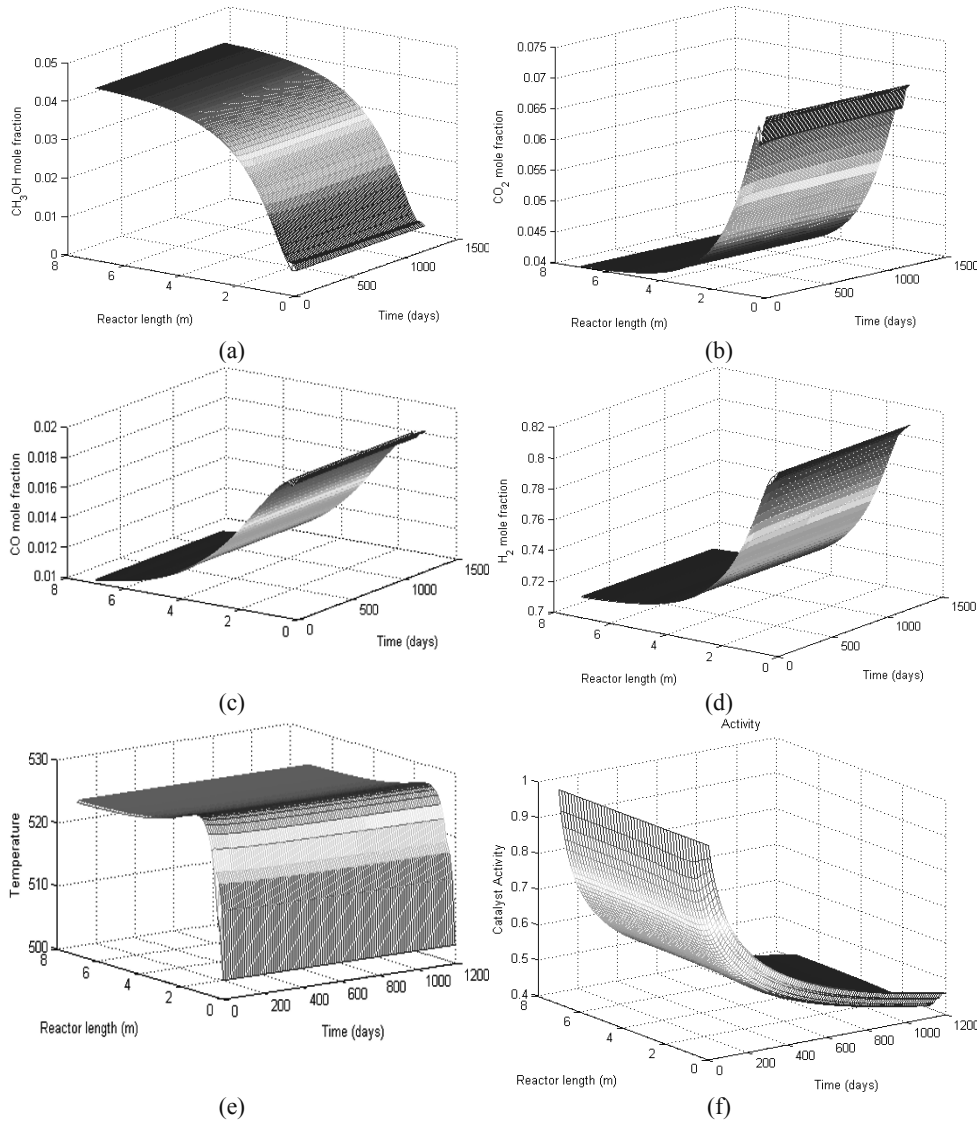

Fig. 2 Dynamic simulation results of MSR and Methanol coupled reactor

The dynamic as well as steady state results obtained from coupling steam reformer and methanol reactor are similar to the results of conventional methanol reactor widely reported in literature [16-20]. No real increase in the production rate of methanol is achieved but our objective to devise an energy efficient reactor is definitely accomplished and at no extra cost. The excess heat from reformer was used to generate high pressure steam that is one of the raw materials of the process, and later for preheating feed gas. By directly coupling the two reactors, many a vessel, equipment, process piping, instrumentation and process control items were skipped without compromising methanol production rate. Heat requirements of secondary reformer and cooling duties were minimized. This not only reduces the operational cost but capital investment as well.

5. Conclusion

A new hybrid reactor was proposed that couples together MSR and methanol reactor. The results of the coupled reactor simulation showed similarity with existing methanol model. The new scheme do not include secondary reformer, shift convertors, and other process equipment that are an integral part of the existing system; hence saving in terms of maintenance and capital cost. The proposed scheme utilizes system heat to produce steam and preheat the reformer feed. Therefore, in this context, the proposed reactor definitely improves the energy efficiency of the plant and may help methanol compete as a potential alternative fuel.

Abstract

The design and operation of crystallization processes pose many challenges, especially where new processes are involved. This work describes the use of model-based approach to efficiently and comprehensively characterize crystallization kinetics (nucleation and growth) from experimental data. The developed and validated model was used to perform exploratory simulation case studies and to optimize the process with respect to the required crystal size. Furthermore, effort to capture hydrodynamic effects for reliable scale-up by linking with computational fluid dynamics (CFD) models will be discussed.

Keywords: Crystallization, Modeling, Parameter estimation, Optimization, Design,

1. Introduction

The purification process in the manufacture of crystal X (the exact chemical name is undisclosed due to confidentiality) in Mitsubishi Chemical Corporation (MCC) is based on crystallization. It is necessary to obtain desired crystal size as it will affect subsequent downstream process. In order to analyze, optimize, and scale-up this process, crystallization modeling is indispensable. Based on lab scale crystallizer data, crystal growth and nucleation kinetics parameters will be estimated. The validated model will subsequently be used to carry out simulation case studies to study the effect of operating conditions on crystal size and to optimize the process. The objective of this article is to illustrate the value that a model-based approach (Bermingham et al., 2000 and Ward et al., 2010) can bring to the development of an industrial crystallization process. gCRYSTAL[1] from PSE Ltd. was used for model development, parameter estimation and optimization.

2. Crystallization Modeling and Experiments

gCRYSTAL employs a population balance approach to represent and describe the evolution of the crystal size distribution resulting from the prevailing crystallization mechanisms and hydrodynamics. The first step is to account for the thermodynamics of the system, in particular the solubility of the solute. The next step is to select appropriate kinetic models to represent the crystallization behavior. Considering the limited experimental data available, it was decided to begin with the simplest crystallization kinetic model or rather the kinetic model with the smallest number of parameters), namely power law model. The employed nucleation and growth kinetic models are:

[1] http://www.psenterprise.com/products/gcrystal/index.html

$$B = k_{n0} M t^m \sigma^n \tag{1}$$

$$G = k_{g0} \exp\left(\frac{-E_{ag}}{RT}\right)\sigma^g \tag{2}$$

$$\sigma = \frac{C - C_{eq}}{C_{eq}} \tag{3}$$

Where, B is the secondary nucleation rate, G is the growth rate, and σ is the relative super-saturation. There are 6 parameters (k_{n0}, k_{g0}, m, n, g, and E_{ag}) that need to be fitted from experimental data.

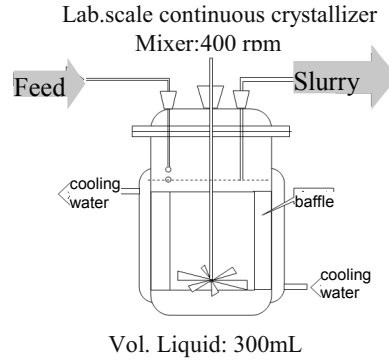

Figure 1. Lab scale experimental setup.

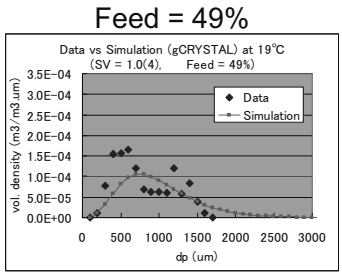
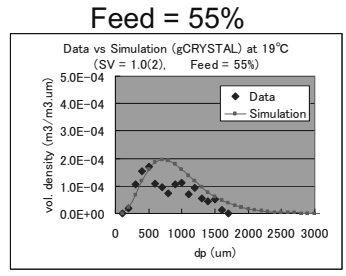
The experimental setup is shown in Figure 1. Crystal size distribution and slurry density data were measured at steady state. Operating conditions varied from one experiments to another include the crystallizer temperature, residence time, and feed concentrations. In addition to crystallization kinetics, solubility data (which were obtained in other experiments not mentioned here) are also necessary.

3. Parameter Fitting and Model Validation

gCRYSTAL's built-in parameter estimation capability was used to estimate the crystallization kinetic parameters described in the previous section. Parameter fitting results showing the effect of residence time and feed concentration are depicted in Figure 2.

τ =2hr	τ =1hr
	(a)	(b)





(c) (d)

Figure 2. Parameter fitting results.

PSD measurements used for parameter estimation are the dp_{25}, dp_{50}, dp_{75}. Comparisons with experimental data show that the developed model is able to represent effect of operating conditions under study. The biggest deviation of median crystal size (dp_{50}) between data and simulation is 100 μ m. This is acceptable because it is within the range of experimental error.

4. Process Simulations and Simple Optimization

Simulation results showing the effect of slurry concentration and crystallization temperature on median crystal size is given in Figure 3. Based on these results, the largest crystal size could be obtained under higher temperature and lower slurry concentration (i.e. maintaining high crystal growth rate, while suppressing nucleation rate). However, this condition will result in low crystal yield and therefore knowledge of optimum operating conditions is necessary.

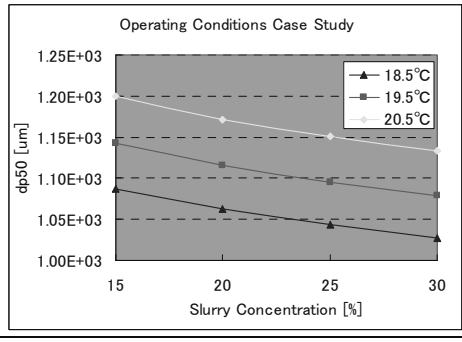


Figure 3. Process simulation results.

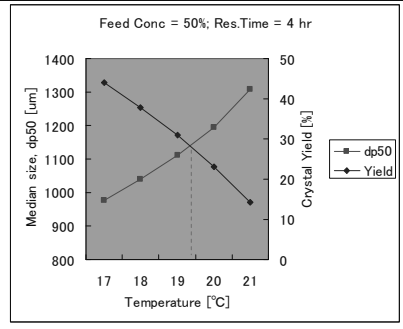

Figure 4. Simple optimization of operating conditions.

The relationships between temperature, median crystal size, and crystal yield are shown in Figure 4. It is obvious from this result that a higher temperature could lead to a bigger crystal size, but at the same time lower yield. Since a median crystal size of around 1100 μ m is desired, crystal yield of around 30% can be obtained by setting the crystallizer temperature to around 19.5℃.

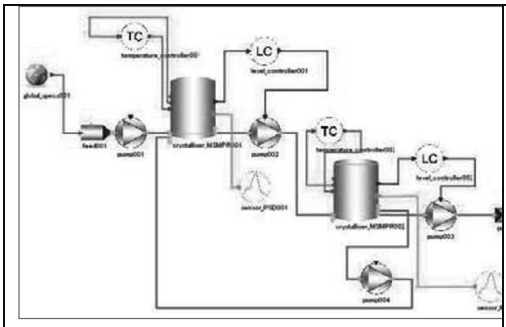

Figure 5. gCRYSTAL flowsheet of 2-stage crystallization process.

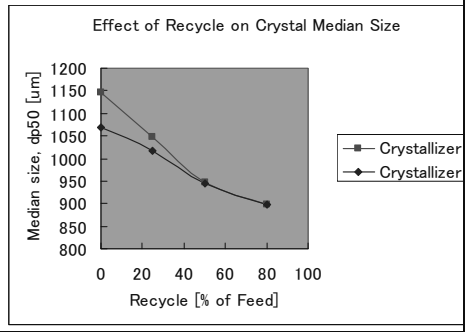

Figure 6. Median size in the first and second crystallizer as a function of recycle rate.

A two-stage crystallization process is also being investigated (Figure 5). This introduces several degrees of freedom that can be used to optimize the process, such as operating temperature of the first crystallizer, the volume of the two crystallizer stages and the recycle policy. Here we illustrate the impact of the recycle rate on the median particle size in the two stages (Figure 6). The bigger the recycle rate, the smaller the crystal size. Based on the simulation results presented here, the second stage does not seem appropriate as the median size without recycle is already less than the desired 1100 μ m . However, the use of a recycle has the advantage of lower growth rates, which may be of importance for product purity.

5. Combining hydrodynamics and crystallization kinetics for scale-up

The validated will subsequently be combined with flow information from a CFD model to construct a so-called Multizonal model (Urban and Liberis, 1999; Bezzo et al., 2004) as shown in the figure below. This multizonal modelling approach allows prediction of local nucleation and growth rates by separating macroscopic hydrodynamics and intrinsic kinetics.

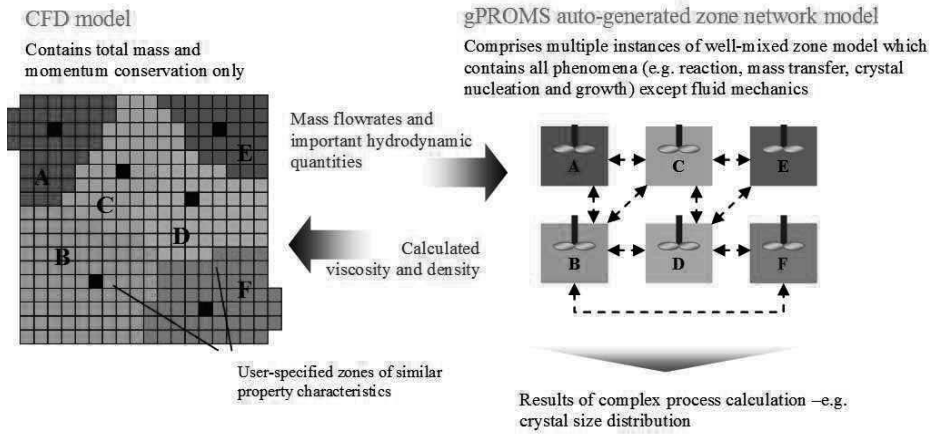

Figure 7. Multizonal interface approach.

In addition, gravity induced particle segregation can be captured by classification functions acting upon the flow rates between the zones. This phenomenon only needs

to be considered when there is a significant density difference between the liquid and solid phase and when the particles in the system are sufficiently large.

6. Concluding Remarks

The application of gCRYSTAL in characterizing crystallization kinetics (nucleation and growth) from experimental data has been demonstrated. Our procedure is summarized by the workflow shown in Figure 8. gCRYSTAL is a very useful tool in most of the crystallization development stages. Instead of performing simulation and optimization of single crystallizer, we will use the model to simulate a whole purification process flowsheet. Furthermore, scale-up investigations based on the hybrid CFD-gCRYSTAL model will also be applied. Efforts in these directions are currently underway.

A new graphical representation of exergy applied to low temperature process design

Danahe Marmolejo-Correa[a], Truls Gundersen[a]

[a]*Department of Energy and Process Engineering, Norwegian University of Science and Technology, Kolbjoern Hejes vei 1B; Trondheim NO-7491, Norway*

Abstract

The paper introduces a novel representation of exergy as well as its application in low temperature process design. This thermodynamic diagram uses a new energy quality parameter called *exergetic temperature* that is also introduced. Processes operating below ambient temperature commonly require the use of refrigeration and therefore compression work. Low temperature cooling corresponds to large requirements of compression work. The novel representation can be used in parallel with the Extended Pinch Analysis and Design (ExPAnD) methodology which uses pressure as an important design variable for networks with heat exchange, compression and expansion.

Keywords: Subambient processes, pinch analysis, exergy analysis, process integration

1. Introduction

The combination of Exergy Analysis (EA) and Pinch Analysis (PA) for the design of Heat Recovery Systems (HRSs) is not a new idea. The traditional PA is characterized by two graphical representations, Composite Curves (CCs) and the Grand Composite Curve (GCC) (Linnhoff et al., 1982) that show the minimum energy requirements for a given HRS. The CCs show the temperature profiles of energy sources (hot curve) and energy sinks (cold curve). However, traditional PA only uses temperature as a design variable and thereby ignoring the possibility to integrate the heat generated in compression or the cooling obtained in expansion. Exergy Analysis, on the other hand, uses temperature, pressure and composition to calculate the energy quality (exergy) of a material stream. A new methodology developed in our research group called ExPAnD (Extended Pinch Analysis and Design) is based on utilizing the heating and cooling generated by changing the pressure of the streams for reducing or eliminating the heat and power requirements (Aspelund et al., 2007). The traditional Composite Curves (*T-H* diagram) were used for illustrating the changes made to the HRS during the stages of the methodology. ExPAnD was applied for developing a novel natural gas liquefaction process for offshore applications (Aspelund and Gundersen, 2009).
The main objective of this paper is to introduce an alternative diagram for representing the exergy transfer in HRSs that can be used in parallel with the ExPAnD method. This diagram will then be applied in an illustrative example of an HRS operating below ambient temperature (T_0) where both temperature and pressure of the streams change.

2. Exergy of material streams

The total exergy of a material stream is equal to the sum of its kinetic, potential, chemical and thermo-mechanical exergies. For streams in an HRS, kinetic and potential exergies can be neglected (do not change much), while chemical exergy can be omitted (no change in composition since there is no reaction, mixing or separation). Thus in an

HRS, the thermo-mechanical exergy is the only one that is transferred. The thermo-mechanical exergy $\dot{E}^{TM}$ of a material stream at temperature T and pressure p relative to ambient conditions (T_0, p_0) is calculated by Eq. (1). The thermo-mechanical exergy can be decomposed into temperature based exergy $\dot{E}^{T}$ and pressure based exergy $\dot{E}^{p}$.

$$\begin{aligned}
\dot{E}^{TM}(T,p) &= \dot{H}(T,p) - \dot{H}(T_0,p_0) - T_0\left[\dot{S}(T,p) - \dot{S}(T_0,p_0)\right] \\
\dot{E}^{T}(T,p) &= \dot{H}(T,p) - \dot{H}(T_0,p) - T_0\left[\dot{S}(T,p) - \dot{S}(T_0,p)\right] \\
\dot{E}^{p}(T,p) &= \dot{H}(T_0,p) - \dot{H}(T_0,p_0) - T_0\left[\dot{S}(T_0,p) - \dot{S}(T_0,p_0)\right]
\end{aligned} \tag{1}$$

This decomposition is not unique and has no fundamental meaning; however, it is commonly accepted despite its inherent arbitrariness. Normally, this decomposition is used for better understanding of temperature and pressure based exergy contributions in processes when one exergy component is transformed into the other (i. e. processes below ambient temperature). Marmolejo-Correa and Gundersen (2011) among other authors have shown this decomposition in an Exergy-Enthalpy thermodynamic diagram. It is worth mentioning that $\dot{E}^{T}$ is positive in the complete temperature range and that its rate of change below T_0 is steeper (asymptotic to 0 K) than above. Thus, process streams that are initially at T_0 require more exergy for taking them below T_0 than above.

3. Exergetic Temperatures

The relationships between the exergy of material streams and their pressure and temperature are non-linear, and therefore not easily visualized. Thus, a specific heat capacity relation in terms of temperature and pressure for $\dot{E}^{T}$ and $\dot{E}^{p}$, and an equation of state for $\dot{E}^{p}$ are needed. If constant specific heat capacities and ideal gas conditions are assumed, then the exergy components can be rewritten as in Eq. (2)

$$\begin{aligned}
\dot{E}^{T} &= \dot{m}c_p\left[T_0\left(\frac{T}{T_0} - \ln\frac{T}{T_0} - 1\right)\right] = \dot{m}c_p T^{E^T} \\
\dot{E}^{p} &= \dot{m}c_p\left[T_0 \ln\left(\frac{p}{p_0}\right)^{\frac{\kappa-1}{\kappa}}\right] = \dot{m}c_p T^{\dot{E}^p}
\end{aligned} \tag{2}$$

The factors enclosed in brackets for both exergy components (Eq. (2)) are called the *exergetic temperatures*. These exergetic temperatures are: (*i*) in a linear relation with exergy; (*ii*) alternative energy quality parameters, and (*iii*) in absolute temperature units (K). In addition, notice that T^{E^p} is intimately related to T^{E^T} i. e. any change in the stream pressure results in a change in temperature. It is possible to take advantage of this to reduce external heating and cooling requirements. For instance, consider a stream with an initial condition (T_s, p_s) that needs to be heated and compressed to (T_t, p_t). If the compression is done first in an isentropic compressor ($\Delta S = 0$), the change in $\dot{E}^{p}$ is given by Eq. (3). After the compression, the stream has raised its pressure and without using any external heating also its temperature, thus the heating requirement has been reduced. The change in temperature based exergy in an isentropic device is given by Eq.

(3). A simple relation between the changes of the two exergetic temperatures (T^{E^T} and T^{E^p}) is also provided in Eq. (3). It is important to mention that the isentropic work $\left(-W_{\Delta s=0} = \dot{m} c_p \left(T_{\Delta s=0} - T_s\right)\right)$ consumed or obtained by manipulating stream pressure depends only on the pressure ratio and the device inlet temperature.

$$\Delta \dot{E}^p_{\Delta s=0} = \dot{m} c_p T_0 \left[\ln\left(\frac{T_{\Delta s=0}}{T_s}\right)\right]$$
$$\Delta \dot{E}^T_{\Delta s=0} = \dot{m} c_p \left[\left(T_{\Delta s=0} - T_s\right) - T_0 \ln\left(\frac{T_{\Delta s=0}}{T_s}\right)\right] \rightarrow \Delta T^{E^T}_{\Delta s=0} = \Delta T_{\Delta s=0} - \Delta T^{E^p}_{\Delta s=0} \quad (3)$$

Notice that for this simple example, the process was divided into two parts: the compression part and the heating part. Depending on at what operating condition the compression is made, the heating requirement can be reduced, and this is exactly where the heuristic rules proposed by the ExPAnD methodology are utilized.

4. New graphical representation of exergy

By only using the supply and target temperatures, the proposed diagram plots exergy sources and exergy sinks as linear composite curves in a $T^{E^T} - \dot{E}^T$ diagram as illustrated in Figs. 1*a* and 1*b*. This means that the new diagram does not require multiple calculations and the exergy targets are explicitly shown. This is in contrast to previous graphical representations of exergy for HRSs such as the Exergy Composite Curves (ECCs) (Linnhoff and Dhole, 1992). For HRSs above T_0, the exergy sources are the hot streams and the exergy sinks are the cold streams while for HRSs below T_0, the cold streams are the exergy sources and the hot streams are the exergy sinks, thus exergy and heat flows have opposite directions below T_0.

Some characteristics of the new diagram are: (*i*): The minimum value of T^{E^T} (zero) is at ambient temperature. Thus, T^{E^T} is positive for the complete temperature range, in contrast with the ECCs where the Carnot factor is negative below T_0. The state with the highest exergy is always placed at the top of the curves while the lowest (closest to T_0) is at the bottom. For streams below T_0, the coldest temperature is the largest *exergetic temperature*. (*ii*): If the minimum temperature approach (ΔT_{min}) between CCs is set, a corresponding exergetic temperature approach ($\Delta T^{E^T}_{min}$) is also obtained. Then, the exergy deficit and surplus are calculated from the exergy cascade by only using the stream data, similar to how minimum external heating and cooling are obtained from the traditional heat cascade. Since exergy destruction is related to heat transfer, it does not influence the exergy deficit and surplus figures. These are based on stream temperatures only. The *heat* and *exergy* pinch points are placed in corresponding enthalpy and exergy intervals, thus if the pinch rules are followed, then exergy is neither imported below nor exported above the *exergy* pinch, and exergy is not transferred across this pinch. (iii): Exergy destruction is graphically shown by transforming the boundary temperatures of the overlapping region obtained in *the traditional CCs* into exergetic temperatures (squares and circles in Figs. 1*a* and 1*b*). (*iv*): The maximum exergy recovery for a given ΔT_{min} is the maximum amount of exergy that the exergy sink curve can accept in the overlapping region, and the minimum process-to-process exergy destruction is the

difference between the process-to-process exergy transferred from the exergy source curve and the maximum exergy recovered by the sink curve. The calculation of exergy targets is given by Eq. (4). Notice that while exergy destruction increases the exergy requirements above *exergy* pinch, it reduces exergy rejection below *exergy* pinch.

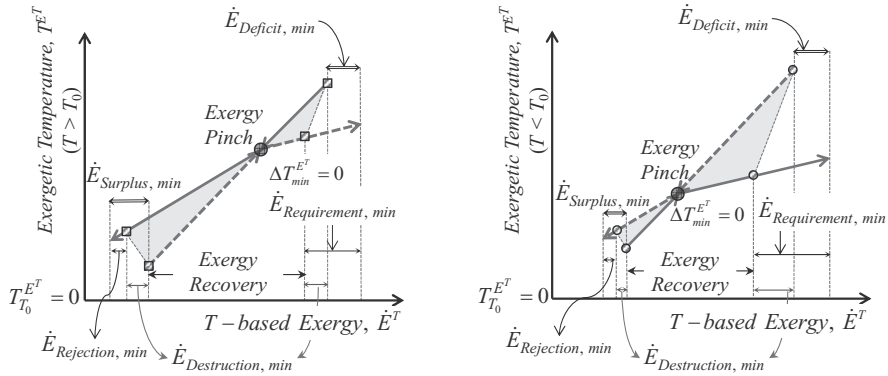

Fig. 1 $T^{E^T} - \dot{E}^T$ diagram (*a*) above T_0 and (*b*) below T_0

$$\text{Above exergy pinch: } \dot{E}_{Requirement,\,min} = \dot{E}_{Deficit,\,min} + \dot{E}_{Destruction,\,min}$$
$$\text{Below exergy pinch: } \dot{E}_{Rejection,\,min} = \dot{E}_{Surplus,\,min} - \dot{E}_{Destruction,\,min} \quad (4)$$

5. Illustrative example of using the new diagram

Table 1 shows the stream data for an HRS that operates entirely below T_0. C1and C2 are cold streams and H1 and H2 are hot streams. C1 and H1 are to be expanded and C2 should be compressed. The heat capacity flow rates (kW/K) are 0.325 for C1, 0.185 for H1, and 0.35 for C2 and H2. The specific heat ratios (κ) are 1.41 for C1 and C2, and 1.30 for H1 and H2. The ambient conditions are assumed to be 15°C and 1 bar.

Table 1 Stream data: T_s, $T_t[=]°C$, p_s, $p_t[=]bar$, $T_s^{E^T}$, $T_t^{E^T}[=]K$ and $\Delta\dot{E}_{T_s\to T_t}^T, \Delta\dot{E}_{p_s\to p_t}^p[=]kW$

	T_s	T_t	p_s	p_t	$T_s^{E^T}$	$T_t^{E^T}$	$\Delta\dot{E}_{T_s\to T_t}^T$	$\Delta\dot{E}_{p_s\to p_t}^p$
C1	-173.15	-43.15	7.00	2.50	160.80	6.80	-35.75	-27.55
C2	-83.15	6.85	1.20	3.00	21.85	0.12	-7.61	26.40
H1	6.85	-123.15	4.50	2.00	0.12	49.97	9.22	-9.98
H2	-23.15	-158.15	1.20	1.20	2.77	91.53	31.06	0.00

Eq. (2) is used for calculating T^{E^T} for supply and target temperatures and the change in exergy components ($\Delta\dot{E}_{T_s\to T_t}^T$, $\Delta\dot{E}_{p_s\to p_t}^p$). Notice that (*i*) the largest T^{E^T} corresponds to the lowest temperature and vice versa, (*ii*) $\Delta\dot{E}_{T_s\to T_t}^T$ is negative for cold streams (exergy sources) and positive for hot streams (exergy sinks), (*iii*) for C1 and H1, $\Delta\dot{E}_{p_s\to p_t}^p$ is negative (exergy sources) and this exergy is transformed into temperature based exergy and shaft work, and (*iv*) for C2, both shaft work and part of the temperature based

exergy are consumed (exergy sources), producing a positive $\Delta \dot{E}^{p}_{p_s \to p_t}$ (exergy sink) (Marmolejo-Correa and Gundersen, 2011). Fig. 2*a* shows the $T^{E^T} - \dot{E}^T$ diagram before changing the pressures. The minimum hot and cold utilities are 6.85 kW (cooling water) and 4.40 kW (refrigeration) for a theoretical ΔT_{min} of 0 K. The *heat* pinch is at -83.15°C. Notice that the *exergy* pinch (21.85 K) corresponds to the *heat* pinch temperature. The theoretical minimum process-to-process exergy destruction (ΔT_{min} of 0 K) is 7.99 kW. In this example, the exergy requirement is smaller than the destruction (exergy surplus prior to destruction). If ΔT_{min} is specified and heat (and exergy) is not transferred across pinch, then the process-to-process exergy destruction is fixed. For HRSs below T_0, exergy destruction can be considerable; even larger than the exergy requirement. Fig. 2*b* illustrates a non-optimized but improved solution where the exergy requirement (refrigeration or cold utility) is eliminated and the total exergy destruction is reduced by 30%. However, hot utility (cooling water) has increased from 6.85 to 10.12 kW. This was achieved by using the ExPAnD method and manipulating the stream pressures.

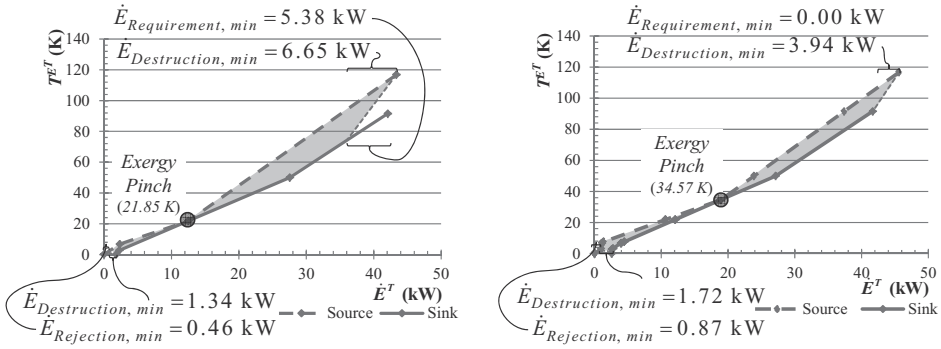

Fig. 2 $T^{E^T} - \dot{E}^T$ diagram (*a*) before pressure manipulation and (*b*) after pressure manipulation

6. Remarks

In this paper, a new diagram for exergy targeting is introduced that uses a novel energy quality parameter called *exergetic temperature*, thereby making the plots linear to reduce computational efforts, while exergy targets are obtained directly. This new thermodynamic diagram and the exergetic temperature are illustrated with an example.

Model based optimal reactor design applied to a free radical polymerization process

P. Klimantos*, and M. Hillestad
Department of Chemical Engineering; NTNU; Trondheim, Norway

Abstract

A computational framework is presented for model based optimal design of chemical reactors and applied to a multistage ethylene polymerization process. Design alternatives are generated on the basis of a state space composite model, accounting for fluid mixing, heat transfer, multiple and distributed feeds, initiator efficiency and others. A free radical polymerization kinetic mechanism is superimposed into the framework to describe the molecular and morphological polymer properties.The complexity of the kinetic mechanism due to the associated infinite dimensional population balance model (large stiff system of ODEs) is reduced by applying a continues variable approximation scheme over the discrete chain length domain. Finally an optimization problem is formulated by discretizing the resulting differential algebraic equation (DAE) system into an NLP model by applying a complete parametrization (CP) technique. Optimal reactor designs and operating modes are identified that minimize an objective function subject to technical and product quality constraints.

Keywords: reactor design, optimization, free-radical mechanism

1. Indroduction

A broad range of methods for process design appears in the literature which can be classified based on the chosen strategy for representing the design alternatives or the design space. In the field of reactor design the methods that have made considerable contributions can be classified into attainable region methods or targeting, and optimisation methods involving either construction of superstructures that are formulated as MINLP problems or state space design representation that exploit analogies from dynamic optimization techniques. Attainable region methods is a representation of the attainable concentration space when reaction and mixing take place and its theoretical framework has been extensively further by Hildebrandt and Glasser (1990). Given a chemical reaction, the method constructs graphically the consecration space based on the fact the all points in its boundaries are represented by the convex hull of combination of ideal reactor (PFR and CSTR) trajectories. The constructed convex hull contains the entire attainable region in the concentration space and given the reaction kinetics one can predict upper bounds of the performance of reaction system. The attainable region can be considered as a fundamental contribution in the area of reactor design since it provides critical insights into the properties of reaction and mixing. However, the applicability of the method has some limitations inherently imposed by the graphical approach considered restricting the designer to analyse problems in two or three dimensions. Superstructure approaches were developed by several authors , Achenie and Biegler (1986) formulated the reactor synthesis problem as a NLP optimisation problem with split fractions, source

*paris.klimantos@.ntnu.no

points and sink points that determine the mixing pattern, this network has been extended also to non isothermal reactors. Kokossis and A. (1990) proposed a reactor representation that utilizes as a basis the continuous stirred tank reactor (CSTR) and approximates the plug flow reactor as a cascade of CSTRs. A reactor network superstructure is presented in which all possible structural configurations of interconnected reactors are embedded. The combinatorial nature of the MINLP superstructure formulations result in a computational intractable problems and most of the aforementioned contributions focused on developing efficient optimisation algorithms and less focus has been given to the practical implementation in real industrial applications.

An alternative formulation for reactor design, based on the model of Hillestad (2010), is presented in this contribution. The main idea is to represent basic operation such a reaction, fluid mixing and heat transfer, through a continues state space model describing a reaction path. A fluid element is tracked along a reaction path and optimal conditions are generated that satisfy a design objective subject to process and product quality constraints. We investigate the proposed formulation for the design of LDPE (low density polyethylene) reactors, a rather complex reactive system of industrial interest.

2. Model Formulation

2.1. Reactor Model

A general state space reactor model accounting for fluid mixing, feed distribution and heat transfer is presented. Consider a fluid mixture of N species S_n described as the $n-$dimensional composition vector $\mathbf{c}^T = \begin{bmatrix} c_1, & \dots & c_n \end{bmatrix}$ of molar concentrations. Any change in composition due to occurrence of chemical reactions can be characterized through a predescribed set of reaction kinetics and denote $\mathbf{R}(\mathbf{c}) = \begin{bmatrix} R_1(\mathbf{c}), \dots, R_n(\mathbf{c}) \end{bmatrix}$ the vector of species molar formation rates $R_i(\mathbf{c})$ per unit volume, usually expressed as the stoichiometric mapping of the species reaction rates [1]. We describe variations in composition due to reaction, mixing and heat transfer through the well known equations describing ideal plug flow volumes (PFR) and perfectly mixed volumes (CSTR), expressed as a function of space time $\tau = \frac{V_R}{F_{v,0}}$. By expressing the well known CSTR component mole balance and temperature equations in a differential form a composite model describing both completely mixed and plug flows models is derived:

$$
\begin{aligned}
&\frac{dc_i}{d\tau} = R_i(\mathbf{c}) + \tau \frac{dR_i(\mathbf{c})}{d\tau} = R_i(\mathbf{c}) + \tau \sum_{k=1}^{n} \frac{\partial R_i(\mathbf{c})}{\partial c_k} \frac{dc_k}{d\tau} \implies \\
&\frac{dc_i}{d\tau} - \tau \sum_{k=1}^{n} \frac{\partial R_i(\mathbf{c})}{\partial c_k} \frac{dc_k}{d\tau} = R_i(\mathbf{c}) \implies \\
&\frac{dc_i}{d\xi}(1 - \xi \tau_R \frac{\partial R_i(\mathbf{c})}{\partial c_i}) - \xi \tau_R \sum_{\substack{k=1 \\ k \neq i}}^{n} \frac{\partial R_i(\mathbf{c})}{\partial c_k} \frac{dc_k}{d\xi} = \tau_R R_i(\mathbf{c})
\end{aligned} \tag{1}
$$

[1] For a set of m reactions and n species $\mathbf{R}(\mathbf{c}) = \nu^{\mathbf{T}} \mathbf{r}(\mathbf{c})$, ν is the $n \times m$ stoichiometric matrix and $\mathbf{r}(\mathbf{c})$ the $m-$dimensional vector of reaction rates

The final form of Eq.(6) is derived by introducing the dimensionless space time $\xi = \frac{\tau}{\tau_R}$. Based on Eqs. 5 we can writte the mole balance for the n species in a matrix form:

$$\left(\begin{bmatrix} 1 & 0 & \cdots & 0 \\ 0 & 1 & \cdots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \cdots & 1 \end{bmatrix} - \xi \tau_R \begin{bmatrix} \frac{\partial R_1(\mathbf{c})}{\partial c_1} & \frac{\partial R_1(\mathbf{c})}{\partial c_2} & \cdots & \frac{\partial R_1(\mathbf{c})}{\partial c_n} & \frac{\partial R_1(\mathbf{c})}{\partial \vartheta} \\ \frac{\partial R_2(\mathbf{c})}{\partial c_1} & \frac{\partial R_2(\mathbf{c})}{\partial c_2} & \cdots & \frac{\partial R_2(\mathbf{c})}{\partial c_n} & \frac{\partial R_2(\mathbf{c})}{\partial \vartheta} \\ \vdots & \vdots & \ddots & \vdots & \vdots \\ \frac{\partial R_n(\mathbf{c})}{\partial c_1} & \frac{\partial R_n(\mathbf{c})}{\partial c_2} & \cdots & \frac{\partial R_n(\mathbf{c})}{\partial c_n} & \frac{\partial R_n(\mathbf{c})}{\partial \vartheta} \end{bmatrix} \right) \begin{bmatrix} \frac{dc_1}{d\xi} \\ \frac{dc_2}{d\xi} \\ \vdots \\ \frac{dc_n}{d\xi} \end{bmatrix} = \tau_R \mathbf{R}(\mathbf{c})$$

$$\Longrightarrow \frac{d\mathbf{c}}{d\xi} = (\mathbf{I} - \xi \tau_R \mathbf{J})^{-1} \tau_R \mathbf{R}(\mathbf{c}) \tag{2}$$

Following the same procedure for the heat balance equation of a complete mixed volume dV, Eq. 5 is transformed to a similar format with Eqs. 6:

$$\frac{d\vartheta}{d\xi} = \tau_R \big(1 - \xi \tau_R (\frac{\partial R_T(\mathbf{c})}{\partial \mathbf{c}} \frac{d\mathbf{c}}{d\xi} - N_{st} \frac{dA}{d\xi})\big)^{-1} (R_T - N_{st} \frac{dA}{d\xi} (\vartheta - \vartheta_c) \tag{3}$$

with $R_T = \frac{-\Delta \mathbf{H^T r(c)}}{\rho c_p}$. Eqs (6) and (7) consist an intital value problem with initial values $\mathbf{y}_{\xi=0} = \mathbf{y}_o$ and $\vartheta_{\xi=0} = \vartheta_o$. The abovementioned reactor model formulation exhibits an interesting property equivalent to that of the one-dimensional axial dispersion model where convective mixing effects are lumped in one parameter the dispersion coefficient. By introducing the function $u_M(\xi)$ we observe that when $u_M \to 0$, Eq. (8) and (9) is reduced to the plug flow model reactor while integrating Eqs (8) and letting the function u_M to increase proportionally with the space time we obtain the compositional and temperature variations of completely mixed volumes with respect to the reactor space time. Any intermediate slope of u_M can be interpreted as a flow with a equivalent degree of dispersion. Feed distribution is introduced through the design function u_F wich is a function of the volume fractions of the added feeds. This additions is equivalent with the notion of the differential side stream reactor DSR, Feinberg and Hildebrandt (1997), and have been considered in various related studies. The final mixing model allows one to represent simultaneously the three main ideal reactors PFR, CSTR and DSR, a desirable task for the process engineer at the early stages of the design. In addition parameterization of the heat transfer area distribution along the reactor coordinate is introduced by defining the desing function $u_H = N_{st} \frac{dA}{d\xi}$. The final form of equations take the following form:

$$\frac{d\mathbf{c}}{d\xi} = (\mathbf{I} - u_M \tau_R \mathbf{J})^{-1} \tau_R \mathbf{R}(\mathbf{c}) + u_F (\mathbf{c} - \mathbf{c}_F) \tag{4}$$

$$\frac{d\vartheta}{d\xi} = \tau_R \big(1 - \xi \tau_R (\frac{\partial\, R_T(\mathbf{c})}{\partial \mathbf{c}} \frac{d\mathbf{c}}{d\xi} - u_H)\big)^{-1} (R_T - u_H(\vartheta - \vartheta_c) + u_F(\vartheta - \theta_F) \tag{5}$$

The reactor design problem is addressed by solving an optimal control problem in the following form :

$$\min_{\mathbf{u}} J \tag{6}$$

s.t.

$$\frac{\mathrm{d}\mathbf{z}}{\mathrm{d}\xi} = \mathbf{f}(\mathbf{z}, \mathbf{u}), \quad \mathbf{z}(0) = \mathbf{z}_0 \tag{7}$$

$$\mathbf{h}(\mathbf{z}, \mathbf{u}) \leq 0 \tag{8}$$

$$lb \leq \mathbf{u} \leq ub \tag{9}$$

Table 1: General Free Radical Homopolymerization Mechanism

Initiation	Chain Transfer to Polymer
$I \xrightarrow{k_d} 2P^*$	$P_p + D_y \xrightarrow{k_{TP}} P_y + D_p$
Chain Initiation Reactions	Termination by Disproportionation
$P^* + M_1 \xrightarrow{k_I} P_1$	$R_n + P_y \xrightarrow{k_{TD}} D_n + D_y$
Propagation Reactions	Termination by combination
$P_n + M_1 \xrightarrow{k_P} P_{n+1}$	$P_n + P_y \xrightarrow{k_{TC}} D_{n+y}$
Chain Transfer to Monomer	Intramolecular Transfer
$P_n + M_1 \xrightarrow{k_{TM}} P_1 + D_n$	$P_n \xrightarrow{k_b} P_n$
Chain Transfer to Solvent	β-scission
$P_n + S \xrightarrow{k_{TS}} P_1 + D_n$	$P_p \xrightarrow{k_{\beta'}, k_{\beta''}} D_{n-y} + P_y$

The new state vector is the vector of molar concentration augmented with the temperature $\mathbf{z} = [\mathbf{c}^T, \vartheta]$ and the model consists of the ordinary differential equations (8) and (9). Thus the proposed model formulation with the parameterized design functions along the reactor coordinate represents a reactor network consisting of a series of CSTR , PFR or DSR volume elements. Process and product design constraints are represented as non -linear inequality constraints on the state variables.

3. Reaction mechanism

3.1. Net formation Rates

Ethylene polymerization is initiated by the generation of free radicals through the decomposition of a thermal initiator and proceed through a mechanism involving, propagation, termination, and transfer reactions. A general accepted mechanism involves the reactions as depicted in Table 1. The net formation rates of the polymer radicals (P_n) and dead polymer chain (D_n) are:

$$\begin{aligned} R_{Pn} = {} & \delta(n-1)\left\{2fk_dI + (k_{tm}M + k_{ts}S)\sum_{m=1}^{\infty} P_m\right\} \\ & + k_pM(P_{n-1} - P_n) \\ & - \left\{k_{tm}M + k_{ts}S + (k_{tc} + k_{td})\sum_{m=1}^{\infty} P_m + k_\beta \sum_{m=1}^{\infty} mD_m\right\} P_n \\ & + k_{tp}nD_n \sum_{m=1}^{\infty} P_m - k_{tp}P_n \sum_{m=1}^{\infty} mD_m \end{aligned} \tag{10}$$

$$\begin{aligned} R_{Dn} = {} & \left\{k_{tm}M + k_{ts}S + k_{tp}\sum_{m=1}^{\infty} mD_m + k_{td}\sum_{m=1}^{\infty} P_m + k_\beta \sum_{m=1}^{\infty} mD_m\right\} P_n \\ & - k_{tp}nD_n \sum_{m=1}^{\infty} P_m + \frac{1}{2}k_{tc}\sum_{m=1}^{n-1} P_mP_{n-m} - k_\beta D_n \sum_{m=1}^{\infty} P_n \end{aligned} \tag{11}$$

The Kronecker delta function accounts for the generation of new radicals and the terms used for transfer to polymer assume that the propabiliy chain trasfered to a cetrain polymer chain D_n is proportional to the chain length n.

3.2. Continues Variable Approximation

The solutions of equations (14) and (15) which are of infinite dimension in the chain length represents the full molecular weight distribution (MWD). Several reduction techniques have been applied to deal with calculation of molecular weight properties, such as continuous approximation, statistical averaging using moments, stochastic methods, discrete weighted residuals etc. When a continues variable approximation is applied the discrete variables P_n and D_n are related to their continuous differentiable functions $P(n)$ and $D(n)$. By taking a Taylor series approximation of live radical concentration the difference term can be written:

$$R(n,t) = R(n-1,t) + \frac{\partial R(n,t)}{\partial n} + \frac{1}{2}\frac{\partial^2 R(n,t)}{\partial n^2} + H.O.T \tag{12}$$

In an analogous way discrete sums of live and dead polymer chains are related to their corresponding integrals by the Euler-McLauring summation formula. The resulting integro-partial differential equations are discretized on the variable n using orthogonal collocation, the integrals are approximated by Gauss quadrature, and the derivatives on the variable n are discretized using Lagrange polynomials.

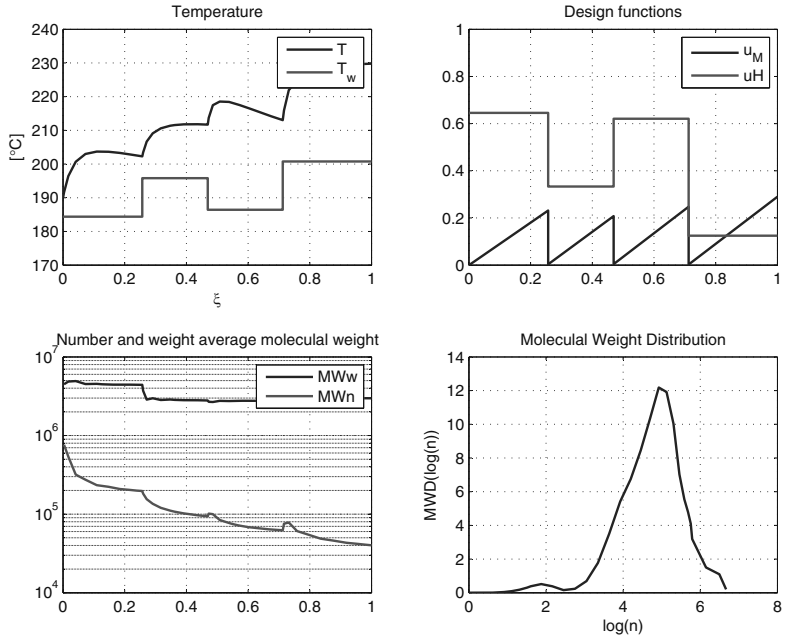

Figure 1: Case with 4-stage reactor path subject to optimization

4. Results and Discussion

For the solution of the optimal control problem of Eqs(10)-13, a direct simultaneous method based on discretization of the state variables using orthogonal collocation on finite elements is applied. The resulting NLP optimization problem is solved to local

optima using a sequential quadratic programming solver available in Matlab (fmincon). For demonstration purposes we present a hypothetical case using kinetic constants from Kim and Iedema (2004). A constant reactor space time of 40s is divided in 4 stages (elements) and an objective function that maximize the monomer conversion at the end of the reactor path has been chosen. For a given kinetic scheme the optimizer select optimal mixing profiles, heat area distribution and coolant temperature. For the hypothetical case presented a sequence of four equal volume CSTRs exhibit the highest conversion with varying temperature profiles and heat transfer area distribution at each stage as shown in Figure 1.

5. Conclusions

A model formulation for the design of reactor systems is presented. Fluid mixing, heat transfer, and distribution of feed are considered through parameterized design functions thus avoiding the combinatorial problem if otherwise discrete decision variables were included. Based on a given chemistry

the reactor path (volume or space time) is divided into a number of stages and the design is subject to optimization. The method was applied to the ethylene polymerization through a relative simple model reduction scheme for the calculation of the full molecular weight distribution and some preliminary results are presented.

Abstract
A sequential design of experiments methodology with adaptive design space has been applied to optimize a nanoparticle deposition process using elevated pressure, elevated temperature carbon dioxide. This methodology is termed Layers of Experiments (LoE) with Adaptive Combined Design (ACD). Optimizing the CO_2-assisted nanoparticle deposition system presents significant challenges: uncertainty in the design region, uncertainty in model structure, a lack of information regarding the process from mechanistic considerations and/or empirical studies, significant costs related to materials processing and characterization, and an engineering tolerance requirement on the characteristics of the products. The contribution of the LoE/ACD methodology presented here is that it *systematically* finds the optimum of a process while robustly managing the aforementioned challenges.
Keywords: Optimization under uncertainty; sequential experimental design; nanoparticle deposition

1. Introduction
Advanced technology processes such as nanomanufacturing present unique challenges not inherent in more traditional materials fabrication techniques. Since nanomanufacturing processes exhibit complicated relationships between process inputs and outputs, reliable mechanistic and/or empirical models are not readily available for process optimization[1, 2]. Moreover, there are often significant uncertainties in the design region for nanofabrication[3]. Lastly, nanomanufacturing processes are expensive in terms of time and money and must still meet engineering tolerance requirements on the products. All of these issues represent unexplored challenges that must be overcome for advanced technology processes.
In this work, we present a systematic methodology to optimize a nanofabrication process that addresses uncertainty in design region and model structure while ensuring that the process meets a strict engineering tolerance requirement. This method is termed Layers of Experiments (LoE) with Adaptive Combined Design (ACD). This LoE/ACD algorithm was able to find the process optimum for a nanoparticle deposition process using the CO_2-assisted process by conducting 8 experiments in two layers. In the first layer, the target mean nanoparticle size was not achieved, exemplifying uncertainty in design region for this process. Consequently, the LoE/ACD algorithm redirected the second layer of experiments to a new design region, resulting in the successful optimization of the process at 69°C.

2. Materials and methods

2.1. Layers of Experiments with Adaptive Combined Design
The LoE/ACD algorithm begins by conducting a set of experiments and collecting data. Then, an empirical model is chosen and the model is fit using the experimental data.

Next, the accuracy of the predictions made by the model is assessed. If the accuracy is within the engineering tolerance set by the experimenter, the model is deemed acceptable and used to optimize the process. If not, the next subregion for experiments is selected using the LoE technique, design points are chosen using the ACD methodology, and the algorithm iterates until the accuracy of the model falls within the engineering tolerance set by the experimenter. Each of these steps is detailed below.

2.1.1. Model selection

Polynomial models for data were selected using the Akaike information criterion (AIC) and Bayesian probability (P_B). Methods for calculating these metrics are given elsewhere[4, 5].

2.1.2. Assessment of model accuracy

A target size T = 20nm and an engineering tolerance d = 5nm were chosen with surface enhanced Raman spectroscopy (SERS) as the motivating application[6]. A novel evaluation metric, L, is implemented to assess the model accuracy and is defined as[7]:

$$L = \max\{|T - (\hat{y}(\mathbf{x}) + CI(\mathbf{x}))|, |T - (\hat{y}(\mathbf{x}) - CI(\mathbf{x}))|\} \quad (1)$$

where $\hat{y}(\mathbf{x})$ is the fitted model and $CI(\mathbf{x})$ is the confidence on the model prediction. If $L > d$, the LoE algorithm specifies that a new layer with additional experiments is necessary. If $L \le d$, the model is sufficiently accurate and the LoE/ACD algorithm stops.

2.1.3. Selection of next layer

The next step in the LoE algorithm is choosing the location and size of the next layer (subregion). To choose the center of the next layer, the optimization problem

$$\min_x |T - \hat{y}(\mathbf{x})| \quad (2)$$

is solved n_j times for each candidate model j by calculating residuals of the model $\hat{y}(\mathbf{x})$ and experimental responses $y(\mathbf{x})$, randomly resampling (bootstrapping) these residuals to formulate synthetic response variables, fitting each candidate model to these synthetic responses, and solving Eq. (2). A histogram of the center points calculated from each optimization of each candidate model, $\tilde{c}_{lj}$, is created; the mean of the most frequent bin in the histogram is chosen as the center point for the next layer, c^*. To choose the size of the next layer, the histogram of potential center points is used: as the size of the subregion increases, the probability for the subregion to include the true optimum with respect to a distance r from the center is given by[7]:

$$\psi(r) = \frac{1}{N}\sum_{j=1}^{m}\sum_{l=1}^{n_j} I(c^* - r \le \tilde{c}_{lj} \le c^* + r) \quad (3)$$

where N is the total number of optimizations performed (i.e. $N = \sum_{j=1}^{m} n_j$) and m is the number of candidate models used in the optimization routine.

2.1.4. Adaptive combined design

A combined design methodology is implemented to choose design points in the layers used in the LoE/ACD methodology. This combined design uses a constrained approach to weight and optimize the design based on two criteria: one for a model free, minimax design, and one for a model dependent, D-optimal design. Let ξ be the design of N design points; then we define $\rho(\xi)$ as the metric to be minimized that yields a design minimizing the maximum distance between adjacent design points. A D-optimal design

seeks to minimize the determinant of the inverse of the information matrix for the most probable model, that is, $\left|\mathbf{M}(\xi)^{-1}\right|$. Thus, the weighted combined design metric to be optimized is[7]:

$$\kappa\left|\mathbf{M}(\xi)^{-1}\right|+(1-\kappa)\rho(\xi) \tag{4}$$

where $0 \le \kappa \le 1$ is the weighting factor between these two design metrics. The parameter κ is calculated as[7]:

$$\kappa = 1-\frac{max\{0, L_{t-1}^{*}-d\}}{L_{0}^{*}-d} \tag{5}$$

where L_{t-1}^{*} is the L^{*} metric from the previous layer and L_{0}^{*} is the L metric calculated fitting a simple mean model $\hat{y}(\mathbf{x})=\mu+\epsilon$.

2.2. Experimental procedure

The silver nanoparticle deposition method by elevated pressure, elevated temperature CO_2 has been detailed elsewhere[8], so only a brief description is presented here. A 2cm x 3cm silicon wafer ((100), p-type, 10-20Ωcm) was purchased from University Wafer and cleaned in an oxygen plasma to populate the surface with reactive silanol groups. The substrate was loaded into a stainless steel high pressure reactor with the organometallic precursor, silver hexafluoroacetylacetonate cyclooctadiene, hydrogen as reducing agent, and carbon dioxide. The reaction was run at 103bar at the specified temperature. Products were characterized by a Zeiss Ultra60 scanning electron microscope (SEM), and mean nanoparticle sizes were extracted from SEM images using automated image analysis in MATLAB 2010a.

3. Results

3.1. First layer

A space-filling experimental design was chosen for the first layer of experiments in the region [120°C, 150°C]. Results from these experiments are shown in Table 1. The AIC and P_B indicated that a linear model was the best fit for the data. Using a linear model, the L^{*} metric was calculated to be L^{*} = 38.8nm at x^{*} = 130°C. Since $L > d$, the LoE/ACD algorithm dictated that another experimental layer was necessary to optimize the process.

Table 1. Results of experiments and model selection criteria in first layer

Temperature (°C)	Mean AgNP size (nm)	Model order	AIC	P_B
120	44.0	1	26.1	0.59
130	41.6	2	28.1	0.41
140	55.2			
150	51.8			

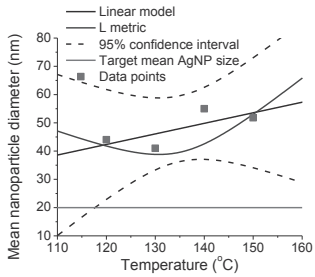

Figure 1. Linear model fit of data collected in first LoE with 95% confidence interval and L metric

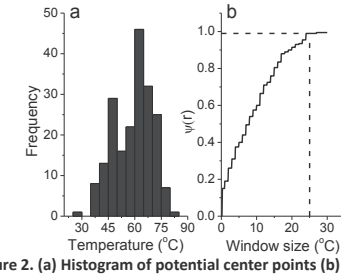

Figure 2. (a) Histogram of potential center points (b) ψ(r) vs. r; dashed lines indicate 99% confidence level and window size

3.2. Second layer

The center and size of the next subregion were calculated using the procedures described above. The histogram of center points is shown in Figure 2a; the mean of the most frequent histogram was $c^* = 63°C$, which was chosen as the center of the next region. The size of the next window was chosen using Eq. (3) to be 25°C, corresponding to a ψ level chosen to be $\psi = 0.99$ in Figure 2b so that there is a higher degree of confidence in the design region than in the model prediction (with confidence interval of 95%). The value for kappa was calculated to be $\kappa = 0.01$ from Eq. (5); using this value in the ACD algorithm resulted in an experimental design that is essentially minimax due to the weighting. Results from this design are given in Table 2; the AIC and P_B metrics indicated a linear model should be fit to the data in this window. Using this model, L^* was calculated to be $L^* = 2.49$nm. Since $L^* \le d$, the model was sufficiently accurate to within engineering tolerance and accepted; the plot of this model is shown in Figure 3, along with the 95% confidence interval and the L metric. Figure 4 shows a typical SEM image with silver nanoparticles deposited on a silicon wafer surface.

Table 2. Results of experiments and model selection criteria in second layer

Temperature (°C)	Mean AgNP size (nm)	Model order	AIC	P_B
44	12.1	1	39.9	0.54
56	17.3	2	40.3	0.46
69	19.2			
82	24.1

4. Discussion

The goal of the LoE/ACD methodology was to rapidly and systematically optimize the epet-CO_2 AgNP deposition process under uncertainty in model structure, design space, and an engineering tolerance requirement on the mean AgNP size, T = 20nm. The

investigators chose the design region [120°C, 150°C] as the initial layer in which to conduct experiments; however, results indicated that this was a poor choice for the chosen target. This is an example of how uncertainty in the design region for a system can affect process optimization. Nonetheless, the LoE/ACD algorithm was able to efficiently redirect the second layer of experiments to a region that was likely to contain the process optimum. However, due to the uncertainty in model structure from the previous layer of experiments (i.e. the relatively large L^* value in the first layer), the weighting parameter between the minimax design and D-optimal design was weighted significantly toward the minimax design in the ACD algorithm. This is because a space-filling design like a minimax design is model free, so it will not suffer bias from a poor model choice in constructing an experimental design; consequently, the design points chosen for the second layer were well "spread out" in order to locate the process optimum.

The results of these experiments indicated that the process optimum did indeed fall within the design region explored in the second layer. Furthermore, the small L^* metric (L^* = 2.49nm) indicated that the linear model structure selected for the specified target in this region was acceptable. If a further layer of experiments were to be conducted, the weighting factor κ would be $\kappa = 1$, weighted completely toward the D-optimal design since there is a higher degree of confidence in the linear model in this region of the design space. These experiments based on the model dependent D-optimal design would refine the model parameters. Last, the method can be generalized to multiple independent variables (such as pressure or reaction time).

5. Conclusion

A sequential experimental design methodology termed Layers of Experiment with Adaptive Combined Design (LoE/ACD) was proposed and implemented to optimize a silver nanoparticle deposition process under structural uncertainty, design region uncertainty, and an engineering tolerance requirement. After eight experiments conducted in two sequential layers, the algorithm found the process optimum at x = 69°C for a target mean nanoparticle size of T = 20nm with a tolerance of d = 5nm.

Modeling and Simulation of Multi-stream Heat Exchanger Using Artificial Neural Network

Mohd Shariq Khan , Yuli Amalia Husnil , Mesfin Getu & Moonyong Lee*

School of Chemical Engineeing, Yeungnam University Gyeongsan, 712-749, Korea

Abstract

A multi-stream heat exchanger (MSHE) is the heart of LNG plant where 40% of the entire energy is consumed in this section. Moreover, the plant operation is subject to number of variations from the plant inlet such as ambient temperature, pressure, feed flow or composition. In industrial application, the mitigating of these variations is usually performed using trial and error approaches. Thus developing a competent and accurate model to predict the performance of the MSHE is an inevitable step to overcome those variations. In this study, a model for the MSHE operation is developed using artificial neural network. The modeling is made in such a way that the information about the internals of heat exchanger could allow the MSHEs from any variation that arises from the process itself or upstream conditions. A number of simulation runs have been made by taking a case study for the MSHE operation. The developed model can predict and provide prior information for the MSHE in order to take action during the plant performance.

Keywords: Artificial Neural Network, Multi-Stream Heat Exchanger, liquefaction, Natural gas

Introduction

Multi-stream heat exchanger (MSHE) is the principal piece of heat transfer equipment in many industrial and cryogenic processes. MSHE compact design enables reduction of material, space and is popular in many cryogenic applications. MSHE typical application includes air separation, natural gas processing, liquefied petroleum gas (LPG), Helium recovery, Petrochemicals and refrigeration systems. The desired properties of MSHE include high heat transfer area with minimum approach temperature as small as 1-3^{o}C [1], large number of complex channels, and high flexibility in flow arrangement, high reliability with capability to withstand a range of pressure. Plate & fin type and Spiral wound are two common type of MSHE. The diversified application of MSHE ranging from sub ambient operation to energy improvement in chemical plant gives the motivation for developing efficient and accurate predictive model. For instance, the predictive MSHE model in LNG operation where 40% of entire energy is consumed in liquefaction gives good prospects of energy saving. MSHE Predictive model reduces the trail & error work in LNG plant operation where most deviations are mitigated by changing operations of cryogenic exchanger. Model building is also necessary for system wide optimization and for implementation of advance control schemes such as MPC. A validated model of MSHE enables the plant operators to predict the possible outcome of any control action before actually executing any control move. Modeling of MSHE can be achieved principally in two ways (i) using rigorous physiochemical model where the information about internal is required and the other is (ii)

operational data model where no information about the internal is needed and the only information needed is inlet and outlet streams temperature, pressure and flow rates, etc. Both methods has their pros and cons for instance, physiochemical model would be time consuming and computer intensive conversely, operational data model would be less time consuming but compromise would be made at the rigorousness of the model. MSHE is proprietary equipment and almost nothing is known about the internal geometry and configuration in public domain thus, we aim to develop operational data model of MSHE using artificial neural network (ANN). ANN is used because of its information processing characteristics such as nonlinearity, high parallelism, fault tolerance and the capability to generalize and handle imprecise information. ANN, over the last few decades has established their reputation in process engineering as alternative approach to information processing. The utility of ANN was demonstrated in Bhat *et al* [2, 3] where the technique was successfully used to characterize nonlinear chemical system and also to interpret biosensor data. ANN has also been used in model based predictive control methodology where neural network model effectively represent the complex nonlinear systems. Some other specific application of ANN includes the auto-tuning of PID controllers [4] and fault diagnosis and the development of intelligent system [5]. From its introduction ANN has gained sufficient maturity and successfully applied in many different fields of engineering [6][7] and their ability to solve process engineering problems has already been illustrated and studied [8].

In this paper, we aim to develop ANN model of MSHE using operational data from Natural gas liquefaction plant, which has been generated by using rigorous Hysys first principal model. To capture the star-up, shutdown and the intermittent dynamics of the MSHE several scenario were created (see section 2.2) and the most representative data were used for ANN training, testing & validation. Finally the simulation results are presented in results and discussion section.

1. First Principal MSHE Model

1.1. Dynamic Model of MSHE

The dynamic model of MSHE was developed in Aspen Hysys® V.7.2 platform as illustrated in *Fig 1.* Due to strong thermodynamic database the developed model in Hysys considered to be the most rigorous one. Peng-Robinson equation of state was used for property calculation and pre-cooled and lean NG was used as feed for MSHE. Steady state model was first developed and the steady state properties of inlet and outlet streams are summarized and presented in *Table. 1.* Once the steady state model has been configured properly, sizing were made which includes calculating the volume of flash drum, the flow coefficient of the valve (*Cv*) and most importantly the geometry of exchanger. To mimic the behavior of real Cryogenic exchanger, heat transfer between hot and cold streams is divided into several zones. Every zone is further partitioned into several layers where the actual heat transfer took place between hot and cold stream. Present model has 10 zones having 38 set of each 4 layers in it. Finally both steady-state and dynamic simulation mode are utilized to validate the developed model and mass & energy balances are checked to verify the interaction between the variables. MSHE is conceptually divided into two sections Precooling Bundle (PCB) and sub-cooling bundle (SCB) where the heavy component of mixed refrigerant provides cooling in PCB and light component of mixed refrigerant provide cold energy in (SCB). PI controller was used to control the Mixed refrigerant (MR) liquid level in flash drum by opening JT1 value whereby the flow rate of LNG is controlled by VLV-100

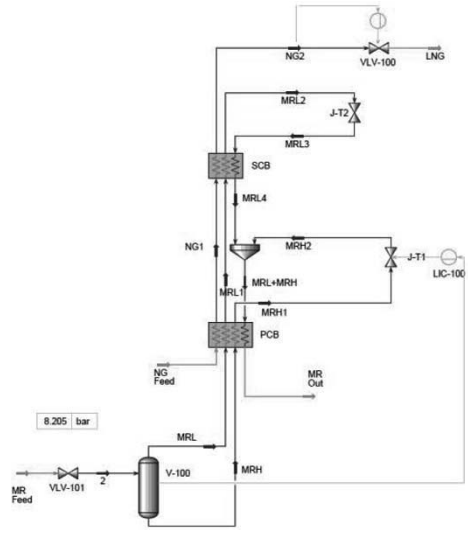

Figure 1. MSHE model in Natural gas liquefaction plant.

Table.1 Steady State properties of inlet streams

	Inlet		Outlet	
	NG feed	MR feed	LNG	MR out
Pressure (bar)	61.7	60.2	60.7	3.9
Temperature (^{o}C)	-32.7	-32.8	-153.2	-35.7
Flowrate (kmole/hr)	286.2	529.1	286.2	529.1

1.2. Data Generation

The data for both neural network training and validation were obtained by the Hysys dynamic simulation model of LNG plant. To obtain the representative data various control actions and disturbances were imposed on the cryogenic exchanger model. To capture startup and the intermittent dynamics six scenarios were created for generating representative data points, scenarios comprises of variations in NG feed temperature & pressure and increase in throughput. After giving disturbance, 3000 data points were generated for every scenario; 2500 were used for training and 500 for independent testing. Cryogenic exchanger in Hysys model is represented by two sections; PCB & SCB and both are treated as separate MSHE for data generation and simulation.

2. Artificial Neural Network Model Development

The application of ANN in chemical engineering began with the pioneering works [9] and in the subsequent years the research work has steadily increased. Process control, dynamic modeling, forecasting fault diagnosis and optimization were few areas in chemical engineering that benefits the most. In this paper the ability of ANN to store knowledge about the process and learn from the quantitative historical data information, has been exploited to develop ANN model of MSHE. The general NN structure that is used in this study is illustrated in *Fig. 2*

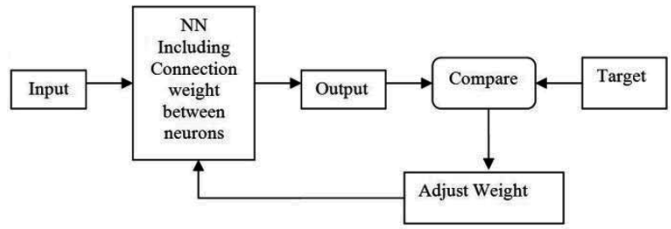

Figure 2. Neural Network Structure used in MSHE Modeling

2.1. Modeling Parameters

Modeling of PCB and SCB has done separately (see section 2.2 & 2.3) hence the modeling parameter used for both the cases are different. In general a two layer feed forward network with sigmoid hidden neuron and linear output neurons are used. The networks for both PCB & SCB were trained with Levenberg-Marquardt back-propagation algorithm. The performance evaluation of trained network was done by using mean square error (MSE) and regression analysis. In training PCB 25 hidden neurons were used whereby 20 hidden neurons in SCB case. The stopping criterion used is either total number of iterations reached or the mean square error reached the specified limit.

3. Results & Discussion

Modeling of MSHE was carried out using ANN and the simulation results are listed in *Fig. 3* to *Fig 6*. PCB and SCB bundles are simulated separately (see section 1.1). *Fig 3* & *Fig 4* represents the training, testing and validation of ANN in both bundles. Mean square value was used as the performance criterion for ANN model. In PCB the training proceeds until 24 epochs and the best validation point happen to be at 17. Training and validation curves are near and the MSE value of 10^{-2} was achieved. Training stopped when no improvement in MSE was achieved in subsequent epochs. Similarly in SCB training proceeds until 37 epochs and best validation happened at 31. Linear regression was also performed for both bundles and R^2 value of 0.9995 was achieved which represents that output tracks the target very well. Finally, ANN response was compared with the actual model developed in Hysys and illustrated in *Fig. 5* & *Fig 6*. PCB has four output temperatures that were predicted by ANN almost closely *(Fig 5)*. In SCB three output temperatures were predicted and their performance was also exceptional. Excellent prediction of ANN can be attributed to its leaning property when exposed to know data. However, this model application is limited to historical plant data and cannot be used for imaginary situations like unusual events not included in training. Considering the normal operation of process plant it will be helpful to get some rough estimate and a rigorous model should be used for real plant operation. In view of the time consumed and prediction results, this kind of model will be helpful since almost instant results can be obtained and can be used in parallel with rigorous model.

4. Conclusions

A neural network based model of MSHE for NG liquefaction is developed using operational data generated by inhouse Hysys dynamic simulator. Data generation was made by considering the possible scenarios in LNG process plant like variation in feed gas, ambient conditions fluctuations etc. The results obtained demonstrate the model behavior within and outside the training data, which is exceptionally good in predicting

behavior. This type of modeling is inexpensive and does not require difficult theories and the previous knowledge of the system moreover, modeling can be achieved in real time performing mapping by parallel distributed processing.

Abstract

Reactive distillation (RD) is a well studied process-intensified technology where the interaction of chemical kinetics and vapor-liquid equilibrium is exploited through integration of reaction and separation in a single column. The in-situ removal of products for an equilibrium-limited chemical reaction in RD helps in realizing enhanced conversion, increased selectivity and reduced recycles. However, in spite of many benefits achievable through RD, several issues typical of a conventional column/packed bed still persist in RD; these include vapor-liquid mass-transfer limitations, inefficient catalyst wetting and constrained flooding limits, and need to be addressed. In this work, we propose a novel, intensified, reactive HiGee distillation (RHD) technology that addresses many of the issues stated above. Design of an industrial-scale, conventional RD column and the proposed RHD technology for methyl acetate (MeAc) esterification is employed as the case study. Rigorous modeling and simulation of RHD process, besides RD process, in Aspen-Plus™ is described. Obtained results suggests that nearly 13.6% reduction in equivalent annualized operating cost (EAOC) and more than 4-fold reduction in packed bed volume can be achieved by RHD over conventional RD.

Keywords: Process Intensification (PI); Reactive HiGee Distillation (RHD); Reactive Distillation (RD); Methyl Acetate Esterification; Modeling

1. Introduction

Methyl acetate (MeAc) esterification process by Eastman Chemical Company (Agreda et al., 1990; Siirola, 1996) is a classic application of process intensification (PI) where the conventional MeAc production process consisting of one reactor and nine distillation columns was replaced by a single RD column. MeAc is a valuable and high-volume commodity chemical, and its production throughput for a typical plant ranges from 18,000 to 200,000 metric tons per year (Celanese Chemicals Co., 2000; Harmsen, 2007). It is primarily used as a solvent, and as an intermediate feedstock in the manufacture of a variety of polymers such as photographic film base, cellulose acetate, Tenite cellulosic plastics and Estron acetate (Hiwale et al., 2004). However, in spite of the benefits achieved, several issues typical of a conventional packed bed still persists in RD; these include vapor-liquid mass-transfer limitations, inefficient catalyst wetting, lower catalytic bed density, excessive pressure drop for small-sized catalysts, and constrained flooding limits.

HiGee (acronym for High Gravity) or rotating packed bed (RPB) involves the rotation of a torus packed bed where liquid and gas interact counter-currently (Ramshaw, 1981). Under the high centrifugal field, liquid forms thin films and tiny droplets, leading to enhanced inter-phase mass transfer. In addition, high centrifugal acceleration raises the flooding limit of the packed bed, allowing for the use of high gas flow rates and high specific surface area of packing (500-4,000 m^2/m^3 compared to 100-1,000 m^2/m^3 in conventional columns). Different packing configurations employed in RPB are single packing (Ramshaw, 1981) and split-packing (Chandra et al., 2005). In a split-packing

RPB, the two coaxial packed disks rotate in opposite directions resulting in large vapor-liquid slip in the gap between the adjacent annular rings. Hence, radical enhancement in vapor side mass transfer coefficient over single packing can be obtained. Furthermore, split-packing RPB permits the introduction of intermediate feed between the packed disk (Agarwal et al., 2010), which is difficult in single packing RPB. Wang et al. (2011) proposed non-packing rotating zigzag bed that reduced the need for liquid distributor and dynamic seal, and allowed intermediate feed and multi-rotor configuration.

The current study proposes a novel reactive HiGee distillation (RHD) process (with split-packing configuration), and its performance is assessed for MeAc esterification using modeling and simulation approach. Rigorous analysis for plant-scale conventional packed bed RD and the novel RHD is performed, and they are compared based on equivalent annual operating cost (EAOC). A new approach to simulate HiGee in Aspen Plus process simulator is also demonstrated. Obtained results are encouraging, and suggest that further research on RHD would be promising.

2. Design and Simulation of Novel RHD Process

2.1 Reaction Kinetics

The esterification of acetic acid with methanol to form MeAc is a reversible and acid-catalyzed (here, Amberlyst 15 catalyst) reaction, and is given as:

Acetic acid (1) + Methanol (2) ⇔ Methyl acetate (3) + Water (4)

Psuedohomogeneous (PH) activity (a_i) based reaction rate (mol/g_{cat}-s) model is (Pöpken et al., 2000):

$$r = m_{cat}\left(2.961\times10^{4}\exp\left(\frac{-49{,}190}{RT}\right)a_1a_2 - 1.348\times10^{6}\exp\left(\frac{-69{,}230}{RT}\right)a_3a_4\right) \quad (1)$$

2.2 Validation of Thermodynamic Property Method

UNIQUAC model is used to determine the liquid phase activity coefficient. Due to the dimerization of acetic acid, Hayden-O'Connell (HOC) second viral coefficient model is used for the vapor phase. Validation of the UNIQUAC-HOC thermodynamic package in Aspen Plus was done with experimental data of Horsley (1973). Absolute errors in temperature and composition predictions are less than 0.5°C and 0.04 mole fraction, respectively (Table 1).

Table 1: Experimental and Predicted Azeotropic Data for MeAc System

	Experimental Value	Simulation Value	Deviation
1	Methanol – MeAc 54.0°C, (0.3590, 0.6410)	Methanol – MeAc 53.6°C, (0.3382, 0.6618)	Temperature: -0.4°C Mole fraction: (-0.0208, 0.0208)
2	MeAc – Water 56.4°C, (0.8804, 0.1196)	MeAc – Water 56.6°C, (0.9107, 0.0893)	Temperature: 0.2°C Mole fraction: (0.0303, -0.0303)

2.3 Modeling and Validation of HiGee Separation Process in Aspen Plus

Aspen Plus does not have a built-in module for HiGee unit. Hence, a novel approach for simulating HiGee using rate-based model in Aspen Plus is proposed in this work. For this purpose, the ability of Aspen Plus to carry out rigorous rate-based calculations by discretizing the process unit into segments and then solving the material balance, energy balance, mass transfer, energy transfer, phase equilibrium and summation equations simultaneously was utilized. RADFRAC module in Aspen Plus has rate-based approach implemented for conventional vertical columns, but HiGee is similar to a horizontal column. Hence, the proposed approach approximates a coaxially oriented horizontal HiGee unit by converting the differential annular rings in HiGee into a series of sequentially attached vertical cylinders (Figure 1). Variable transformation is thus

carried out based on conservation of material flux and volume (Equations 2 and 3) for different differential segments within RPB. Hence, for an annular segment within RPB (with $r_{s,i}$, $r_{s,o}$ and $h_{s,RPB}$ as the section inner radius, outer radius and height, respectively) that is approximated as a cylinder (with diameter, D and height, $h_{cylinder}$), calculations are shown as follows, and validation of the proposed approach is shown in Section 3.1:

1) Conservation of area for constant material flux for a differential segment:

Area for material flow in RPB = Area for material flow in cylinder

$$2\pi r_{lm} h_{s,RPB} = \frac{\pi D^2}{4} \rightarrow D = \sqrt{8 r_{lm} h_{s,RPB}} \text{ where, } r_{lm} = \frac{r_{s,o} - r_{s,i}}{\ln\left(r_{s,o}/r_{s,i}\right)} \quad (2)$$

2) Conservation of volume for a differential segment:

Volume of the annular ring = Volume of the cylindrical block

$$\pi\left({r_{s,o}}^2 - {r_{s,i}}^2\right) h_{s,RPB} = \frac{\pi D^2}{4} h_{cylinder} \rightarrow h_{cylinder} = \frac{4\left({r_{s,o}}^2 - {r_{s,i}}^2\right) h_{s,RPB}}{D^2} \quad (3)$$

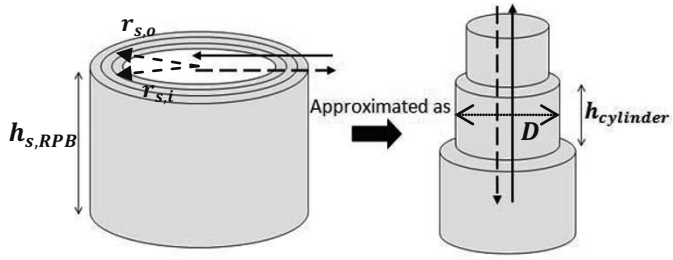

Figure 1: Schematic showing the approximation method of HiGee (left sketch) as a conventional column (right sketch) in Aspen Plus. The arrows represent the direction of material flow (solid line: vapor flow, dashed line: liquid flow).

2.4 Design of a Plant Scale Split-Packing RHD Unit

The novel split RHD unit comprises of both solid catalytic (reactive section) and non-catalytic packing (rectifying and stripping sections), and vapor-liquid-solid mass-transfer happens under high centrifugal field. Main steps for designing a RHD unit are to find the three dimensions of the entire HiGee unit, namely, inner packing radius (r_i), outer packing radius (r_o), and packing axial height (h_{RPB}).

Inner radius: Minimum inner radius of RHD is given as (Agarwal et al., 2010):

$$r_i = \left(\frac{\bar{V}}{\pi v_{jet}(1-f_d)}\right)^{0.5} \left(\frac{\rho_V p}{\rho_L}\right)^{0.25} \quad (4)$$

where, $\bar{V}$= volumetric vapor flow rate (m^3/s), v_{jet}= liquid jet velocity (4-5 m/s), f_d = fraction of packing inner radius occupied by liquid distributor (0.25-0.33), p= liquid jet to exit vapor kinetic energy ratio, ρ_V= vapor density (kg/m^3), ρ_L= liquid density (kg/m^3).

Axial height: The axial height of the split-packing HiGee unit is found for operating the unit below flooding limit. Generalized flooding correlation is (Wallis et al., 1969, Agarwal et al., 2010):

$${C_V}^{0.5} + 1.51{C_L}^{0.5} = 130{N_g}^{0.434}{a_p}^{-0.9343} \quad (5)$$

$$C_V = \bar{V}_S\left(\frac{\rho_V}{\rho_L - \rho_V}\right)^{0.5},\ C_L = \bar{L}_S\left(\frac{\rho_L}{\rho_L - \rho_V}\right)^{0.5}, \text{ and } N_g = \frac{r_i \omega^2}{g}$$

where, a_p= specific packing area (m^2/m^3), ω = angular velocity of the packed bed (rpm), N_G= dimensionless centrifugal acceleration, $\bar{L}_S$ = liquid superficial velocity (m/s), $\bar{V}_s$ = vapor superficial velocity (m/s).

Outer radius: Due to mechanical constraints on HiGee, a conservative ratio of $h_{RPB}/2r_o$ < 0.5 (Trent, 2003) is assumed. Feasible range of r_i/r_o for a HiGee unit is determined by

collecting 30 sets of experimental data on the dimensions of RPBs in the literature, and is between 0.1 and 0.7. A constraint of $0.2 < r_i/r_o < 0.6$ is set in the present study for a conservative design. Moreover, based on an industrial scale RPB, maximum limit on the outer radius was set as 1 m (Trent, 2003). In summary, outer radius of HiGee is determined under the following three constraints: $r_o > h_{RPB}$, $5r_i > r_o > 1.67r_i$ and $r_o \leq 1$ m. Mass transfer coefficient correlations for split-packing from Agarwal et al. (2010), and correlation of Onda et al. (1968) for effective interfacial area for heat and mass transfer, were used for this study.

3. Results and Discussion

3.1 Validation of Modeling HiGee Separation and Conventional RD in Aspen Plus

Verification of the proposed methodology for simulating a HiGee unit in Aspen Plus was done for lab-scale experimental data on HiGee stripping for O_2-water-N_2 system (Chen et al., 2005). Aspen Plus does not have built-in liquid and vapor side mass transfer correlations for HiGee, and hence they were calculated using correlations of Chen et al. (2005) and Onda et al. (1968), respectively. Figure 2a compares the experimental and simulation results (R^2= 0.9774). The results justify the proposed approximation method for modeling HiGee in Aspen Plus. Validation of conventional RD process simulation using rigorous rate-based approach in Aspen Plus is done using experimental data of Pöpken et al. (2001). As can be seen in Figure 2b, simulated profiles of liquid phase composition are close to the experimental data.

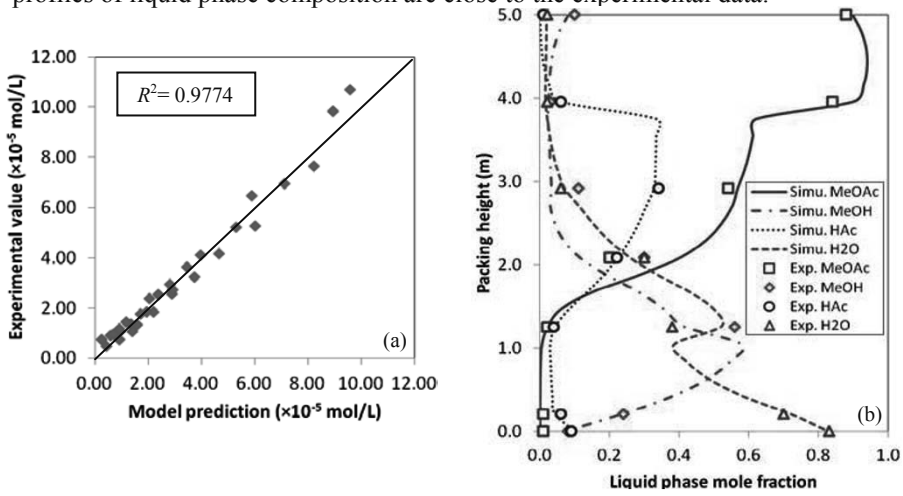

Figure 2: (a) Parity plot for experimental and simulated outlet O_2 concentration in HiGee, and (b) Experimental and simulated liquid phase composition profile in RD.

3.2 Techno-economic Analysis of Plant Scale Conventional RD & Novel RHD Process

Process conditions: Acetic acid and methanol feed flow rates are 30 kmol/hr each (for a throughput of ~21,000 metric tons/yr), and process product specifications are set as 99 wt% for MeAc in the product stream and 97 wt% for water in the bottom stream.

RD and RHD comparison: EAOC is the indicator selected to compare the performance of RD and RHD process. A FORTRAN code was built within Aspen Plus for estimating EAOC. Optimization for conventional RD column was done by employing SQP method available in Aspen Plus. Optimization of RHD has not been performed for the current study. However, the dimensions obtained from the procedure detailed in Section 2.4 provides a reasonable design for RHD, and used for this study. Table 2 shows the

techno-economic comparison between non-optimized, novel RHD process and optimized, conventional RD process for MeAc production. Obtained results show that 3 integrated RHD units ([inner radius, outer radius, height (all in m)] as [0.2, 1, 0.18], [0.2, 1, 0.2] and [0.17, 0.85, 0.18] for the 1st, 2nd and 3rd RHD unit, respectively) can replace a 8.6 m tall (1.2 m, 6 m, and 1.4 m for rectifying, reactive and stripping section, respectively) and 1 m diameter of a conventional RD column. Hence, packed bed-size reduction of 4.4 folds and EAOC reduction of 13.6% can be achieved by split-packing RHD over RD process (Table 2). Rotation of the packed bed would incur additional operating cost for RHD. Hence, in the present study of MeAc production process, extra electricity power of 133 kW is needed for RHD over RD (Table 2). However, there is further scope to reduce the EAOC of RHD by performing the process optimization (as done for RD), and is the subject of our future work.

Table 2 Comparison of Volume and EAOC for RD and Split-packing RHD Units

	Conventional RD	Split-packing RHD
Total bed volume (m^3)	6.75	1.54
Reboiler duty (W)	692,100	798,100
Electricity power (W)	-	132,800
AOC, Annual Operating Cost ($)	298,400	351,200
TCI, Total Capital Investment ($)	831,800	251,600
EAOC ($)	**464,700**	**401,500**

4. Conclusions

Although RD has many advantages over conventional reactor-followed-by-separator approach, it still has several limitations inherent to conventional gravity-driven packed beds. Novel RHD process proposed in this work reduces many of these limitations in RD. Both the conventional RD and split-packing RHD were simulated in Aspen Plus and were analyzed for MeAc production. Results show that 4.4-fold reduction in bed volume and 13.6% reduction in EAOC can be achieved by the proposed RHD over conventional RD.

Simulation and Analysis of Carbon-in-Leach (CIL) Circuits

Divyamaan Wadnerkar, Ranjeet P. Utikar, Moses O. Tade, Vishnu K. Pareek

Department of Chemical Engineering, Curtin University
Perth, WA 6102

Abstract

Carbon in leach (CIL) is an important process in gold processing involving simultaneous leaching and adsorption. The process holds the key to profitability in gold extraction. While the mechanism of leaching and adsorption are well known, the effect of different operating and design parameters on the CIL circuit performance is still empirical. The focus of this paper is to study the effect of parameters like cyanide concentration, oxygen concentration and mean particle diameter on the overall efficiency of CIL circuit. A dynamic model based on first principles is developed for the entire CIL circuit. Suitable kinetic models for both leaching and adsorption are adopted from the literature. Customizable simulator is written in MATLAB to simulate the model. Simulation results are first validated using previously published results. The validated model is then used to perform sensitivity studies on different parameters that affect the gold extraction process. The model can be used for controlling the operating parameters and to optimize the CIL circuit in order to achieve higher efficiency.

Keywords: Carbon-in-Leach, gold, cyanide concentration, particle diameter, oxygen concentration

1. Introduction

CIL process is widely used in the mining industry and in particular, it is an integral part of gold extraction plant. It is a continuous process in which gold is recovered by cyanide leaching of ore slurry and simultaneous adsorption on activated carbon in agitated tanks (Figure 1). From the time CIL process was introduced in the gold processing, a lot of progress and modifications have been made in the industry. However, the dynamics of the process are not yet studied in depth. Various operating parameters like cyanide and oxygen concentration, particle size, competitive adsorption, preg-robbing, carbon transfer cycle affect the dynamics and for the industry to increase the recovery rate, a clear understanding of kinetic mechanism and dynamics is necessary. While a lot of effort has been focused on understanding the kinetic mechanism of leaching and adsorption, the system dynamics has not received due attention. In order to increase the recovery rate, understanding real time response to changes in the operating parameters is essential. In this paper, we discuss a dynamic model for simulating CIL circuits. Transient simulations are carried out to understand the dynamic behavior of the system. The effect of various operating parameters on the performance of the system is also assessed. In the next section the model development is described.

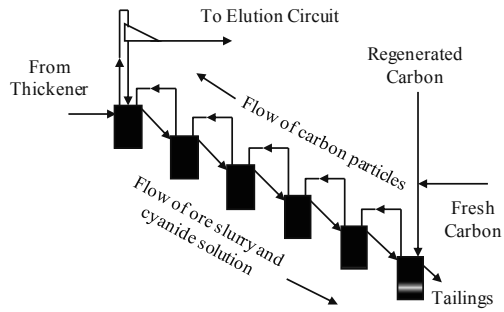

Figure 1. Carbon-in-Leach (CIL) process

2. Kinetics of leaching and adsorption

Table 1 summarizes various models that have been reported for the leaching and adsorption kinetics. Habashi (1966) devised a leaching rate equation that demonstrated the dependence of the leaching on the concentration of oxygen and cyanide. Schubert et al. (1993) modified this equation by including a dimensionless occlusion factor, s, and reduced the reaction rate to a realistic one. Kinetic equation proposed by Crundwell et al. (1997) dependent on electrochemical mechanism, surface passivation and the shrinkage of gold particle. The limitation of all these rate equations is the high probability of error in the exact determination of exposed and passivated surface area through experiments. Moreover, the practical use of such equations in the plant design, scale-up and optimisation is limited (Lima et al. 2005). Particle diameter and reagents concentration are critical for the leaching rate kinetics. But, these parameters were not considered in the models proposed by Brittan (1975), Nicol et al. (1984), Wadsworth et al. (2000) and Coetzee et al. (2005). Ling et al. (1996) developed an empirical equation which included cyanide and oxygen concentration. This work was followed by Lima et al. (2005) in which the particle diameter was also included in the rate equation. Since, this rate equation includes most of the critical process parameters, this equation was used for the calculation of leaching rate.

Adsorption is dependent on the gradient between the gold in liquid and the equilibrium concentration of gold on carbon. But, Kn models are independent of the gold loading on carbon and the model is based on assumption of a constant gold concentration in liquid. It provides highly inaccurate adsorption rate especially in CIL circuits, where, the gold concentration in liquid changes considerably. First order rate equation was only found to be applicable in the initial lower gold concentrations (Le Roux et al. 1991). Freundlich isotherm, Langmuir isotherm and Dixon model provided better fit over a range of data, but only deviated for a comparatively large values of gold concentration, which is practically not faced in the industry (Woollacott et al. 1990). Since there is no significant difference in the adsorption rate calculated using these three models, Langmuir isotherm was used for the adsorption rate kinetics in this paper.

Table 1. Leaching and adsorption rate kinetic models

Author and year	Leaching Rate Equation	Author and year	Adsorption Rate Equation
Habashi (1966)	$\frac{dn_{Au}}{dt} = \frac{2A_{Au}D_{CN^-}C_{CN^-}D_{O_2}C_{O_2}}{\delta\left(D_{CN^-}C_{CN^-} + \chi D_{O_2}C_{O_2}\right)}$	First Order Rate (Fleming et al. 1984)	$\frac{dq}{dt} = k_1 C$

3. CIL model and kinetics

A dynamic model based on the first principles for the CIL tanks was written. Following assumptions were made in developing the governing equations: Perfect mixing; negligible back-mixing with previous tank; negligible deterioration or fouling of carbon; no carbon loading profile; carbon transfer occurs simultaneously at regular intervals; constant pH; no pregrobbing and absence of competitive species. Based on these assumptions, the equations for CSTRs were framed and the mass balance equations were written incorporating leaching and adsorption. The reaction kinetics of Lima et al. (2005) were used. A MATLAB program was written for simulating the behavior of the CIL battery. The balance of flow on a reactor i can be written as follows:

$$Q_{fs_i^*} = Q_{f^*} + Q_{s^*_{i+1}} \tag{1}$$

where Qfs is the downflow stream, Qf is the slurry feed stream, Qs is the flow rate of slurry with carbon transfer.

The balance equations for Gold in liquid phase, in ore and on carbon are given by equations 2, 3, and 4 respectively.

$$\varepsilon_{li} V_i \frac{dC_i}{dt} = \frac{\varepsilon_{l(i+1)}}{\varepsilon_{l(i+1)} + \varepsilon_{o(i+1)}} Q_{s^*_{i+1}} C_{(i+1)} + \frac{\varepsilon_{l(i-1)}}{\varepsilon_{l(i-1)} + \varepsilon_{o(i-1)}} Q_{fs^*_{i-1}} C_{(i-1)} - \frac{\varepsilon_{li}}{\varepsilon_{li} + \varepsilon_{oi}}\left(Q_{s_i^*} + Q_{fs_i^*}\right) C_i + r_{leach} - r_{ads} \tag{2}$$

$$M_i \frac{dG_i}{dt} = \frac{\varepsilon_{o(i+1)}}{\varepsilon_{l(i+1)} + \varepsilon_{o(i+1)}} Q_{s^*_{i+1}} \rho_o G_{(i+1)} + \frac{\varepsilon_{o(i-1)}}{\varepsilon_{l(i-1)} + \varepsilon_{o(i-1)}} Q_{fs^*_{i-1}} \rho_o G_{(i-1)} - \frac{\varepsilon_{oi}}{\varepsilon_{li} + \varepsilon_{oi}}\left(Q_{s_i^*} + Q_{fs_i^*}\right) \rho_o G_i - r_{leach} \tag{3}$$

$$W_i \frac{dQ_i}{dt} = \frac{\varepsilon_{c(i+1)}}{\varepsilon_{l(i+1)} + \varepsilon_{o(i+1)}} Q_{s^*_{i+1}} \rho_c Q_{(i+1)} - \frac{\varepsilon_{ci}}{\varepsilon_{li} + \varepsilon_{oi}} Q_{s_i^*} \rho_c Q_i + r_{ads} \tag{4}$$

The rate equations are:

Leaching: $$r_{leach} = k\left(C_{CN^-}\right)^{\beta}\left(C_{O_2}\right)^{\beta}\left(C_{Au} - C^*_{Au}\right)^{\varepsilon} \tag{5}$$

Adsorption: $$r_{ads} = \frac{6 k_{fj} W_i}{\rho_c d_c}\left(C_i - C_{i,s,c}\right) \tag{6}$$

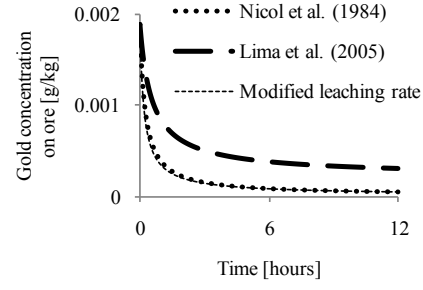

Figure 2. Comparison of leaching rates.

Cyanide Consumption: $$-r_{CN^-} = \left(\frac{1.69 \times 10^{-8}}{\frac{0.547}{\bar{d}} - 6.40} \right) [CN^-]^{3.71} \quad (7)$$

where ε is the volume fraction, C is the gold concentration in leaching tank, Q is the gold concentration on carbon, G is the gold concentration in ore, ρ_o is the ore density and ρ_c is the carbon density, W is the mass of carbon in tank, M is the mass of ore in tank, $C_{i,s,c}$ is the equilibrium concentration on carbon given by Langmuir isotherm.

There is a significant difference in the leaching rate calculated using different kinetic equations. In lieu of valid plant data, Mintek rate equation (Nicol et al. 1984) was used as a reference. The leaching rate calculated from Lima and Hodouin (2005) is slower compared to the Mintek rate equation (see Figure 2). This deviation can be attributed to the dependence of the leaching kinetics parameters, especially residual gold concentration on ore type. The leaching rate was modified so that the predicted reaction rate closely resembled Mintek rate equation. The modified residual gold concentration and k values are given by:

$$C^*_{Au} = 0.357 \times 10^{-4} \left(1 - 1.49 \exp\left(-0.0176 \bar{d}_{ore}\right)\right) \quad (8)$$

$$k = 0.00513 \left(1 - 2.28 \times 10^{-10} \exp\left(-2.93 \bar{d}_{ore}\right)\right) \quad (9)$$

4. Results and Discussion

4.1. Comparison with the literature Data

Due to lack of industrial data on the process, the simulation results were compared to previous studies of Deventer et al.(2004). Deventer et al. (2004) used Mintek leaching rate in their simulations which does not consider the effects of oxygen concentration and particle diameter. Simulations carried out using this rate equation (Figure 3a) closely agree with Deventer's results. Simulations were also carried out using modified Lima and Hodouin (2005) kinetics. These simulations shown in Figure 3b match with Deventer's data.

The Carbon-in-leach process is a countercurrent leaching-adsorption process. The slurry containing ore, lime and cyanide enters the CIL circuit from the first tank and carbon enters from the last tank. The concentration of gold in the solution was observed to decrease across the tanks. This is due to the simultaneous adsorption by the carbon particles in the tank with countercurrent flow. The countercurrent flow ensures a consistent high concentration gradient of gold between the carbon particles and the liquid throughout the circuit. Consequently, according to Le Chatelier's principle, high adsorption rates are observed. Consequently, as the carbon moves countercurrently across the circuit, the loading on the carbon increases exponentially with maximum loading observed in first tank. After the first tank the carbon is removed and is sent to the elution circuit. Even though the gold concentration in the liquid is low, the carbon is able to remove the remaining small quantity of gold leaving a low residual gold concentration.

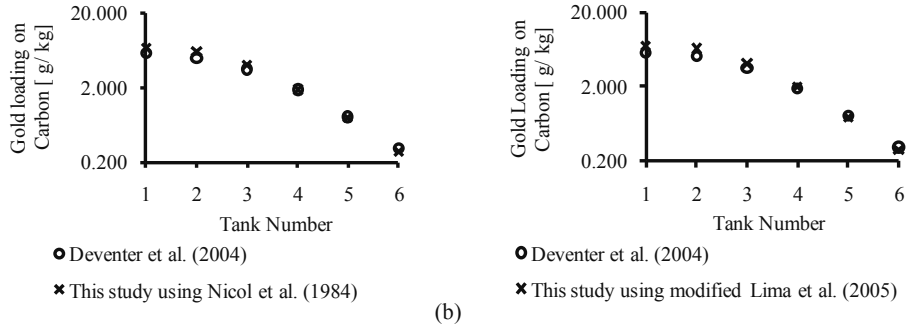

Figure 3. Comparison with literature data

4.2. Dynamic Simulation of CIL in Series

Figure 4 shows the dynamic behavior of gold loading on carbon for in different tank. Simulations were carried out using validated model with the initial gold concentration in liquid = 5 g/m^3 and initial gold loading on carbon = 0 g/kg. While the ore and liquid flow was continuous through the circuit from tank 1 to tank 6, carbon was transferred countercurrently (from tank 6 to tank 1) in a semi batch mode. The carbon transfer cycle was 12 hours with a loading time of 30 minutes.

For any given cycle, in any particular tank, the gold loading on carbon increased with time. It tends to attain an equilibrium value corresponding to the gold concentration in liquid. A reverse trend is observed for gold on ore. As the ore and liquid flow concurrently, the leaching rate decreases along the CIL circuit. Therefore a lower

gold concentration in liquid is observed. Therefore, a decrease in gold loading is observed throughout the circuit.

In general, the concentration in the initial tanks increases with time periodically dropping down as the transfer cycle kicks in. The loading vacillated within a band as a pseudo-steady state is reached. In the later tanks (tanks 4, 5, and 6), the loading first increases quickly (due to the high gradient in initial guess) and then dampens to reach a pseudo steady state value. For the first tank pseudo steady state is achieved within 108 hours (9 cycles). Longer time is required for the other tanks to achieve pseudo steady state with the 6th tank taking longest time.

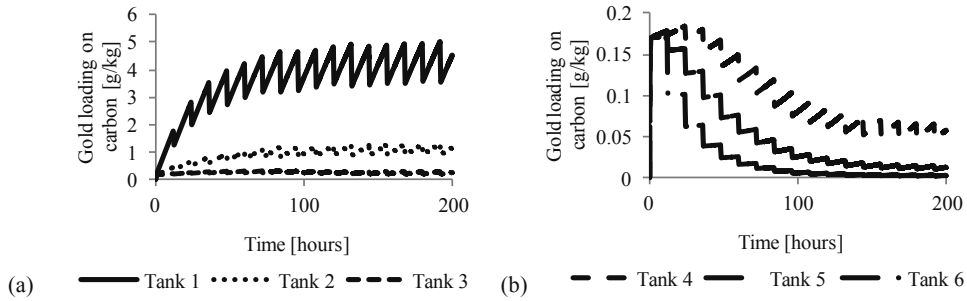

Figure 4. Gold loading on carbon as a function of time for the six tanks of CIL circuit.

4.3. Effect of Process Parameters

Ore particle diameter, cyanide and oxygen concentration have an effect on gold recovery. In order to assess their effect, dynamic simulations were carried out. The values reported below are the time averaged values after steady state was achieved. The results of the simulations with respect to the influence of these process parameters on the efficiency of gold recovery are discussed in the subsections below.

4.3.1. Cyanide Concentration

Cyanide concentration has a prominent effect on the efficiency of the CIL circuit as shown in Figure 5a. With the increase in the cyanide concentration, the efficiency of the CIL circuit increases. The positive impact of cyanide on leaching is due to the Le Chatelier's principle of equilibrium. For a particular particle diameter, the recovery was seen to increase initially with increase in cyanide concentration. Further increase in cyanide concentration did not have any effect on recovery as a plateau was observed. Thus, increasing the cyanide concentration over a certain limit only results in incurring losses.

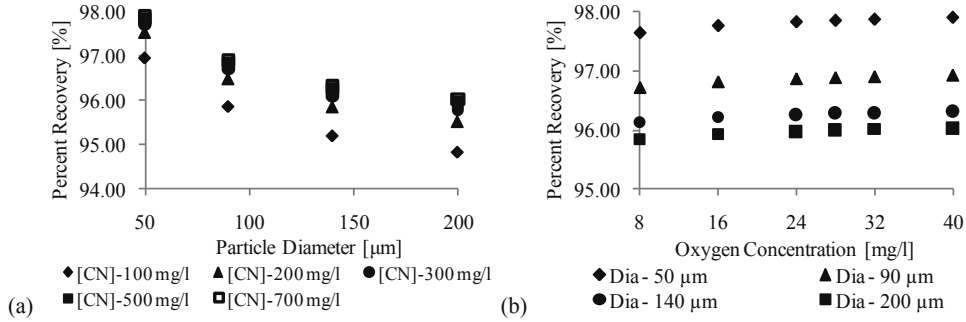

Figure. 5. Effect of (a) cyanide concentration and (b) oxygen concentration on gold recovery.

For low cyanide concentration (100 mg/l), a significant 2.5% change in the percent recovery with respect to particle diameter was observed. At the low cyanide concentration, although the percent recovery was low, the effect of particle diameter was dominant and rate was found to be more sensitive to the particle diameter. This shows that the impact of particle diameter on the CIL process is prominent. For the highest cyanide concentration studied (700 mg/l), although the improvement in percent recovery was 1.9% as compared to the maximum of 2.5%, but the recovery was also much higher. The rate of decrease in cyanide concentration is dependent on particle diameter. The rate of consumption of cyanide decreases with the increase in particle diameter. Therefore, the residual cyanide present is higher for the case of larger particles. This gives the reason for the change in the percent recovery that is slightly higher for the bigger particle than that for the smaller particle for any two cyanide concentrations.

Size reduction increases the surface area of particle and hence, increases leaching. Therefore, decrease in particle diameter increases leaching and so the efficiency of CIL process is increased. The effect of particle

diameter is incorporated in the model through rate constant and the residual gold concentration. The difference in the percent recovery is substantial, but the curve approaches a plateau value for higher particle diameter. That means, the decrease in particle size highly increases the recovery rate. Various size reduction operations in industry, i.e. crushing, grinding, etc. are cost intensive, and in order to obtain a cost effective output, it becomes necessary to conduct an optimization study to obtain an appropriate value of particle diameter, as the size reduction cost increases with the fineness of the particle. Similar case applies for the cyanide concentration, where excess cyanide will only result in excessive running cost. As is clear from the plot, the optimum CN^- concentration for the process lies around 300 mg/l.

4.3.2. Oxygen Concentration

Oxygen is involved in the cyanidation reaction; therefore, its availability is necessary for gold dissolution. The oxygen is incorporated in the leaching kinetic equation and its concentration is assumed to be independent of particle diameter. That is, a constant supply of oxygen is assumed for each CIL tank. Figure 5b shows the effect of oxygen concentration at different particle diameters. For a given particle diameter, increasing oxygen concentration marginally improves gold recovery. The increase in recovery diminishes as the oxygen concentration is increased beyond a certain level. Hence, similar to cyanide, excess oxygen will not result in any significant increase in the recovery. The oxygen is supplied in the CIL tanks through spargers. The flow rate through the sparger can be regulated in order to maintain the oxygen concentration in the CIL tank. To increase the air flow rate in order to gain only a marginal increase in the percent recovery only adds up to the running cost of the plant without any significant profit. Therefore, it is necessary to conduct such study for the ore used and run the plant in the optimized limits.

5. Conclusion

Gold extraction process in a CIL circuit was modeled and simulated. A dynamic model for the CIL circuit was developed and used to study the variation in gold concentration in the liquid and on carbon. The impact of various process parameters on the residual gold in the ore was studied. The results obtained by the model were compared with existing literature and were found to be in close agreement. The main conclusions of this study are summarized below:

1. The particle size and cyanide concentration are critical for the gold leaching. Decrease in the particle size and increase in cyanide concentration result in increase in the efficiency of the process.
2. It is necessary to obtain an optimized value of particle size and cyanide concentration with respect to the cost associated with it in order to save the running cost and obtaining higher efficiency of the process.
3. Oxygen concentration did not show significant effect on the efficiency. Although, a similar optimization study for the oxygen concentration is needed for the prevention of loss due to running costs or increasing the efficiency of the process.

The conclusions from the study will help device suitable strategies for optimizing gold extraction process.

The Numerical Simulation of Pneumatic Drying of Polycarbonate in Vertical Tube

Lingqi Kong*, Shiqing Zheng

Research center of Computer and Chemical engineering, Qingdao university of science and Technology,Qingdao 266042 China

Abstract

The mathematical model of pneumatic drying of polycarbonate material in vertical tube was established based on particle dynamics and Eulerian multiphase fluid model. The numerical solution of the model showed a good agreement with experimental data obtained from polycarbonate pilot production on particle moisture and air humidity along the length. Analyses of influencing factors of gas inlet temperature, gas velocity and particle size on moisture of polycarbonate material along tube length were given. The distributions of radial parameters of gas velocity and particle temperature were illustrated. The model can be used for further investigation of the drying of particulate material of industry.

Keywords: Particle dynamics; Eulerian multiphase model; Pneumatic drying; Numerical Simulation.

1. Introduction

Polycarbonate (PC) is a transparent synthetic resin which widely used in fields of electronics, construction, aircraft, security, medical and so on(Yang Wen-hua, et al., 2010). But PC is difficult to convey and dry for two reasons, one is its thermo sensitivity (S M Liu&Y Z Zhou, 2006), the other is that many factors have important influence on the pneumatic drying process. This problem is mainly depends on experimental measurements which consume lots of valuable resource and manpower (W Namkung & M Cho, 2004). These experiments are benefit for solving some practical problems. However, the mechanisms underlying the flow regimes identified and their transition are not clearly understood, which has hindered the development of a general method for reliable scale-up, design, control, and optimization of this technology.Recently, only a few literatures dealing with pneumatic drying modeling or simulation have been published(T J Jamaleddine & M B Ray, 2010). However, no publication presents the comparison between experimental data and theoretical calculation and analysis of pneumatic drying process. In this work, pneumatic drying was conducted experimentally at the pilot scale capacity of PC.

2. Experimental Setup

Use pneumatic drying of a PC pilot as an example, the vertical tube of 15 meters length and its diameter of 0.05 meters, and there are 6 sampling points with 2, 4, 6, 8, 10, 12 meters far from its feed inlet. The experiment was conducted with the following conditions: The flow rate of PC crude material is 88.2kg/h with about 20% water content by weight; air flow rate is 50Nm^3/h with its inlet temperature 373-423K. The

* To whom correspondence should be addressed.Tel.+086(532)84022515. Fax：+086(532)84859913.E-mail: konglingqi@qust.edu.cn

water content of the sample point is the average of particle moisture which sampled and analyzed 12 times with samples interval of 0.5 hour. The temperature can be calibrated by precise instrument with 0.5K accuracy. Three different particle sizes were used: 12-18 mesh(d_S=1.5mm), 18-35 mesh(d_S=1.0mm), and >35 mesh(d_S=0.5mm).

3. Description of Model

3.1. Model Assumption

The model in this work based on the Eulerian multiphase model which assumes both phases as an interpenetrating continuum and permits the solution of the Navier-Stokes equation with the assumption of incompressibility for both the gas and dispersed phases. The other assumptions as follows: (1) the gas phase is a mixture of air and water vapor, while the dispersed phase is a mixture of PC material and liquid water, and both phases are considered incompressible. (2) There is no shrinkage of PC material, only water evaporation during the drying process. (3) The dispersed phase is of uniform size and spherical in shape. (4) Electrical and surface tension forces are absent.

3.2. Hydrodynamic Model Equations

The mass conservation equation(I Skuratovsky et al., 2003) for phase (q=g, s) is

$$\frac{\partial}{\partial \mathrm{t}}\left(\rho_q \alpha_q\right)+\nabla \cdot\left(\rho_q \alpha_q \overline{V}_q\right)=\sum_{\mathrm{p}=1}^{n} S_{pq} \tag{1}$$

Here, S_{pq} represents source term which represents the mass transfer from the *p*th phase to the *q*th phase. The momentum balance equations for the gas (g) and solid(s) are:

$$\frac{\partial}{\partial t}(\rho_g \alpha_g \overline{V}_q)+\nabla \cdot(\rho_g \alpha_g \overline{V}_q \overline{V}_q)=-\alpha_g \nabla P+\nabla \cdot \tau_g+\rho_g \alpha_g \overline{g}+\overline{\beta}_{gs}+S_{sg} \overline{V}_{gs}+\overline{F}_{vm} \tag{2}$$

$$\frac{\partial}{\partial t}(\rho_s \alpha_s \overline{V}_s)+\nabla \cdot(\rho_s \alpha_s \overline{V}_s \overline{V}_s)=-\alpha_s \nabla P+\nabla \cdot \tau_s+\rho_s \alpha_s \overline{g}-\overline{\beta}_{gs}-S_{sg} \overline{V}_{gs}+\overline{F}_{vm} \tag{3}$$

Here, $\overline{V}_{\mathrm{gs}}=\overline{V}_g-\overline{V}_s$. Wen&Yu's formula(Wen C Y & Yu Y H, 1996) was used for the drag force. Drying Model Equations:

$$\frac{\partial}{\partial \mathrm{t}}(\rho_q \alpha_q H_q)+\nabla \cdot(\rho_q \alpha_q \overline{V}_q H_q)=-\alpha_q \nabla P+\tau_q \cdot \nabla \overline{V}_q+Q_{pq}+S_{\mathrm{pq}} H_q \tag{4}$$

The species transport equation (convection-diffusion equation) was used t:

$$\frac{\partial}{\partial t}(\rho_g \alpha_g Y_g)+\nabla \cdot(\rho_g \alpha_g \overline{V}_g Y_g)=\nabla \cdot(\alpha_g \rho_g D_v \nabla Y_g)+S_{sg} \tag{5}$$

The modified k- ε model equations for the continuous phase are:

$$\frac{\partial}{\partial t}(\rho_g \alpha_g k)+\nabla \cdot(\rho_g \alpha_g \overline{V}_g k)=\nabla \cdot(\alpha_g \frac{\mu_{t,g}}{\sigma_k} \nabla k_g)+\alpha_g G_{k,g}-\alpha_g \rho_g \varepsilon_g \tag{6}$$

$$\frac{\partial}{\partial t}(\rho_g \alpha_g \varepsilon_g)+\nabla \cdot(\rho_g \alpha_g \overline{V}_g \varepsilon_g)=\nabla \cdot(\alpha_g \frac{\mu_{t,g}}{\sigma_k} \nabla \varepsilon_g)+\alpha_g \frac{\varepsilon_g}{k_g}(C_{1\varepsilon} G_{k,g}-C_{2\varepsilon} \rho_g \varepsilon_g) \tag{7}$$

$$G_{k,g} = \mu_{t,g}(\nabla \cdot \overline{V}_g + (\nabla \cdot \overline{V}_g)^T)\nabla \overline{V}_g \tag{8}$$

$$\mu_{t,g} = \rho_g C_\mu k_g^2 / \varepsilon_g \tag{9}$$

$$\tau_g = -\frac{2}{3}(\rho_g \alpha_g k_g + \rho_g \alpha_g \mu_{t,g} \nabla \cdot \overline{V}_g) I + \rho_g \alpha_g \mu_{t,g}(\nabla \cdot \overline{V}_g + (\nabla \cdot \overline{V}_g)^T) \tag{10}$$

3.3. Solution Method

3.3.1. Calculated Regional Grids

In the pneumatic drying process with high gas velocity along the vertical tube, the velocity of gas and solid particles in radial and tangential direction, cannot be affected by gravity and drag force, and be taken for zero. And the simulation of the process can be handled for a two-dimensional problem. The computational domain of the two-dimensional vertical tube was divided into non-uniform grid, with finer grid at the entrance and the maximum one less than 0.05m at the exit in the axial direction, and the finest grid was used at the wall and the coarsest one at the center with the thickness less than 0.005m in the radial direction.

3.3.2. Boundary Conditions

Uniform velocity-profile for the gas phase at the riser inlet is oriented vertically upward in the axial direction of the flow; pressure-outlet condition is specified at the riser exit. The turbulent kinetic energy for the gas phase is set as $K = 1.5(V_q I)^2$, where I is the turbulent intensity set at $I = 0.16(Re_{D_H})^{-0.125}$. The turbulent dissipation rate: $e = \rho C_u^{3/4} K^{\frac{2}{3}} / l$ C_u=0.09, l = 0.07 L, in the full turbulent development of hydraulic diameter is equal to the L. Particles are assumed to collide with the wall with a specularity coefficient φ of 0.01. There are nonslip and nonpenetrating wall conditions for the gas phase. An inelastic collision between the particle and wall is assumed with a restitution coefficient e_w of 0.6.User-defined subroutines were added to extend FLUENT capability to account for mixture properties and to simulate the drying rate for surface moisture evaporation and moisture diffusion inside the particulate phase.

4. Results and discussion

4.1. The comparisons of the model and experimental data

Fig. 1 shows the comparisons of numerical solution and experimental data about the particle moisture and air humidity along the tube length. See from Fig. 1, the drying process can be divided into two processes of constant and falling drying rates, which is dominated by the temperature difference, relative velocity, heat and mass transfer of hot gas and particles around. It can be seen that the numerical solution showed a good agreement with the experimental data.

4.2. The effect of gas temperature, gas velocity and particle size on drying

4.2.1. The effect of gas temperature on drying

Fig. 2 illustrated the variation of particles moisture along the tube length with different inlet gas temperature. The higher the inlet gas temperature the faster the drying rate during the constant-rate period and the lower the particles moisture at the entrance. So the inlet gas with higher temperature is favor of drying. But PC is prone to degradation at higher temperature. Here the inlet gas temperature 150℃ is preferable.

4.2.2. The effect of gas velocity on drying

Fig. 3 illustrated the variation of particles moisture along the tube length with different inlet gas velocity. It showed that the inlet gas with higher velocity is favor of drying. This is because the elevation of gas-solid relative velocity enhanced heat and mass transfer. But too high gas velocity makes large consumption of hot gas and energy, so the gas velocity 25m/s is reasonable in Fig. 3.

4.2.3. The effect of particle size on drying

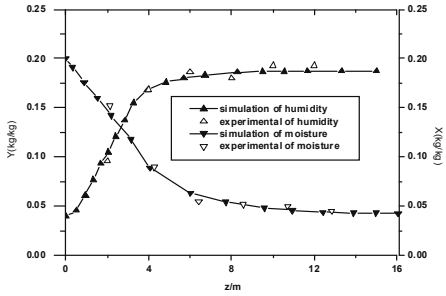

Fig. 1 Comparison of humidity and moisture

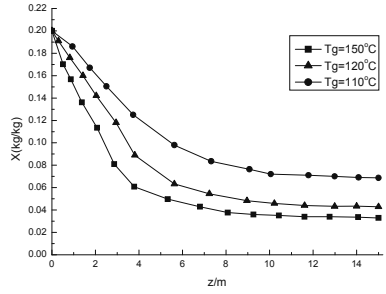

Fig. 2 Particles moisture of different T_g

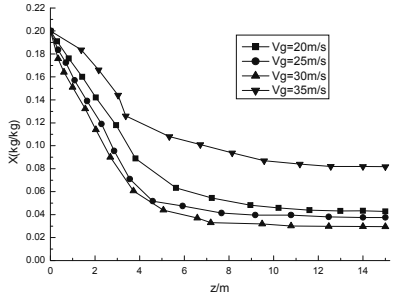

Fig. 3 Particles moisture of different Vg

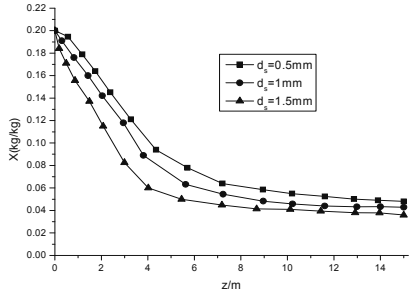

Fig. 4 Particles moisture of different d_S

Fig. 4 illustrated the variation of particles moisture along the tube length with different particle size. It showed that the smaller particle (d_S=0.5mm in Fig. 4) is favor of drying for its larger specific surface area, which intensifies the mass and heat transfer process. But at the end of tube the decrease amplitude of particles moisture is not obvious as that of the initial point. This is because larger particle, with lower velocity of upward moving and longer residence time, offsets part of the effect of contact area. But at the conveying process of higher gas velocity, the effect of gravity is secondary factor compared with drag force of hot gas.

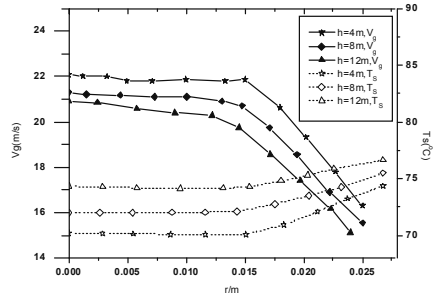

Fig. 5 The radial distributions of Vg and T_S

4.3. The analysis for distribution of radial parameters

The radial distribution of gas velocity and particle temperature is shown in Fig. 5 with different distance apart from inlet (h=4, 8 and 12 meters). It showed the gas velocity is the minimum at the wall with higher velocity gradient because the friction force of tube wall and particle surface reduces it, and on the contrary the gas velocity in the center is the maximum and has a slightly decrease around. It also showed that the gas velocity is decreased along the tube length because of the decrease of the gas temperature. It also showed the particle temperature is the maximum at the wall with higher temperature gradient. This is because the particles near the tube wall has a lower velocity and longer residence time to transfer heat and mass with gas, and has a higher temperature. It can also be deduced that particle moisture near the tube wall is lower。

5. Conclusions

The mathematical model of pneumatic drying of PC material in vertical tube was established based on Eulerian multiphase model. Model predictions showed a good agreement with experimental data, which proved that the model is reasonable and credible. The model was also used for the analysis of the effect of gas temperature, gas velocity and particle size on particles moisture along tube length in drying process and the distribution of gas velocity and particle temperature in radial direction, and reasonable explanation was given. Since the 15m vertical tube is pneumatic dryer used for the drying of PC material of a pilot production, the model can also be used for further investigation of the drying of various other materials of relative importance to the industry.

List of symbols

α_q	volume fraction of phase q	C_d	drag coefficient
d_s	particle diameter (m)	D_v	diffusion coefficient of vapor (m^2/s)
e_w	particle-wall restitution coefficient	$\overline{F}_{vm}$	virtual mass force per unit volume (N/m^3)
I	turbulence intensity	K_q	turbulence quantity of the phase q (m^2/s^2)
k_{cond}	thermal conductivity (W/(m K))	k_c	convective mass transfer coefficient (m/s)
S_{pq}	source term	X	mean particle moisture content
Y	mass fraction of vapor	V_q	velocity vector of phase q (m/s)

Abstract

Dynamic simulation and online control problems in liquid extraction columns are still unresolved issues due to the two-phase flow and the particulate character of the dispersed phase. In this work, the One Primary and One Secondary Particle Model (OPOSPM) with two autocorrelation parameters is used as an alternative to the full population balance model. The model presents the base hierarchy of the SQMOM and consists only of two transport equations for droplet number and volume concentrations. Using the full population balance model or online experimental data, the autocorrelation parameters are identified using a constrained weighted nonlinear least square method. Compared to the experimental data in RDC and Kühni columns, the autocorrelated OPOSPM predicts accurately the dynamic and steady state mean population properties with a simulation time amounts to only 3% of that required by the detailed model.

Keywords: Autocorrelation, OPOSPM, Liquid Extraction, Image Analysis.

1. Introduction

Steady state design of chemical equipment is confronted by dynamic and controllability issues. In this regard, it is often easy to design a chemical process based on steady-state conditions, which is practically uncontrollable and unrealistic. In order to avoid any wrong assumption during process synthesis and design, and to ensure safe and stable plant operation, the dynamic behavior of the relevant units should be known. Two-phase flow liquid extraction equipment is widely used in the chemical industries, which is characterized by varying time constants, inherent nonlinearities and different time scales. Population Balance Modeling (PBM) is a fast emerging mathematical framework, which takes into account different physical and chemical phenomena that lead to the evolution of the discrete particulate (droplet) phase. Despite recent progress in model development, numerical methods and the computational power of modern computers, PBM is still not widely used in process control, dynamic analysis, online and model predictive control. In this contribution we present a novel One Primary One Secondary Particle Model (OPOSPM) as the simplest case of the hierarchical SQMOM [1,2]. The OPOSPM consists only of two transport equations; namely, the continuity equations of the volume and number concentrations of the particulate phase. The source term of the number concentration transport equation contains two adjustable constants, which takes into account model deviation from the reference (detailed) population balance model. These constants compensate for model deviation due to breakage and

coalescence events and can be correlated offline using prescribed changes in the major input variables such as inlet phase flow rate and rotor speed. These constants are identified by formulating the system at hand as a nonlinear minimization problem with simple bounds on the two identified parameters. For this purpose, experimental facilities are designed to measure droplet size distribution and population mean properties under different disturbance [3,4].

2. The OPOSPM as a nonlinear autocorrelation PBM

Online autocorrelation and parameter identification using full population balance models is extremely difficult and complicated due to the increase in the size of the differential algebraic system, which governs the system dynamic behaviour. The OPOSPM [2] is modified using two autocorrelation parameters: $\boldsymbol{\theta} = [K_b \quad K_c]^{\mathrm{T}}$. In one-dimensional space the model is given by:

$$\frac{\partial \mathbf{U}}{\partial t} + \frac{\partial (u\mathbf{U})}{\partial z} = \mathbf{S}(\mathbf{U}, \boldsymbol{\theta}),\ \mathbf{U} = \begin{bmatrix} N & \alpha \end{bmatrix}^T$$
$$\mathbf{S} = \begin{pmatrix} \dfrac{u^{in}}{v_{in}} \delta(z - z_{in}) + K_b(\vartheta(\bar{d}) - 1)\Gamma(\bar{d})N - \dfrac{1}{2} K_c \omega(\bar{d}, \bar{d}) N^2 \\ u^{in} \delta(z - z_{in}) \end{pmatrix} \tag{1}$$

In the above equations, N and α are the total number and volume concentrations, which are equivalent to zero and third moment of the droplet population in the extraction column. The mean-mass droplet diameter ($\bar{d}$) is an adaptive Gauss-Christoffel quadrature node or position of the secondary and primary particles. This mean droplet diameter couples the two state variables (N and α) through the mean droplet volume. The dispersed phase velocity relative to the column walls is u, while $u^{in}$is the superficial velocity of the dispersed phase. The breakage and coalescence frequencies are $\Gamma$and ωrespectively, which are functions of rotor speed, column internal geometry and system physical properties. Due to breakage of liquid droplets by internal (turbulent) and external (rotor blade) forces, a mean number of daughter droplets (ϑ) can be statistically estimated. The reduced model above can be derived from the SQMOM by setting the number of primary and secondary particles and $\boldsymbol{\theta}$ equal to one [1,2]. As phenomenological reduced model, it is able to capture most the essential physical information contained in the full PBM and is still computationally tractable. The respective autocorrelation (learning) parameters (K_b and K_c) for breakage and coalescence kernels can be estimated off or online. In the above model, both α and $\bar{d}$ are amenable to on- and off line measurements [3,5]. However, due to the complication of optical droplet size distribution, the uncertainty in droplet mean diameter is higher than that in measured holdup. To take this into account and during model learning, a weighted least square method is used where the measured $\bar{d}$ and α are combined by forming the weighted sum of residuals:

$$\begin{aligned} &\min_{\theta} \mathbf{e}^T \mathbf{W} \mathbf{e}^T, \\ &s.t.\ \ \mathrm{Eq.}(1), \\ &\mathbf{e} = (\Delta\alpha_1 ... \Delta\alpha_{N_\alpha} ... \Delta\bar{d}_1 ... \Delta\bar{d}_{N_d}), \mathbf{W} = diag(w_1^\alpha ... w_{N_\alpha}^\alpha .. w_1^d ... w_{N_d}^d) \end{aligned} \tag{2}$$

With appropriate model functions and parameters, the model is learnt according to the formulation in (2), which can be viewed as a solution of an online inverse problem. The

diagonals in the weight matrix **W** are chosen to give less weight to the uncertain mean droplet diameter residuals. The steady state sensitivity of the model to changes in the parameters vector **θ** is derived and is found to be:

$$S_{\alpha,j} = \frac{\partial \alpha}{\partial \theta_j} = -\alpha u \frac{\partial u}{\partial \theta_j}, \; H_{j,k} \approx 2 \sum_i \frac{\partial \alpha_i}{\partial \theta_j} \frac{\partial \alpha_i}{\partial \theta_k} \tag{3}$$

where **H** is the Gauss-Newton approximation of the Hessian matrix. The Hessian matrix itself is used to estimate an order-of-magnitude confidence intervals of the learning parameters. It is interesting to note that the model sensitivity is a strong function of explicit droplet velocity [6] and is damped by the continuous phase velocity ($u = u_r - u_x$) and α. By referring to the source term of Eq.(1), it is also interesting to notice that droplet breakage tends to increase model sensitivity with respect to $K_b\Gamma$. The eigenvalue analysis of H indicates the importance of $K_b\Gamma$ and its strong dependence on the rotor speed. The detailed PBE is resolved using an extended fixed-pivot technique [6] with respect to droplet diameter and finite volume method with respect to physical space. Since droplet coalescence is highly sensitive to the hydrodynamics and physicochemical properties, interfacial dynamics and mass transfer [6], Coulaloglou and Tavlarides (1977) coalescence model had been studied to identify the two coalescence parameters, which are named here as C_1 and C_2 [7, 9]. The first parameter (C_1) appears in the droplet coalescence frequency, while the second one (C_2) is used to adjust the droplet coalescence efficiency. In the second phase, data acquisition system is needed for both dynamic and steady state measurements. Accordingly, experimental facilities are developed for online measurement of droplet size distribution and dispersion mean properties using different types of columns (Kühni and RDC). Once the OPOSPM is learnt under specified column operating conditions, it can be used effectively to predict the mean dispersed phase properties due to different external disturbances.

3. Experimental setup and particle image processing

The experimental setup is designed for online measurement and prediction of droplet size distribution and in particular transient process changes using stirred columns. For experimental determination of droplet size distribution, two techniques are used: An optical measurement and a conductivity based method. The stirred column used here is a Kühni column of 1.0 m height and 0.15 m internal diameter. The column has seven conductivity measurement points and two optical measurement points. With the optical measurement technique [4], droplets can be captured locally and temporally while conductivity technique is used to measure integral holdup. The images obtained by the image analysis method are evaluated by algorithms based on population moments. The core elements are a segmentation followed by Euclidean distance transformation [8]. The centres of the circles are allegorised by the maximum distance to the background. Because of separation difficulties of overlapping circles, an implementation of watershed segmentation algorithm is used. Thus the setting, position and radius of droplets in the image can be found. The approach allows reliable online analysis of more than 300 droplets per image in transmitted light mode and up to 3-5 pictures per second (online, single-core) with concentrations up to 15% (vol./vol.) with a relative error less than 5% [3]. Due to restrictions of image analysis and camera speed, duration of measurement is in the range 5-10 seconds per measurement point. This corresponds to 15-50 pictures in online and 150-300 pictures in offline mode per measurement point.

4. Results and Discussion

In the steady state learning phase of the model, the OPOSPM and the full PBM are both tested using the chemical system toluene-water in a pilot plant RDC column (80 mm diameter). The steady state experimental data [5] on α and $\bar{d}$ are used first in the detailed PBM to estimate the Coulaloglou and Tavlarides (1977) model parameters. This results in values of $3.41\times10^{-2} \pm 2\times10^{-3}$ and $1.33\times10^{11} \pm 1\times10^{6}$ m^{-2}, which corresponds to 95% confidence interval for C_1 and C_2 respectively. The eigenvalues of the Hessian matrix are 1.0 and 4.6×10^{3} approximately, indicating that the objective function is not very sensitive to changes in the parameter C_2. Following the published literature on C_2, this parameter is held constant [7].

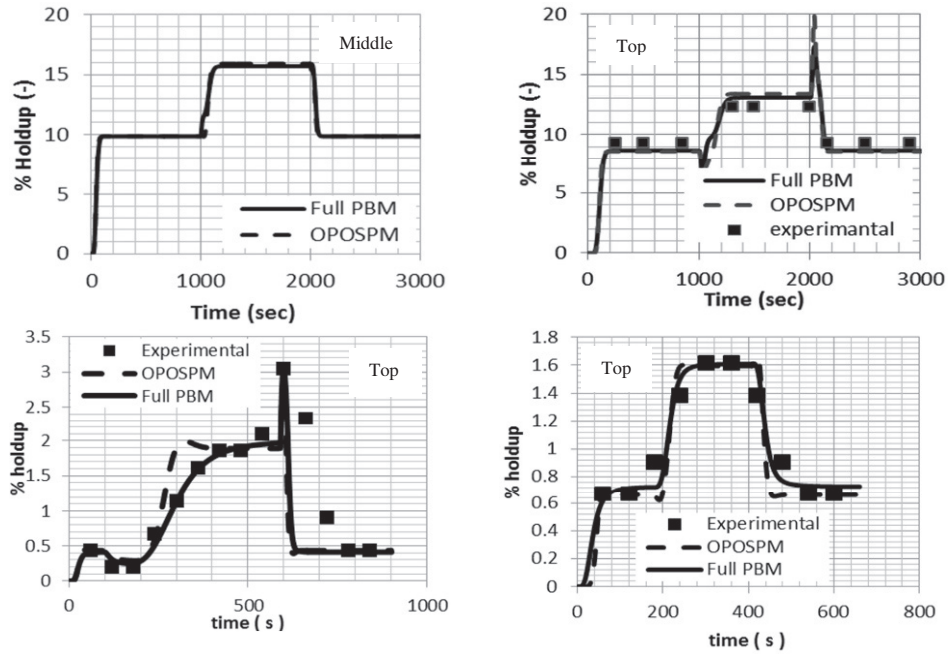

Figure 1: Simulated mean holdup using the OPOSPM compared to the full PBM and experimental data in RDC (upper panel) and Kühni (lower panel) extraction columns.

In the second phase, the model with optimal C_1 and C_2 is learnt using Eq.(2) at two different steady states along the column height with 200 and 400 rpm rotor speed. The weights, which appear in Eq.(2) are set to 0.65 for α and 0.35 for $\bar{d}$. The estimated parameter vectors $\boldsymbol{\theta}$ are [0.10 2.4] and [0.21 2.4] respectively. It is clear that droplet breakage increases due to the increase of the energy dissipated in the continuous phase at high rotor speed. The upper panel of Figure (1) shows the response of the dispersed phase holdup (α) due to rectangular pulse (200-400-200 rpm) in rotor speed. The OPOSPM of Eq.(1) follows accurately the detailed model at the middle and top of the column. The sharp changes in the dispersed phase are due to the hyperbolic structure of the system (1). At the beginning, the sudden decease of the droplet size at the distributer results in increased phase holdup at the bottom of the column, which results in a decrease of the effective continuous phase velocity. This in effect increases the effective velocity of the continuous phase and hence the holdup is decreased. As the disturbance propagates along the column, the dispersed phase increases everywhere and rises

gradually to its final steady state. The reverse occurs due to a negative step change in rotor speed(at ≈ 2000 s). The experimental data of Garthe (2006) are at steady state, and therefore the inverse response due to step changes in the rotor speeds could not be verified. To verify this interesting behavior, a dynamic experiment is designed using 150 mm diameter Kühni column with column geometry as stated in the previous section. While the column is at steady state (80 rpm, 170 & 11.2 liter/h for the continuous and dispersed phases respectively) a rectangular pulse (80-160-80 rpm) in the rotor speed is introduced. The OPOSPM was learnt at steady state with parameters: $K_b = 1.4$ and $K_c = 2.551$ using the measured holdup (α). The mean inlet diameter is held approximately constant at 1.8 mm using toluene as the dispersed phase in water and the optimal C_1 is $4.5 - 250.0 \times 10^{-3}$ and C_2 is held constant as in the first case. Note that the change in breakage frequency as function of rotor speed compensates for any extra change in K_b, while C_1 reflects the change in coalescence frequency. Fig.(1, lower panel) compares the experimental and the OPOSPM simulation of the dispersed phase holdup. The inverse response is clear at both corners of the rectangular step change and the OPOSPM follows the experimental data fairly well. In the last panel of Fig.(1), the dynamic response of the dispersed phase holdup due to a rectangular pulse in the dispersed phase rate (7.5-14.9-7.5 liter/h) is measured. The rotor speed is kept constant at 120 rpm. The solid line is the OPOSPM simulation with constant learning parameters $K_b = 1.4$ and $K_c = 2.551$ and $C_1 = 3.55 \times 10^{-2}$. As can be seen, the agreement between the dynamic data and model prediction is excellent. Furthermore, K_b, K_c and C_1 are clearly insensitive to the dispersed phase flow rate as expected [9]. This is because both breakage and coalescence frequencies are not strong functions of the dispersed or continuous flow rates. The simulation shows that the OPOSPM can simulate the column mean properties with a simulation time amounts to only 3% of that required by the full model. Furthermore, the optimization algorithm based on the interior-point method in MATLAB, is found to converge in a few iterations (5-8) with CPU time about 1.3 seconds on a laptop of 2.4 GHz speed.

5. Conclusions

The OPOSPM with two learning parameters is used for off- and online dynamic and steady state simulation of particulate flow in liquid extraction columns. These learning parameters are successfully autocorrelated using a weighted nonlinear least square optimization subject to a nonlinear differential system constraint. The OPOSPM can easily predict the mean dispersed phase holdup along the height of extraction column, with a simulation time not greater than 3 percent of that required by the detailed model. The the present reduced OPOSPM with autocorrelation parameters can be used for solving online inverse problems and model predictive control strategies.

The Simulation and Analysis of Coal to Liquids Processes

Li Sun, Robin Smith

Centre for Process Integration, School of Chemical Engineering and Analytical Science, University of Manchester, Manchester, M13 9PL, UK

Abstract

Coal to liquids process is becoming industrially important for chemicals production and the cogeneration of electricity. The tail gas treatment and process syngas consumption lead to different polygeneration arrangements. In this paper, CTL process integrated with the utility system are simulated, and three configurations with different tail gas treatment are analyzed. The tail gas as fuel in the utility plant can satisfy process power and energy demands and create a surplus.
Keywords: CTL, polygeneration, Fischer-Tropsch, reforming, tailgas

1. Introduction

With the rapid rise in the crude oil price, coal to chemicals and liquids oil (CTL) through Fischer-Tropsch (FT) synthesis is increasingly being exploited and becoming a priority, especially in the United States and China [1].

CTL process basically includes raw synthesis gas production, syngas purification for to meet FT synthesis requirement and the liquids oil production. The tail gas from FT synthesis, mainly containing CH_4, CO, H_2, CO_2, can be used as fuel and combusted in gas turbines or boilers for power and heat generation in the utility plant. Coal to chemicals production with cogeneration of electric power means polygeneration. In addition, the components CO and H_2 in the tail gas are syngas key compositions for FT synthesis, and their recovery and recycle would be beneficial for liquids production.

In this paper, based on the simulation of CTL integrated with the utility system, different CTL configurations are analyzed from the view of liquids oil production, process power demands, and power generation in the utility plant.

2. Process configurations

Figure 1 shows the CTL flowsheet blocks. Syngas consumption and tail gas treatment would allow various CTL configurations.

2.1. Syngas for power generation and chemicals production

The syngas for the FT liquids production is involved in the typical CTL process. If the syngas is only for power generation, it is so called Integrated Gasification Combined Cycle (IGCC) [2]. In this paper, only the first case is studied.

2.2. FT process tail gas treatment

FT process tail gas contains CO, H_2, C1-C4 light alkanes, and a small amount of heavy alkanes. There are three ways to treat this tail gas.

1) The tail gas is fully burnt as fuel in gas turbines for power generation or in boilers for very high pressure (VHP) steam generation in the utility plant.

2) The components CO and H_2 in the tail gas are recovered and recycled to the FT synthesis by separation units. H_2 recovery is carried out by membrane separation, and CO by pressure swing adsorption (PSA) [3]. This recycle can be achieved because there

are no components in the tail gas to poison FT catalysis reaction. It is beneficial for FT production profit with the recourse of supplying extra fuel in the utility plant.
3) The tail gas is fed to the reforming process to regenerate more CO and H_2 from C1-C4 alkanes in the tail gas, and recycle these CO and H_2 to the FT synthesis.

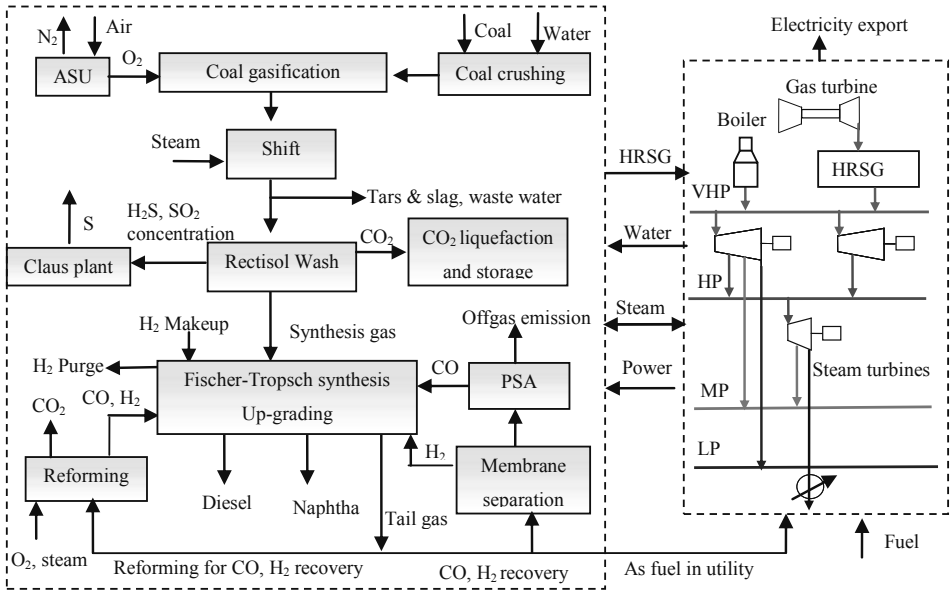

Figure 1 CTL flow sheet blocks

3. Process simulation

In this paper, both the liquids oil production process and utility system are simulated as an integrated system to provide streams detail, process heat and power demands, utility system energy and energy supply or further process analysis and optimization.
The CTL production and tail gas recovery processes are simulated and fully converged using Aspen Plus. The utility system simulation is carried out with the software 'STAR' developed by Centre for Process Integration, University of Manchester[4], which has been verified and utilized in industrial projects.

3.1. Liquids oil production

An air separation unit (ASU) supplies O_2 for the coal gasification and N_2 mainly as diluent gas for NO_x control in gas turbines for power generation. ASU contains units of air pre-treatment, air cooling, liquefaction, and cryogenic air separation.
Coal gasification is operated for the syngas production from the coal slurry and oxygen in the gasifyer at a pressure of 5.6MPa [5]. The gasification temperature is about 1350°C. Before the coal is fed to the gasifyer, it is crushed to the required particles sizes. The gasification reactions are shown in equations (1). The raw syngas consists primarily of H_2, CO, water steam, CO_2, with small amounts of H_2S, COS, CH_4, Ar and N_2.

$$C + 0.5\ O_2 \rightarrow CO$$

$$C + O_2 \rightarrow CO_2$$

$H_2 + 0.5\ O_2 \rightarrow H_2O$
$C + H_2O \rightarrow H_2 + CO$
$C + 2H_2O \rightarrow 2H_2 + CO_2$ (1)

A 2-stage sour shift unit is for the syngas production with the required molar stoichiometric ratio (SR) of about 2. SR is a key value for the syngas composition for the following liquids FTproduction. Equation (2) shows the shift reaction.

Molar Stoichiometric Ratio, SR $=H_2/CO$

The shift reaction: $CO + H_2O \leftrightarrow H_2 + CO_2$ (2)

Raw syngas purification includes acid gas removal by Rectisol wash technology, and sulphur recovery in a Claus plant [6]. Rectisol wash is a physical absorption process by removing H_2S, COS and CO_2 at very low temperature (-54°C) and higher pressure (33 MPa) with methanol as solvent[7]. It consists processes of sour components absorption, solvent regeneration and dehydration. In terms of the units operation, they are flashing, stripping, rectification, and heat exchange. The purified syngas is FT synthesis feed. The H_2S and SO_2 concentration stream is converted to sulphur by high temperature thermal reaction and lower temperature catalytic reaction (equations (3-4)) in the Claus plant. CO_2 offgas, almost free of H_2S, is compressed to 8.0 MPa for underground storage.

Oxidation stage: $H_2 + 0.5O_2 \rightarrow H_2O$
$CO + 0.5O_2 \rightarrow CO_2$
$CH_4 + 2O_2 \rightarrow CO2 + 2H_2O$
$H_2S + 1.5O_2 \rightarrow SO_2 + H_2O$
$2NH_3 + 1.5O_2 \rightarrow N_2 + 3H_2O$
$COS + 1.5O_2 \rightarrow CO_2 + SO_2$ (3)

Catalytic stage (Sulphur forming) : $2H_2S + SO_2 \rightarrow 3S + 2H_2O$ (4)

FT synthesis plus product upgrading is to produce liquid transportation oils from the cleaned syngas. To obtain long-chain alkane products (more diesel and Naphtha oil production), the high-temperature FT synthesis with Fe or Co catalyst is carried on at about 320°C[8].

3.2. Tail gas recovery

For the tail gas direct recovery and recycle process, H_2 is recovered through a membrane module made from Polyimide (PI) at the permeating pressure 2.9 kPa(g). PSA for CO recovery adopts 5-1-1/RP VPSA technology with Cu^+Y sorbent at the entrance pressure of 0.8 MPa(g). The recovery efficiency of H_2 and CO is 93.3% and 85.6% respectively.

The auto thermal reforming reaction would convert C1-C4 alkanes in the tail gas into extra CO and H_2 reacted with pure oxygen and steam at 300°C, 3.0Mpa. C1-C4 alkanes conversion ratio is 97.3%. The mol fraction of CO in the tail gas rises from 12% to 28% after reforming, and H_2 from 16% to 56%. The gas after reforming would remove H_2O by flashing and CO_2 by Rectisol wash before recycled to the FT synthesis. The followings are reforming equations.

$CH_4 + H_2O \rightarrow CO + 3H_2$
$CH_4 + 0.5O_2 \rightarrow CO + 2H_2$ (5)

3.3. Utility system

The utility system is the process of fuel combustion for steam and power generation. The fuel would be natural gas, coal, tail gas, etc.

The tail gas or fuel is fully burnt in gas turbines (GT) for power generation or in boilers for very high pressure (VHP) steam generation. The exhaust from GT generates VHP steam in heat recovery steam generators (HRSG) and distributes to multi-pressure-level

steam network through steam turbines and letdowns for the process heating demands or expands in steam turbines (ST) for extra power generation.

4. Process analysis

For the different options in a polygeneration arrangement, the liquids production processes are similar, but the tail gas treatments and utility fuel consumption would result in variations of process steam and power demands, chemicals production, CO_2 capture and storage, and utility system power and heat generation.

The feed coal contains carbon 58.9%, ash 5.6%, moisture 20.0%, and others 15.5%. Main feeds and products data are listed in Table 1. Table 2 gives the tail gas data. Power demands in the CTL process are shown in Table 3.

Table 1 Main feeds and products data

		Mass Flow, kg/h
Feed	Coal	1.05×10^5
	O_2 from ASU	7.36×10^4
Semi product	Syngas (FT Feed)	7.26×10^4
Liq products	Diesel	1.47×10^4
	Naphtha	6.81×10^3
Tail gas from FT	As fuel in utility plant	1.88×10^4
CO_2	CO_2 storage	1.136×10^5

Table 2 Tail gas data

Refrigerant Power	Refrigerants generation	1.01×10^4
FT	Process pumps. etc	3.22×10^3
Site demand	Pumps of BFW, CW, effluents, air fans,etc.	3.73×10^4
Total		5.67×10^4

Table 4 Products prices

	Price
Diesel, US$/ton	1234
Naphtha, US$/ton	1277
Coal, US$/ton	159
Electricity, US$/kwh	0.087

Three CTL configurations with different tail gas treatment are analyzed from the view of liquid products, CO/H_2 recovery, process power demands, fuel supply to the utility plant, and power export to the grid.

Table 4 lists the products prices data. Table 5 gives the comparisons of CTL with different polygeneration arrangements.

From Table 5, it is clear that the tail gas as fuel can satisfy the CTL process power and heat requirement and export extra power to the grid. It is also the simplest flowsheet compared with other two configurations without extra tail gas separation units. Considering products benefit and utility costs, the last configuration of tailgas reforming for more CO and CH recovery would generate 2287 US$/h more than the first

configuration with the compensation of extra reforming unit and complex operation. What is more, CO_2 emission in the 3rd configuration increasing 8.4% with the comparison of the 1st configuration means greater environmental burden and less carbon conversion. However, with flexible products prices and fuel supply, the last two configurations could also challenge.

Table 5 Comparisons of CTL with different polygeneration arrangements

Tail gas treatment		As fuel	CO, H_2 Direct recovery	Reforming + CO, H_2 recovery
Liq products, kg/hr	Diesel	1.47×10^4	1.47×10^4+413	1.47×10^4+3596
	Naphtha	6.81×10^3	6.81×10^3+187	6.81×10^3+1664

* Process income=Liquids benefit (Diesel, Naphtha) + Power export income –fuel supply cost

5. Conclusions

Considering the Integration of the CTL process with the utility system, different tail gas treatment would cause several of polygeneration arrangements. The CTL configuration of the tail gas as fuel in the utility plant is energy/power self sufficient. The tail gas recovery is beneficial for liquids production with additional fuel supply to the utility plant as pension. The tail gas reforming process can realize more CO and H_2 conversion and recycle with extra reforming units as recourse.

The choice of the available configurations would be helpful for the products and power production balance to meet flexible market changes.

Abstract

The electrification of vehicles presents a viable solution towards the reduction in reliance on fossil fuels and greenhouse gas emissions. However, the electrification of public bus transportation requires making several key decisions on the form of technology selection, operation requirements and cost management. An agent-based multi-paradigm modelling framework is proposed to enable detailed analysis to support this decision process. In this work, a framework for the modelling of a bus depot undergoing electrification is presented along with a modest example.

Keywords: Electric Vehicles, Public Buses, Agent-Based Modeling, Electrification

1. Introduction

Historically, gasoline and diesel fuels have been used for transportation, but the possible decline of oil supplies in the future is forcing nations to consider alternative fuels. Electric Vehicles (EVs) are viable options that can help reduce the dependence on these fossil fuels. Public transportation is an integral part of the transportation network in most major cities. The electrification of this network could potentially help both to generate significant cost savings and to achieve reduction in greenhouse gas emissions.

The electrification of this system represents a major investment and careful management of this transition is crucial in avoiding unwanted costs. Furthermore, the management of an electrified fleet poses increased challenges in resource management, requires new approaches to bus scheduling, and careful selection and maintenance of these new technologies. Although there have been abundant research conducted in the operations and management of traditional bus depots and interchanges, the electrification of such systems may require new and innovative ways in analysis.

2. Background

A literature search reveals that the body of literature available that is related to the electrification of public transportation systems, especially mass transport systems like public buses is quite limited. Most of the literature on the electrification of the transportation fleet has focused on the electrification of private vehicles or more conventional hybrid vehicles. Certain niche markets such as transforming school buses(Sadiq et al., 2007) and trolley buses(Leo, 2010) into Plug-in Hybrid Electric

Vehicles (PHEVs) have been examined, although the operation and optimization of such systems have not been analyzed. Sinhuber et al. have discussed the conceptual technical requirements of electric buses needed for public transport electrification. They have found that the shallow cycling of batteries would be the optimal for the preservation of the batteries and allow for lower overall costs, analysis of bus schedules could further help in reducing operational costs(Sinhuber et al., 2010).

3. Methodology

Agent-based modelling approaches are composed of interacting, autonomous agents; which through their interactions can give rise to patterns, structures and behaviours that were not explicitly programmed into the models(Macal and North, 2010). The electrification of a bus depot allows for a natural formulation in which electric buses and the charging stations are treated as intelligent agents capable of making charging and route decisions. Eventually, the framework could be extended to passengers and bus drivers allowing for even more in-depth analysis into operations management.

An agent based, multi-paradigm modelling approach is proposed for the analysis of the electrification of a public bus depot. This approach has been successfully used in the analysis of energy systems (Hodge et al., 2011). In this study we are proposing to adapt that framework to the analysis of a bus depot. The overarching framework for the analysis of such a scenario can be seen in Figure 1. The depot would consist of a fleet of public buses that could either be an electric vehicle or conventional diesel bus. Charging structures would need to be installed to ensure smooth operation of the vehicles. A central scheduling agent would seek to optimize and coordinate vehicle flows in and out of the depot. An overall optimization engine for the simulation would be used to determine optimal policy and operational parameters.

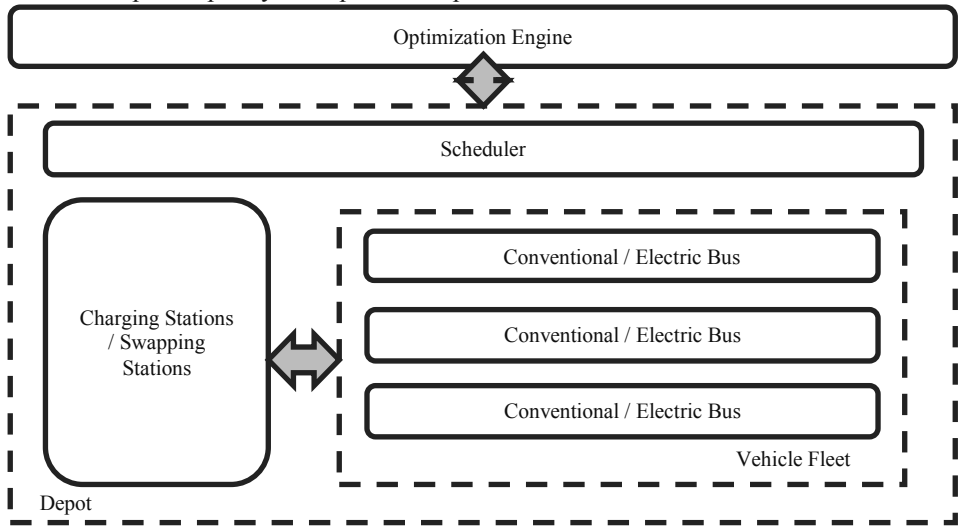

Figure 1: Simplified framework for the analysis of the electrification of a bus depot

In this paper, we would examine in detail the framework for the electrification of an agent based bus depot, specifically the framework for the buses and charging stations. There are several competing technologies that would be available for such an analysis and the model should provide for such competing alternatives.

3.1. Buses

A basic schematic diagram of an electric bus is shown in Figure 2. The agent at any time could be in any of the four states. It starts a daily cycle in a home bus depot until its scheduled departure for a route. It could be assigned an inter bus depot route which brings it to another bus depot or a loop service which brings it back to the bus depot. Once back at the home depot, it would check if it would need to replenish its battery charge or go back to waiting for another scheduled departure. A central planning agent could modify its pre-determined schedules to meet certain operational benchmarks.

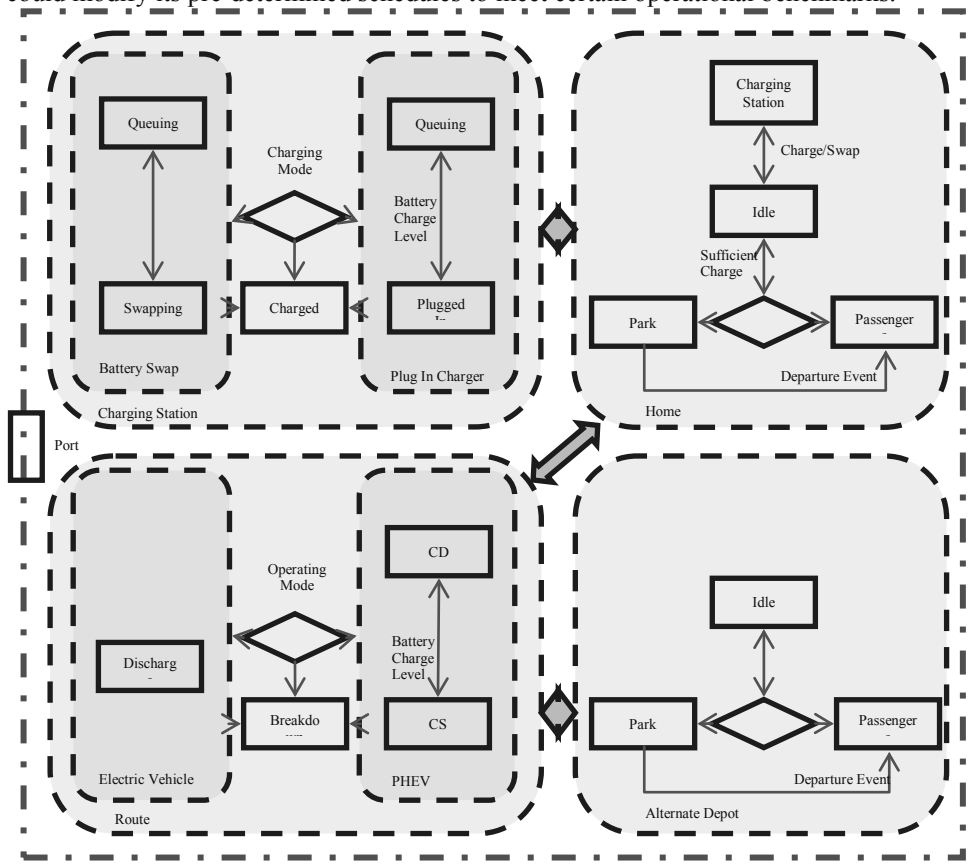

Figure 2: Schematic diagram of an agent electric bus

the form of a decision variable during optimization. a pure Electric Vehicle (EV) or a plug-in version (PHEV). An EV has the advantage of potentially not emitting any greenhouse gases. However, an EV could be hampered by its limited range which restricts its applicability in long-distanced routes originating from the bus depot. A PHEV has an alternative fuel supply on board which it could tap on to extend its electricity range; however, it potentially does this through consuming fossil fuel which produces greenhouse gas emissions. The PHEV operates on two modes, a Charge Depleting (CD) mode which utilizes only electricity for mobility and a Charge Sustaining (CS) mode which uses an alternative fuel for locomotion. There could be two configurations for a bus, a 12 meter conventional bus or an 18 meter articulated bus. A 12 meter electric bus would consume on average 1.8 kWh/km while an articulated one would consume about 2.75 kWh/km (Sinhuber et al., 2010). During its

CS mode, a PHEV bus can be assumed to consume similar amounts of fuel as a PHEV school bus at about 8 miles per gallon or 3.4 kilometers per liter (Pritchard and Johnson, 2004).

3.2. Batteries and Charging Infrastructure

The batteries considered in this study are lithium-ion based technologies, however at the level of detail appropriate for this study, consideration of specific chemistries is not of primary importance (Dinger et al., 2010). Battery costs are estimated to be around US$1000 per kWh at the moment but are expected to reach US$500 by 2020 (Dinger et al., 2010). Due to weight limitations, the capacity of batteries would be limited to 200 – 250 kWh(Sinhuber et al., 2010). It has been suggested that the optimal Depth Of Discharge (DOD) of batteries should not be more than 16%(Sinhuber et al., 2010); however, this may not be applicable to all battery chemistries(Peterson et al., 2010). Efficiency of batteries were assumed to be 95%(Joos et al., 2010). Charging of batteries could be either through level 2 or level 3 chargers and their specifications can easily be found in literature(Santini, 2010). Potential costs for level 2 charging stations could range from $700 to $4000 while level 3 stations could cost upwards of $35,000 each (Santini, 2010). Battery swapping is another viable alternative to plug-in chargers with the potential of recharging a bus in just several minutes. The estimated cost for a vehicle swapping station could be as high as $500,000 (Yarow, 2009).

4. Applications

4.1. System Policy Applications

Investment planning problems could be investigated using this framework. An example case would be the comparison of investment options between public transport alternatives such as public buses and taxi fleets. Utility level analysis such as capacity planning, transmission planning and rate tariff formulations could be conducted. Secondary usage policies, such as battery leasing strategies, peak energy management which can help subsidize these investments could also be examined.

4.2. Operational Applications

Operational issues related to the operation of an electrified bus depot could also be studied. These studies could be related to optimal resource allocation in investment planning, such as the number of buses to retrofit/procure, number of charging points, stations to build, number of routes to electrify and even additional manpower resources needed. All these parameters could be optimized such that operational benchmarks for a bus depot like punctuality, breakdown rates, are maintained when compared to a conventional bus depot.

4.3. Sample Scenario

A conventional bus depot in Singapore was used as a sample case for the framework. The bus depot selected was the Woodlands bus depot in Northern Singapore (SMRT, 2012). The depot has 21 routes that could be electrified. As a demonstration case, 7 routes with short loops were selected to be electrified. In order to maintain operational benchmarks, different numbers of charging stations were compared with the minimum charge level required for buses during operation. The benchmark that was considered was the percentage of missed or late departures to within 5 minutes of scheduled departures from the depot. Table 1 shows a summary of results with different operational parameters.

Table 1: Percentage of missed or late departures from depot with different operational parameters

		Minimum Charge Level				
		0.9	**0.8**	**0.7**	**0.6**	**0.5**
Charging Stations	**5**	4.37%	3.30%	3.04%	2.85%	2.50%
	4	11.63%	4.83%	3.81%	3.17%	2.78%
	3	26.97%	16.13%	11.32%	8.15%	7.77%

The operational target was 15% in 2008, with actual operations at 0.06% (SMRT, 2009). With 7 routes electrified, 4 charging stations are needed to bring the operational figure below 5% but not to current levels. This could represent a challenge to the optimization problem and would be discussed in more detail in a future publication.

5. Conclusion

Electric vehicles have the potential of replacing diesel powered public transportation in the future. In order to aid in the transition of this sector while conserving resources, detailed analysis of electrification is not only needed, but crucial. In developing such a tool, an adaptation of our previous agent-based multi-paradigm modeling framework is proposed. In this work, the approach is illustrated with the case of a bus depot undergoing electrification is presented.

Modeling and Control Challenges in the development of Discrete Microfluidic Devices

Jeevan Maddala,a Raghunathan Rengaswamy,a *
a Department of Chemical Engineering; Texas Tech University; Lubbock, Texas, USA

Abstract

Droplet-based microfluidics is an emerging area that has important applications in chemical engineering and several other disciplines. For example, these devices have applications in the areas of bubble computers, cancer diagnostics and development of microfactories on a chip. Some of the challenges that need to be overcome to realize the potential of this area are related to experimental uncertainties and development of devices that offer multiple functionalities, thereby reducing the footprint and aiding in miniaturization. Achieving precise functionalities in microfluidics is challenging because droplets exhibit complex dynamic behavior in these devices due to hydrodynamic interactions and discontinuities that are a result of discrete decision-making at junctions. Remarkably, transitions from periodic to aperiodic/chaotic behavior based on input conditions can be witnessed even in a simple loop device. Hence rational design frameworks that handle this complexity are required to make significant progress. Further, passive designs that achieve such functionalities might entail large footprint. As a result, active control might become a necessity for developing efficient device designs. The main purpose of this paper is the identification of the challenges and opportunities for the PSE community in this area of emerging importance. Further, our work in the area model predictive control (MPC) for active control in a microfluidic loop device will also be briefly described.

Keywords: Droplet microlfuidics, modeling and control, model predictive control

1. Introduction

Droplet based microfluidics forms the basic building block for lab on chip devices. In droplet microfluidics, discrete volumes (droplets) are produced using immiscible fluids. These droplets provide a unique environment for conducting reactions or producing concentration gradients with high precision. Droplet based microfluidic devices have been used in protein crystallization (Zheng et al., 2004), high throughput screening of cells (Brouzes et al., 2009) and single cell analysis (Huebner et al., 2007). The attractiveness of these droplet microfluidic devices vis a vis microfluidic devices stems from the fact that droplet based devices offer precise control of flow without the attendant scaling issues of general microfluidic devices, where the device size scales linearly with the number of experiments/tasks that need to be performed. Since droplet microfluidic devices use discrete flows, a large number of reactions/experiments can be performed without increase in size or complexity (Teh et al., 2007). As a result, several lab-on-a-chip applications with reduced footprint can be realized. From a chemical engineering perspective, these devices could provide breakthroughs in the development of microprocessing facilities that are relevant for high value and hazardous applications. For such applications, development of

*raghu.rengasamy@ttu.edu

rational design and control frameworks is still in its infancy. Almost, all of the developments in the area of systems engineering are likely to find applications in this exciting new area. The aim of this brief conference paper is to discuss some of the promising PSE tools that are directly relevant in the area of discrete droplet based microfluidics. Given the limited space, it is not possible to provide an exhaustive account of the various themes in PSE that we believe are relevant in this area. The intention is then to describe some of the interesting application concepts and also tie that with our ongoing work in this field.

2. Modeling opportunities

We envisage a microfactory in a discrete microfluidic platform to consist of a large of number of operational units that are tightly interconnected and form a network akin to a large chemical engineering processing facility. Similar to the tremendous impact simulation and modeling tools such as ASPEN/gPROMS have had in typical chemical engineering facilities, we expect discrete bubble microfluidic simulation tools to have an analogous significance. One of the main challenges is to conceptualize a discrete microfluidic network as consisting of repeating model fragments similar to the mass, momentum and energy transfer devices that one routinely encounters in chemical engineering problems. There are unique challenges that are related to the identification of a compact set of fundamental unit operations. One set of basic operations in droplet based microfluidic systems consists of droplet generation, droplet sorting, droplet merging, droplet splitting, droplet transporters and droplet storing units. These operations can be combined to produce various microfactory designs. An associated challenge is the development of computationally tractable models for these operations. One direction is the development of CFD models for these operations but that might not be very useful for design and control studies. Another approach is to develop conceptually simple models that are able to capture the rich dynamic behavior of these systems. A striking example of such a model development is the network model for droplet dynamics in a simple loop device that was proposed by Schindler and Ajdari (2008). This simple model based on resistive network ideas is able to explain complex and rich nonlinear behaviors that are experimentally observed (Jousse et al., 2006). This model is also extremely useful for design studies as discussed in Maddala and Rengaswamy (2012). However, this simple model might not be sufficient for online control, where the impact of the so called "thinking time" (Epstein, 2007) at the entrance of the loop device might be significant. A challenge and an opportunity then is to be able to enhance these models to higher fidelity levels without losing their computational tractability. Further, such simple models need to be developed for other operations that are relevant from the viewpoint of microfactory design.

3. Control opportunities

Control challenges abound in this area. Precise control is required in almost all the unit operations such as droplet generation, droplet sorting and droplet merging. In case of droplet generation, achieving uniform droplet size is contingent on achieving precise control over the size and shape of the droplets. Since droplets are used for drug discovery and biosensing, uniform dosing and concentrations must be ensured (Teh et al., 2007). Traditional approaches in particle formation result in broad particle size distribution, whereas droplet based systems produce monodisperse droplets with less than 1% size variations (Teh et al., 2007). Most of the droplet generation techniques use syringe pumps, where the oscillations in the pump can affect the droplet production. Further, the droplets present

in the channel can affect the upstream droplet production due to the resistance change that the syringe pump encounters. As a result, producing a large number of uniform size droplets is a challenging problem. A good model for this system and a feedback control strategy to manipulate the bulk and dispersed phase flows could be a worthwhile research direction.

Similar to droplet production, droplet sorting is an important task for high throughput screening of cells. The maneuvering of droplets to various branches of a network either by an external force or by incorporation of a moving component in the network are classified as active techniques. In droplet microfluidics either external valves or electrodes are used as active components. Valve mechanism demonstrated by Abate and Weitz (2008) is an example of active sorting. The valve constricts the flow in the channel thereby modulating the instantaneous flow the droplets face as they move through the channel. This idea can then be used to sort the droplets to different arms by manipulating the differential resistance that they encounter. Through this approach (Abate and Weitz, 2008), sorting error was shown to be less than 0.001% and droplets are sorted at a rate of 250Hz (Abate et al., 2010). Only basic on/off control is performed using this valve. To perform more complex tasks a good model of the valve needs to be developed and the droplet motion in the bifurcating channels needs to be studied. A passive device to sort droplets is developed by Cristobal et al. (2006). This device sorts the droplets alternately into the right and left branches. The article highlights the importance of incorporating a bypass near the bifurcation, which impacts the sorting scheme. When more droplets enter the channels, the decision is based on the least resistance branch. Having bypasses ensures that the decision is based only on one droplet at a time as once the droplets move past the bypasses, the resistances of both the branches as viewed from the bifurcation point are equal. Passive techniques such as these, while appealing due to their simplicity, might lack the ability to handle broad range of flow rates and disturbances in the input flows.

We now discuss MPC implementation for a particular application system to highlight the opportunities and challenges in the design and validation of model-based active control strategies in this area (Maddala et al., 2011a,b). We consider the task of sorting and synchronization of droplets to explain the model predictive control framework. We do so by considering a simple fluidic loop with two actuators and develop model predictive control strategies to achieve droplet sorting, synchronizing and merging tasks similar to that depicted in Fig. 1. The passive synchronizer (Prakash and Gershenfeld, 2007) design assumes that the black and white droplets arrive in two arms, whereas a single arm delivers the droplets into the loop device. Hence, the loop is required to perform a more complicated function which is a combination of sorting and synchronization. Clearly, a loop device with no active control will not perform either the sorting or synchronization. There are several questions that need to be answered for a solution to this active control problem. The first pertains to the mea-

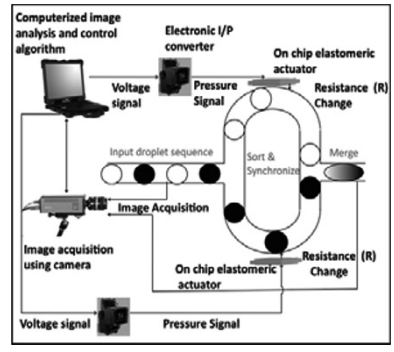

Figure 1. Possible implementation of model predictive control on loop device

surement and actuation strategy. As shown in Fig. 1 we propose an image processing system as the measurement technology. This system would allow online calculation of all droplet positions in the loop within the viewing area of the microscope. This measurement system will be able to sense the two critical parameters that are required for the sort-synchronize operation. The system will be able to specify which droplet (B/W) is entering the system and will also provide all the droplet positions in the system. From this, the controlled variable, which is the projected time difference between the exit times of the droplets at the upper and lower arms, can be calculated. The actuation for this problem will be realized using on-chip elastomeric valves. Given that valve control can be achieved experimentally, hydrodynamic resistance of any section in the loop can be actively manipulated. The next question relates to the choice of an appropriate algorithm for active control. We argue below that standard PID type control is not suitable for our purpose. First it becomes apparent that sorting control requires modulation of resistances in both the arms. This is because it is not possible for the microvalve to decrease the resistance below the inherent branch hydrodynamic resistance, but only increase. As a result, the sort-synchronize control would require two types of actuation. One is logic actuation where a resistance change is made whenever a droplet is at the entrance. Based on the current hydrodynamic resistances, the resistance in the arm that the droplet is not supposed to enter is increased than the other arm. It is clear that precise estimate of resistances through a physics-based model can help reliably perform this control. We further note that the idea of steady-state gain and time constant used in typical PID tuning are not applicable to this problem. This is because output time periods can show multiplicities in response to changes in the inputs. Further, the notion of steady-state is not valid as the output switches between different periods. Lastly, the system is highly interactive in the sense that changing the resistance in any one of the arms affects the droplet behavior in both the arms. All of these reasons basically rule out any simple PID type control and also any purely data driven model based control. A predictive controller is required. The main objective in MPC is to maintain outputs at their set points through the use of manipulated variables (actuators). MPC possesses the following important attributes: (i) simplicity, (ii) richness to solve a variety of control problems, and (iii) constraints handling (equipment constraints, operational constraints) These attributes make MPC an attractive choice for control of discrete microfluidic systems.

Notice that while the preliminary work published by Maddala et al. (2011a) demonstrates the promise of MPC based active control, there are several aspects that need to be studied further. These are: (i) How robust is the MPC to uncertainties in the droplet sequences and inlet arrival times? If one used an enhanced model would the MPC still work? What effects of the physical process (such as droplet resistance varying with flow, thinking time) are important to be included in the internal model that the controller uses yet still generate acceptable control results? These are computational questions that require considerable further work before resolution. Another major challenge is that the MPC approach has to be experimentally verified with microvalves in the loop device. While doing so, experimental issues related to droplet breakage due to active control might have to be considered. Further, concerns related to actuator dynamics and computational complexity of MPC calculations need to be addressed. For the loop structure, the droplets exit at around 40 milliseconds (ms) time intervals. The time required for one actuator move is about 10 ms. If the sampling time is chosen to be 10 ms, then about four actuator moves can be made before the exit of droplet. However, other systems might require faster dynamics and this needs to be taken into account. Further, computational complexity in terms

of the ability of the MPC approach to identify the actuations in milliseconds needs to be addressed. Parametric programming approaches (Sakizlis et al., 2004) might play an important role here.

4. Conclusions

In summary, the modeling and control opportunities in the field of discrete droplet microfluidic systems were identified. The idea of breaking down a discrete microfluidic network into discrete model fragments and modeling approaches for such fragments were discussed. From the context of control, the application of MPC for the control of discrete bubble microfluidic systems was discussed.

Abstract

Continuous hydrothermal flow synthesis (CHFS) is an attractive process for producing high quality inorganic nanoparticles. The direct collection of detailed data about the CHFS process during experiments is not always feasible due to the supercritical conditions, hence affecting optimisation and control and scale-up. In this paper, computational fluid dynamics models are developed for confined jet reactors of a CHFS system for nanomaterial production at both laboratory and pilot-plant scales. The flow, mixing and temperature profiles in the reactors were simulated using the ANSYS Fluent package. The predicted temperature profiles were compared with the available experimental data and the mixing between supercritical water and precursor streams was examined in detail. The hydrodynamic and thermodynamic features of the reactors at both size scales were also compared.

Keywords: Confined Jet Reactor, Computational Fluid Dynamics, Supercritical Water, Scaling-up, Mixing

1. Introduction

Supercritical water (ScW) hydrothermal synthesis has been used to produce metal oxides that have a wide range of applications. Continuous hydrothermal flow synthesis (CHFS) method was developed to overcome the limitations of hydrothermal batch reactions since CHFS is easy to implement automatic control, relatively green, and able to produce very fine nano-particles for a number of functional materials. However, the laboratory and pilot-plant scale systems cannot produce the required amount of nanomaterials for commercial use. Therefore scaling-up and optimization of the system becomes very important.

In scaling up a process from laboratory to pilot plant and industrial scale, direct collection of detailed experimental data in order to study and optimise scaling-up factors is difficult due to the huge number of experiments that need to be conducted and the extreme conditions of the experiments. Computational fluid dynamics (CFD) modelling is a useful tool to study the potential effects of these factors at different size scales and to evaluate alternative designs. CFD modelling has been used to study ScW oxidation processes by some researchers (Bermejo and Cocero, 2006; Lester et al., 2006; Moussiere et al., 2007; Narayanana et al., 2008; Aimable et al., 2009; Kawasaki et al., 2010; Demoisson et al., 2011; Ma et al., 2011a; Ma et al., 2011b; Sierra-Pallares et al., 2011). The application of CFD modelling to ScW hydrothermal synthesis for production of nanoparticles is limited in literature. Lester et al. (2006) used CFD to

simulate the velocity distributions of a nozzle reactor. However, the simulation was based on a pseudo ScW reactor with methanol and sucrose being used to represent ScW and metal salt. Aimable et al. (2009) carried out prediction in the mixing zone of a reactor and obtained temperature and velocity profiles but with little details being given. Kawasaki et al. (2010) studied ScW hydrothermal process in a T-shaped mixer using experiment and CFD simulation. CFD simulation was performed to understand the mixing behaviour in the mixer. Sierra-Pallares et al. (2011) attempted to quantify the nixing efficiency in ScW hydrothermal reactors, but without comparisons to experimental data. Demoisson et al. (2011) performed CFD simulations for the design of a reactor operating in ScW conditions but without detailed comparisons with measurements.

In this paper, CFD models were developed to predict the process in confined jet reactors at different size scales of a CHFS system. The predictions of flow, mixing and temperature profiles in the reactors were carried out using the ANSYS Fluent package (2010). The predicted temperature profiles were compared with the available experimental data and the mixing between ScW and precursor streams was examined. The hydrodynamic and thermodynamic features at both size scales were also compared.

2. Mathematical formulation

2.1. Hydrodynamic and mixing models

The Reynolds-averaged continuity, momentum and enthalpy equations are numerically solved to obtain hydrodynamic and heat transfer profiles (Ma et al., 2011a). The most commonly used turbulence model is the k - ε model (Jones and Launder, 1972) where the turbulent kinetic energy k and its dissipation rate ε are solved using k and ε equations with standard empirical constants. Simulation of mixing was carried out by introducing an inert tracer into the primary liquid in the reactor. The tracer concentrations were obtained from the solution of the species transport equation:

$$\frac{\partial \rho Y_i}{\partial t} + \frac{\partial \rho u_j Y_i}{\partial x_j} = \frac{\partial}{\partial x_i}\left(\Gamma_{i,eff}\frac{\partial Y_i}{\partial x_j}\right) \quad (1)$$

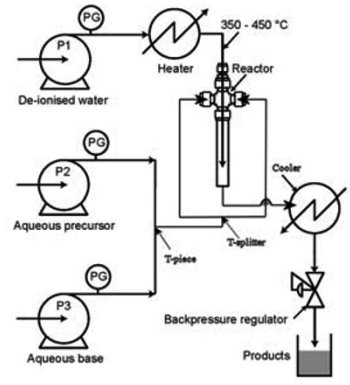

Figure 1 Flow diagram of a confined jet CHFS system.

where the effective diffusion coefficient of species i, $\Gamma_{i,eff} = \Gamma_i + \mu_t / Sc_t$, ρ is the mixture density, u_j the mixture velocity, p the pressure, τ_{ij} the viscous stress, Y_i the species mass fraction, Γ_i the species diffusion coefficient, μ_t the turbulent eddy viscosity, and Sc_t the turbulent Schmidt number.

2.2. Thermodynamic properties

In this study, the water properties obtained from National Institute of Standard and Technology (2009) using the 1995 IAPWS formulation for the thermodynamic properties of ordinary water substance (Wagner and Pruß, 2002) were piece-wise curve-fitted in polynomial forms over several temperature ranges at 24.1 MPa, and used to calculate water properties efficiently and accurately. The diffusion coefficient correlation from Liu and Macedo (1995) was used to estimate water diffusivity.

3. Experimental study

The flow diagram of a CHFS confined jet reactor system used for temperature profiling and also nanoparticle production experiments is shown in Figure 1. Deionised water was pumped through a heater system using pump P1 at 24.1 MPa and constant flowrates of 20 and 400 mL/min for the laboratory and pilot-plant scale reactors. Aqueous precursor and base streams were pumped using P2 and P3 at 24.1 MPa with fixed flowrates of 10 and 200 mL/min for the laboratory and pilot-plant scale reactors from each pump. The fluids from P2 and P3 were mixed thoroughly and the resulted mixture was split equally into two streams before entering the reactor through two inlets. The streams mixed with the stream from P1, and reacted to generate nanoparticles. The generated product stream leaves the reactor and enters a tubular heat exchanger. In order to study the effect of scaling-up on fluid flow and heat transfer in the reactors, the mixture stream from P2 and P3 was mimicked by deionised water during experiments and CFD modelling.

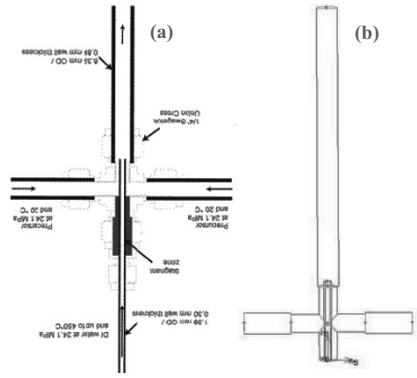

Figure 2 (a) Schematic diagram of a confined jet reactor at laboratory size scale; (b) Computational domain.

The schematic diagram of a typical reactor is shown in Figure 2(a). The reactor consists of an inner tube inserting into an outer tube. The superheated water flows in the inner tube to the mixing point to mix with the metal salt solution. Several fine J-type thermocouples were inserted into the reactors at different locations along the z direction. The tips of the thermocouples were floated in the bulk flow with an estimated tip position variations of ≤ 2 mm across the tube cross-section.

4. Simulation of confined jet reactors

4.1. Computational details

Figure 2(b) shows the computational domain of the laboratory scale reactor and similar reactor configuration was used for the pilot-plant scale reactor with the tube diameters being about 4 times bigger than those in the laboratory scale reactor. The inner diameters (D_i) of ScW are 0.99 and 3.87 mm for the

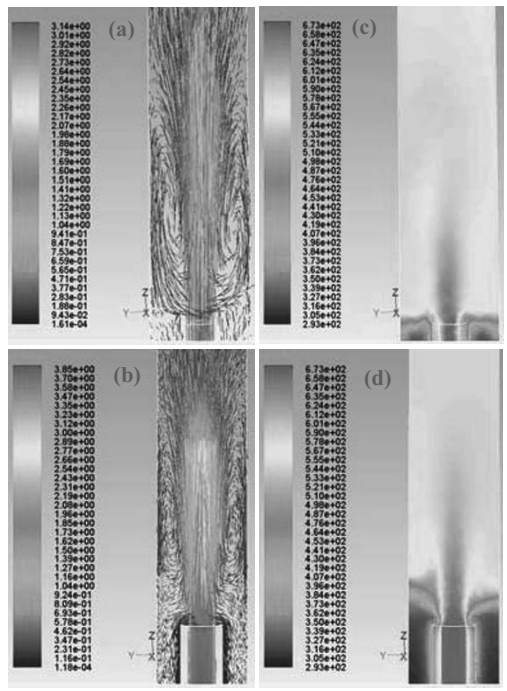

Figure 3 Velocity vectors (a, b) and temperature contour (c, d) in the ScW exit regions of confined jet reactors at laboratory scale (a, c) and pilot-plant scale (b, d).

laboratory and pilot plat scale reactors. The three-dimensional domain was discretised with 1.32×10^5 and 8.06×10^5 cells for the laboratory and pilot-plant scale reactors. The inlet conditions for the simulations were taken from experiments with the inlet temperatures of ScW and precursor streams being fixed at 400 and 15°C. For the study of mixing, a tracer identical to the ScW was introduced into the ScW stream. The flowrates of the tracer and ScW streams were 1% and 99%, respectively, of the total ScW flowrate used in the confined jet reactors.

4.2. Solution method

The mass, momentum, energy and species equations, together with the k and ε equations, are solved using ANSYS Fluent software (2010). The species equations were solved with the obtained steady-state flow and temperature profiles as the initial values. SIMPLE pressure-velocity coupling was used with a second order upwind scheme being employed for the discretisation of the convection terms. A turbulent intensity of 10% and the corresponding hydrodynamic diameters were used for the turbulence inlet conditions. Standard non-slip wall boundary conditions were applied with a standard turbulent wall function.

5. Results and discussion

Figure 3 shows the contours of velocity vectors and temperature contour around the ScW exit region. The ScW stream ejected from the inner tube and entrained the co-flowing precursor from the annual section to form a recirculation zone surrounding the ScW jet, which enhanced the mixing between the ScW and precursor streams. Even temperature distribution after the exit for the laboratory reactor (Figure 3c, d) is found which indicates that the recirculation zone in the laboratory reactor is stronger and closer to the exit as shown in Figure 3a, b. The predicted and measured temperatures along the z direction were compared in Figure 4. It can be seen that the predicted results are in good agreement with measurements.

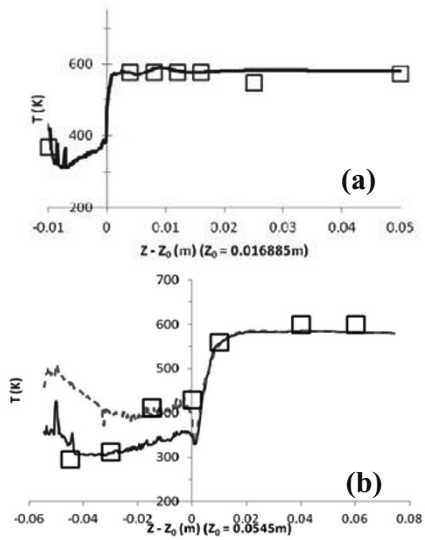

Figure 4 Predicted and measured (□) temperatures along the z direction of a mixer (a) at laboratory scale (solid line); (b) at pilot-plant scale (solid line – y=3.8mm; dashed line – y=3.4mm).

The monitored tracer mass fraction distributions were normalized by their local fully mixed mass fraction, c_∞. The mixing times, defined as the time required for the local tracer mass fraction to reach 99% of c_∞ , for the 5 monitoring points ($\triangle L/D_i$ = 0, 1, 2, 5, 8 with $\triangle L$ being the distance between the ScW exit point and monitoring point) were estimated from simulations with values of 1.0, 2.0, 2.2, 2.4, 2.5s, and 0.6, 0.7, 0.9, 1.6, 2.1s, for the laboratory and pilot plat scale reactors, respectively. However, the local tracer mass fraction reaches the fully mixing level at the reactor outlet (mass fraction of 0.005) after $\triangle L/D_i$ = 5 and 8 for the laboratory and pilot plat scale reactors, which indicates that stronger mixing happened in the reactor at laboratory scale.

6. Concluding remarks

In this study, CFD modelling was used to predict the fluid flow and heat transfer profiles in confined jet reactors of a CHFS system. The predicted temperatures along the z direction were compared with experimental data with good agreement. The mixing study indicates that strong mixing happened in the shear layer between the recirculation zone and ScW jet stream. However, scaling-up led to weaker mixing at pilot plant scale.

Modeling, Simulation and Experimental Investigation of a Reactive Hybrid Process for the Production of Dimethyl Carbonate

Johannes Holtbruegge, Philip Lutze, Andrzej Górak,

TU Dortmund University, Laboratory of Fluid Separations, Emil-Figge-Str. 70, 44227 Dortmund, Germany

Abstract

Process intensification has been identified as a main tool to achieve higher efficiencies leading to a more sustainable production. Especially hybrid as well as reactive separations allow for increased separation efficiency at the same time reducing the energy consumption. Integrating reactive and hybrid separations within one process may create even larger positive synergy effects. However, by this integration several process configurations exist and the identification of the best process operation remains unsolved. Hence, a process analysis tool has been developed to identify the most promising intensified process configuration based on simple calculations and secondly, to identify the influence of the process parameters on the target variables. To underline the potential of this tool, the equilibrium-limited transesterification of propylene carbonate forming dimethyl carbonate is investigated. For this system, a reactive hybrid process integrating reactive distillation and vapor permeation is designed in this work.

Keywords: process analysis, hybrid separation, reactive distillation, vapor permeation

1. Introduction

Due to decreasing fossil fuel reserves, the development of new and innovative processes leading to improvements in energy efficiency and sustainability is necessary. Process intensification (PI) is considered to be a key to realize this for the present and future chemical and petrochemical industry. Two main groups within PI, which have the potential to achieve this target, are hybrid and reactive separations.

Hybrid separations are the combination of two unit-operations which offer substantial synergy effects for each operation compared to the stand-alone operation, leading to increased separation efficiency and a decreased energy use [1]. Besides, the separation of multi-component mixtures with non-ideal behavior (e.g. azeotropes) is possible.

Reactive distillation is a process in which chemical reaction and distillation occur at the same time within one apparatus. Continuous product removal out of the reaction zone leads to a higher yield of equilibrium-limited reactions (e.g. transesterifications) [2].

Hence, in case of strongly non-ideal reacting systems a hybrid process which makes use of reactive distillation (RD) has a high potential for process improvement.

Despite all advantages, reactive hybrid processes are not yet fully established in industry. The reason is a lack of process know-how and process design tools. Additionally, industry was not interested in improving energy efficiency in the past which is the main advantage of reactive hybrid separations. This paper presents a process analysis tool for the selection and design of those processes, thus contributing to a broader application of hybrid reactive processes.

The potential of these processes is demonstrated for different hybrid alternatives for the transesterification of propylene carbonate consisting of RD and vapor permeation (VP).

2. Process analysis tool for the design of reactive hybrid systems

The aim of the presented process analysis tool is to identify the best reactive hybrid process for a specified reaction and separation task. A 5-step approach, shown in Figure 1, is used. First, the objective function and process constraints are defined. In the second step, a detailed investigation of the thermodynamics as well as of the reaction properties of the system is performed to identify the possible equipment and their feasible configuration. Third, the influence of important process parameters on the process configuration is investigated. Especially the influence of the feed properties is analysed by simple performance indicators to identify the best suited reactive hybrid process. Fourth, a rigorous model of the reactive hybrid process, which is validated experimentally, is set-up to perform a detailed analysis of this process using the objective function defined in step 1. After this, an optimisation is performed to identify the optimal process variables for the hybrid alternative. Currently the investigation considers RD, distillation and VP.

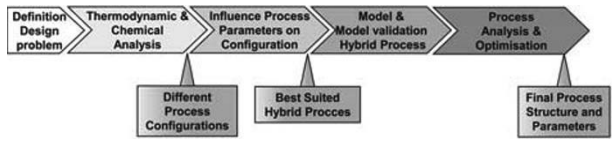

Figure 1: Workflow of the process analysis tool

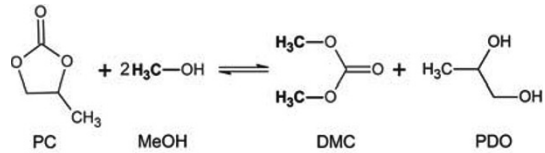
3. Case-Study

In this case-study, we analyse the equilibrium-limited transesterification of propylene carbonate (PC) with methanol (MeOH) forming the target product dimethyl carbonate (DMC) and 1,2-propanediol (PDO). The reaction scheme is given in Eq. (1).

The product DMC can be used as biodegradable octane enhancer because it decomposes to carbon dioxide and methanol in contact with water [3]. Further applications of DMC are the production of polycarbonates and the use as an alkylation agent [4].



(1)

3.1. Definition of the design problem

In the first step, the design problem is defined with respect to the fixed product specifications and process boundaries as well as the objective. We fixed the total mass flow of DMC to 1700 kg/h and its purity to 99.9 wt.-%. The byproduct PDO should have a purity of 99 wt.-%. The objectives are to minimize the production costs and to have a simpler process as the base case. The base case for producing and purifying DMC consists of a continuous reactor and a sequence of four distillation columns including a pressure swing distillation to overcome the azeotrope (see Figure 2) [5].

3.2. Thermodynamic and chemical analysis

Here, the thermodynamics and the reaction of this system are investigated. Analyzing the vapor-liquid equilibrium of the system, the purification of the target product DMC is hindered by the formation of a low boiling azeotrope between DMC and MeOH shown at a pressure of 1.013 bar (see Figure 2). The diagram was computed using the UNIQUAC model and was validated with experimental results from literature [6]. For MeOH fractions higher than 0.868 mol/mol, the purification of DMC using a simple distillation is not possible. In those cases, the use of a membrane separation is advisable.

The chemical equilibrium concentration and reaction kinetics using the homogeneous catalyst sodium methoxide have been measured in our batch reactor. The equilibrium constant is in the region of K_x = 0.2 indicating that chemical equilibrium lies on the side of reactants. To overcome this equilibrium limitation the use of an RD for this chemical system is recommendable. Based on this analysis, different process concepts consisting of an RD column, a VP membrane and a distillation column are proposed and investigated with the aim to increase economics of DMC production. Using the information of the operating windows of each of these units, three promising configurations are identified. These configurations are shown in Figure 3. The first process configuration is a combination of an RD column and a distillation column for the purification of dimethyl carbonate. This configuration works for top products with a methanol mole fraction lower than the azeotropic mole fraction. Configurations 2 and 3 that additionally consist of a vapor permeation membrane are designed for the case, that the methanol mole fraction in the distillate stream of the RD column is higher than the azeotropic mole fraction. In this case, the membrane is used to overcome the azeotrope allowing the purification of DMC.

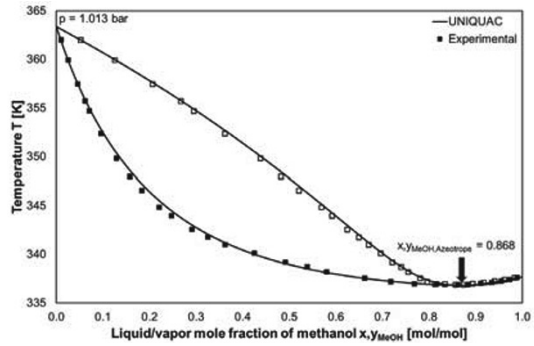


Figure 2: Vapor-liquid equilibrium for MeOH/DMC

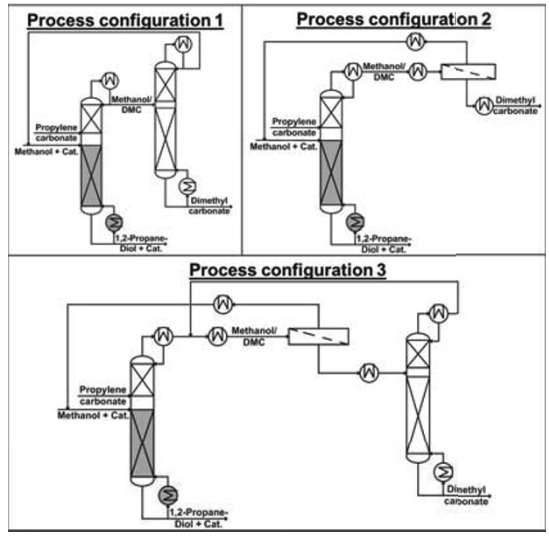

Figure 3: Process alternatives for DMC production

3.3. Influence of the process parameters on the process configuration

A simple sensitivity analysis shows, that the operational parameter with the highest influence on the distillate composition of the RD column is the molar reactant ratio χ in the feed (see Figure 5), defined as follows:

$$\chi = \dot{n}_{MeOH,Feed} \Big/ \dot{n}_{PC,Feed} \tag{2}$$

Focusing on the RD column first, the influence of the reactant ratio on the PC conversion and the PDO mole fraction in the bottom stream of the RD column is investigated (see Figure 4). The MeOH mole fraction in the distillate stream of the RD column is shown on the second y-axis.

The diagram shows, that a full PC conversion in the RD column is only possible by ensuring a reactant ratio higher than 19. Lowering this reactant ratio leads to a contamination of the bottom product PDO with PC and thus requires a further

distillation column for the bottom product. Due to the high methanol concentration in the azeotrope, a large amount of methanol is drawn in the distillate stream. This amount is not available for the chemical reaction and thus needing for high reactant ratios in the feed stream of the RD column. The diagram also shows that the reactant ratio has a minor influence on the distillate composition. For all investigated reactant ratios, the distillate stream is on the right side of the azeotrope. To purify DMC, a VP membrane allowing to overcome the azeotrope is necessary so that configuration 1 is excluded from the investigation.

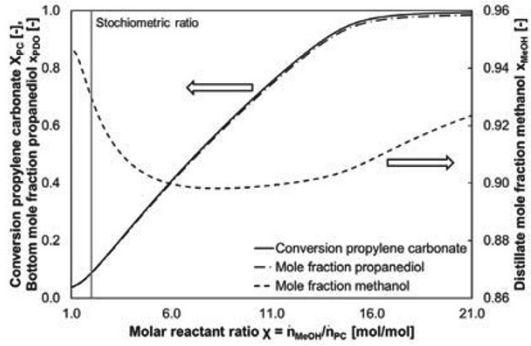

Figure 4: Influence of the reactant ratio on the performance of the RD column

An economic analysis performed on the remaining process alternatives (not shown here), shows that configuration 3 promises more benefits since the purification of the target product up to the required specification using only a membrane separation needs a large membrane area and causes higher costs. Hence, only configuration 3 is further investigated.

3.4. Process modeling and experimental model validation

The model of the RD column is based on a rate-based approach and was developed by Klöker [7]. The separation of the azeotropic mixture using the VP membrane is described using a model developed by Kreis [8] which is based on an empirical solution-diffusion model. For the determination of model parameters, lab-scale permeation experiments using the membrane Sulzer PERVAP^{TM} 1255-30 were performed. Furthermore, functions for cost calculation were taken from literature [9]. A simplified simulation flow sheet of the hybrid process is shown in Figure 5. The parameters that are varied within the simulation studies are printed in bold italic letters.

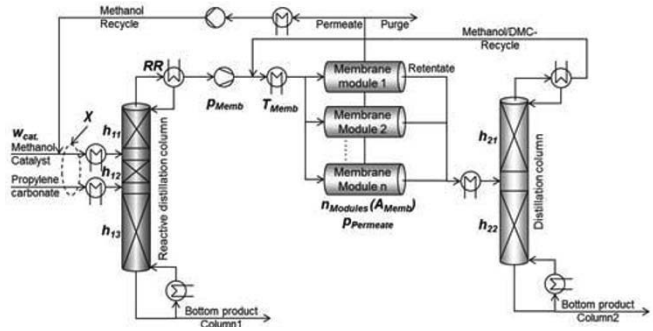

Figure 5: Scheme of the simulation flow sheet for configuration 3

3.5. Detailed process analysis for the design of the hybrid process

A detailed process analysis has been carried out for process configuration 3 to identify the best process operation. Here, membrane area, PC conversion and membrane selectivity are analyzed to identify the best savings in the costs (objective function).

The left part of Figure 6 shows the influence of the MeOH mole fraction in the retentate stream on the required membrane area and the production costs per ton of DMC. The membrane area increases exponentially with a decrease of the MeOH mole fraction. A large membrane area is necessary due to the low driving force for methanol permeation at low concentrations. This underlines the high benefit of configuration 3 in comparison to configuration 2 (see Figure 3). The reboiler duty of the second distillation column

increases with increasing MeOH mole fraction. Due to this, the DMC costs which are also shown in the diagram have a minimum for a membrane area of 2580 m².

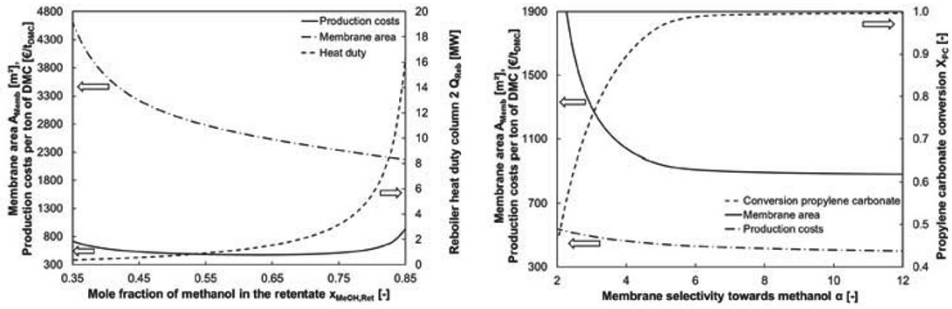

Figure 6: Influence of the membrane separation on the hybrid process

The right part of Figure 6 shows the influence of the membrane selectivity towards methanol on the membrane area, the PC conversion and the DMC costs. As expected, the membrane area and the DMC costs decrease with increasing membrane selectivity due to low DMC losses through the membrane. The more important point is the PC conversion in the RD column that decreases with decreasing membrane selectivity because a higher amount of DMC is recycled to the RD column shifting the chemical equilibrium. This leads to increasing impurities of propylene carbonate in the bottom stream of the RD column. These diagrams show the high complexity of the hybrid process and the difficulty of the selection of suitable membrane materials. Based on these results the initialization of an optimization routine to solve the final optimization problem for final tuning of the process, which is not shown here, was possible. Savings in the economics and energy consumption compared to the base case are achieved.

4. Conclusion and Outlook

A process analysis tool for the simple, quick and reliable identification of the best configuration of a reactive hybrid process was shown within this work. Within this process analysis tool a new simulation model of the hybrid process has been developed incorporating cost evaluation at early stages. For the production of dimethyl carbonate, the economically best reactive hybrid process consists of a reactive distillation column, a vapor permeation membrane and a distillation column. It was shown, that this process is able to overcome thermodynamic and chemical limitations, making savings in capital and energy use and also an increase in sustainability possible.
In further studies, pilot-scale reactive distillation experiments as well as pilot-scale hybrid experiments will be performed with this system to validate the obtained solution.

Estimation of Predictive Accuracy of Soft Sensor Models Based on One-Class Support Vector Machine

Hiromasa Kaneko[a], Kimito Funatsu[a]

[a]*Department of Chemical System Engineering, The University of Tokyo, Bunkyo-ku, Tokyo, Japan*

Abstract

Soft sensors are widely used to estimate process variables that are difficult to measure online. By using soft sensors, analyzer faults can be detected by estimation errors. However, it is difficult to detect abnormal data and determine the reasons because estimation errors increase not only due to analyzer faults but also due to variations caused by changes in the state of chemical plants. To separate those factors, we previously proposed to construct the relationships between distances to soft sensor models (DMs) and the accuracy of prediction of the models quantitatively and estimate the prediction accuracy of new data online. In this paper, we employed a one-class support vector machine (OCSVM) to estimate data density and the output of an OCSVM as a DM. The proposed method was applied to real industrial data and the superiority of the proposed DM to the traditional ones was demonstrated by comparing their results.

Keywords: Soft sensor; Predictive accuracy; Applicability domains; Distances to models; One-class support vector machine.

1. Introduction

Soft sensors have been widely used to estimate process variables that are difficult to measure online [1]. An inferential model is constructed between those variables that are easy to measure online and those that are not, and an objective variable is then estimated using that model. Through the use of soft sensors, the values of objective variables can be estimated with a high degree of accuracy. Their use, however, involves some practical difficulties.

One of the difficulties is the degradation of soft sensor models. The predictive accuracy of soft sensors gradually decreases due to changes in the state of chemical plants, catalyzing performance loss, sensor and process drift, and so on. In order to reduce the degradation of the soft sensor model, a regression model is updated with new data or a time difference model, which is constructed between time difference of explanatory variables, **X**, and that of an objective variable, **y**, is employed, for example.

Meanwhile, if the degradation is reduced and the accuracy of soft sensor models is maintained, a **y**-analyzer fault can be detected by prediction errors. In actual plants, a threshold value of the prediction errors of **y** is set and fixed with training data, and when the prediction error of **y** exceeds a threshold value, it is considered to be abnormal. However, it is difficult to detect abnormal data and determine the reasons [2]. Prediction errors increase not only due to a **y**-analyzer fault but also due to variations in the process variables caused by changes in the state of chemical plants. In fact, reliability of a soft sensor model is affected by process conditions.

Kaneko et al. introduced applicability domains (ADs) and distances to models (DMs) [2] concepts, which are researched mainly in the field of quantitative structure-activity relationship analysis and obtained the relationships between a DM and prediction accuracy quantitatively using the distances to the average of training data as a DM. False alarms could be prevented by estimating large prediction errors when the state was different from that of training data and actual **y**-analyzer faults could be detected with certain accuracy.

The distances to the average of training data, however, cannot handle a nonlinear relationship among process variables. Additionally, if distributions of data are multiply separated, the distances cannot represent the true DM appropriately. Improvement of the ability for estimating the prediction errors or the predictive accuracy of soft sensor models is desired for process control.

We therefore propose to apply data density to a DM of soft sensors. A soft sensor model will be well trained in data regions where data density is high and the predictive accuracy of the model will be high in the same regions. On the other hand, a model will not be trained enough in data regions where data density is low and the predictive accuracy of the model will be low in the same regions. In this research, we employ a one-class support vector machine (OCSVM) [3] to estimate data density and the output of an OCSVM as a DM.

The proposed method is applied to real industrial data and the superiority of the proposed DM to the traditional ones is demonstrated by comparing their results.

2. Method

2.1. OCSVM

An OCSVM is a method in which an SVM is applied to a domain description problem. Given a set of training data in a high–dimensional input space, the objective of an OCSVM is to learn a function that will take the value +1 in the region where the majority of the data is concentrated and the value –1 everywhere else. The function to be learned is modeled as a hyperplane in a transformed space, and the hyperplane parameters are estimated so that its margin with respect to the training data is maximized, as dictated by the data–driven distribution–free paradigm.

The maximum margin solution of the OCSVM problem is obtained by solving the following quadratic optimization problem:

Minimize

$$\frac{1}{2}\|\mathbf{w}\|^2 + \frac{1}{\upsilon l}\sum_i \xi_i - b \tag{1}$$

subject to

$$\mathbf{w}\cdot\Phi(\mathbf{x}_i) \geq b - \xi_i$$
$$\xi_i \geq 0 \tag{2}$$

where $\mathbf{w} \in R^n$ denotes a weight vector; b, a bias; ξ_i, slack variables; and υ, the parameter that represents the upper bound on the fraction of outliers in the data. Finally, the decision function inferred by the learned hyperplane is as follows:

$$f(\mathbf{x}) = \mathbf{w}\cdot\Phi(\mathbf{x}) - b \tag{3}$$

In our application, a kernel function is a radial basis function:

$$K(\mathbf{x},\mathbf{x}') = \exp\left(-\gamma|\mathbf{x}-\mathbf{x}'|^2\right) \tag{4}$$

where γ is a tuning parameter that controls the width of the kernel function. By using (4), a nonlinear model can be constructed because the inner product of **x** and **w** in (3) is represented as the kernel function of **x**. The output of an OCSVM f(**x**) is the proposed DM of soft sensors.

2.2. Area under coverage and RMSE curve (AUCR)

The relationship between the coverage and the root-mean-square error (RMSE) is used to compare the performance of DMs [2]. First, data are sorted in ascending order of each DM and we calculate the coverage that is the rate of the number of the data within each AD to the total number of the data N_{all}. Then, the coverage of the i^{th} data is defined as follow:

$$coverage_{\,i} = i / N_{\text{all}} \tag{4}$$

The i^{th} RMSE value is calculated with the i data as follows:

$$RMSE = \sqrt{\frac{\sum \left(y_{obs} - y_{calc,\,pred} \right)^2}{i}} \tag{5}$$

where y_{obs} is the measured **y**-value; $y_{calc,pred}$ is the calculated **y**-value for the i data in training data or the predicted **y**-value for the i data in test data. It is desired for ADs that the smaller the values of the coverage are, the smaller the RMSE values are and vice versa. To compare DMs quantitatively, area under coverage and RMSE curve (AUCR) is introduced in this paper. The basic concept of AUCR is shown in Figure 1. The relationship between the coverage and the RMSE of A is a more desired curve than that of B, which is mentioned above and the AUCR of A is smaller than that of B. It can be said that the performance of A as a DM is better than that of B.

3. Case Study

We applied the proposed method to actual industrial data obtained during an industrial polymer process at Mitsui Chemicals, Inc. to verify the performance of DMs. There can be a nonlinear relationship between a polymer quality variable (**y**) and other process variables (**X**). Accordingly, it is difficult to estimate the predictive accuracy of the soft sensor model between **X** and **y**. We therefore attempted to model a relationship between a DM and the predictive accuracy of the model.

First, we collected data recorded for many grades and constructed support vector regression [3] models between **X** and **y** by considering the dynamics of process variables in this study. The **y**-variable is density and the melt flow rate (MFR), and the

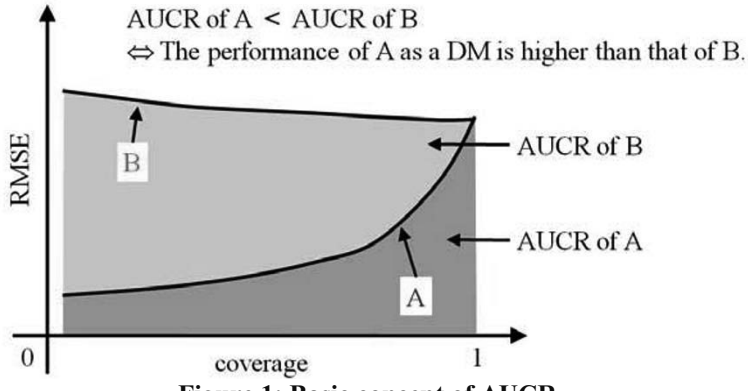

Figure 1: Basic concept of AUCR

X-variables are 37 process variables such as the temperature in the reactor, the pressure, and concentrations of the monomer, comonomer, and hydrogen. Then, we calculated relationships between DMs and calculation or prediction errors. The Euclidean distance (ED) and the Mahalanobis distance (MD) to the average of training data, and the output of an OCSVM (the proposed method) were applied as DMs.

Figure 2a shows the relationships between AUCR of training data and that of test data for each DM when **y** is density. In OCSVM modelling, a parameter ν was changed from 2^{-20} to 2^{-4} by squaring and from 0.1 to 0.9 in steps of 0.1; the other parameter γ was changed from 2^{-20} to 2^{10} by squaring; and accordingly 806 OCSVM models were constructed. The blue points represent the results of OCSVM; the red circle represents that of ED; and the green triangle represents that of MD. The distribution of the results of the proposed method locates at the bottom left compared with those of ED and MD, reflecting that the proposed DM had the better performance in most OCSVM parameters than the traditional DMs did. The OCSVM models could represent the nonlinearity among process variables. In addition, the OCSVM model having the smallest value of AUCR of training data in the all parameters had also high performance for test data. We can say that an optimal OCSVM parameter can be decided using training data.

Then, when **y** is MFR, the relationships between AUCR of training data and that of test data for each DM are shown in Figure 2b. In this case, the AUCRs of both training data and test data were relatively small when ED was used as a DM. This will come from a physical relationship between MFR and **X** and even ED of **X** could represent some information on MFR. Meanwhile, the some results of OCSVM were more left and lower than that of ED, indicating the high performance of the proposed method.

The relationships between the coverage and the RMSE of test data are shown in Figure 3. In each figure, the OCSVM parameters γ and ν were the ones where the AUCR value of training data was smallest. The blue continuous lines represent the results of OCSVM; the red dashed lines represent the results of ED; and the red chain lines represent the results of MD. As shown in the results of OCSVM, the smaller the values of the coverage are, the smaller the RMSE values are. By comparing the values of the RMSE for each coverage, at only small coverage for MFR, the values of the RMSE calculated with the proposed method were smaller than those of the other methods. This means that the model could predict more number of data with higher predictive accuracy by using the proposed index.

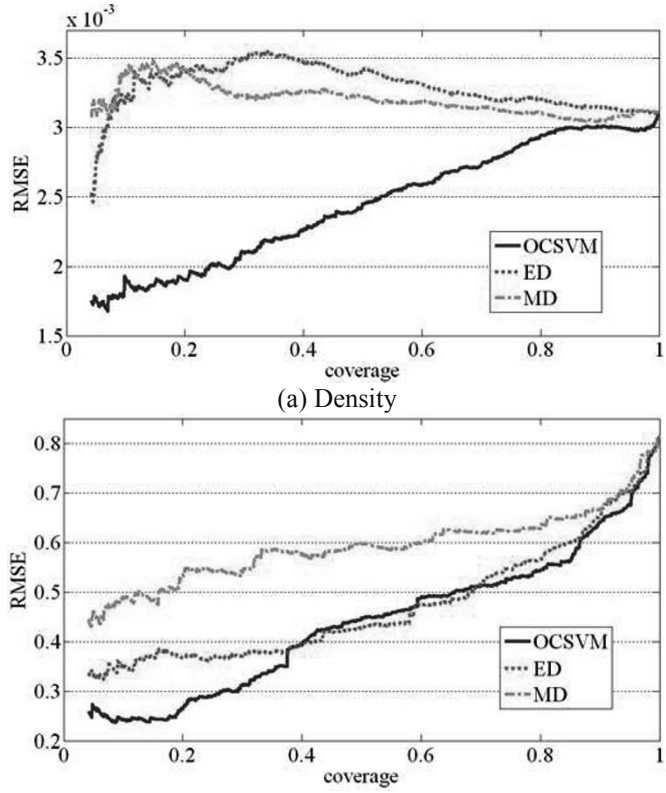

Figure 3: Relationships between the coverage and the RMSE

4. Conclusion

In this paper, we proposed a DM calculated by using OCSVM to estimate prediction errors of soft sensor models accurately. Then, AUCR was introduced as a comparative indicator, and hence, the performance of DMs could be compared quantitatively. Through the analysis of real industrial data, we confirmed that the predictive accuracy of each data could be estimated with high accuracy by using the proposed method even when there is a nonlinear relationship between **X** and **y**. By applying this method to process control, industrial plants will be operated stably.

Abstract

This paper describes an optimization-based approach to reducing the fatigue caused by structural loads during emergency shut-down (EST) of multi-megawatt wind turbine generators. A low-order, dynamic model is developed, which accounts for the first fore-aft tower mode. This model is used to cast the EST problem as an optimal control problem that involves switched dynamics and can be solved using direct solution approaches. The optimized EST strategies are validated against a high-fidelity model in the simulation environment Bladed™ for an industrial 3MW wind turbine generator. Fatigue reductions as high as 45-60% can be obtained at various above-rated wind speeds compared to standard, constant pitch rate EST procedures.

Keywords: wind turbine, emergency shut-down, fatigue reduction, optimal control

1. Introduction

With the size of wind turbine generators (WTG) increasing steadily, there has been a growing interest in alleviating structural fatigue through better control (Bossanyi, 2003). For multi-megawatt WTG (MMWTG), transient operation such as emergency shut-down (EST) has received far less attention than normal power production operation, despite the fact that EST events can contribute significantly to the overall structural fatigue. Current practice still relies on a set of *ad hoc* rules, whereby the collective pitch control is ramped to feather, while maintaining the generator torque at its maximum value (which is itself dependent on the generator speed) (Burton et al., 2011). Systematic methodologies are still lacking for fatigue minimization during EST procedures.

Reducing fatigue during EST events is challenging because good reference trajectories for the collective pitch rate and for the generator torque are hard to assess. Besides, the dynamics are highly nonlinear, and limitations on the actuators are likely to become saturated as well as other process constraints. Such problems are naturally addressed under the framework of optimal control (Bryson and Ho, 1975). In particular, direct solution methods, whereby the optimal control problem (OCP) is converted into a nonlinear program (NLP) through parameterization of the control and/or the state trajectories can efficiently tackle such problems with point and path constraints as well as switched dynamics (Vassiliadis et al., 1994; Biegler et al., 2002). This is the approach used in this work.

In the remainder of the paper, a low-order model is presented in §2 and the optimal control problem for reduction of the tower fatigue during an EST event is given in §3. The results of a case study are presented and analyzed in §4, including a validation in the high-fidelity simulation environment Bladed™. Finally, conclusions are drawn and directions for future investigations are discussed in §5.

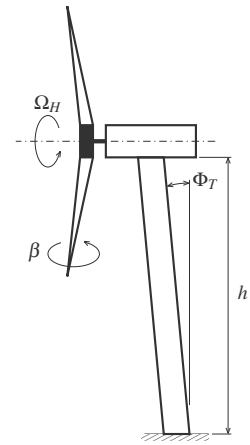
2. Low-Order Model for Wind Turbine Generators

In order to make the optimization of EST events tractable, a low-complexity, differentiable model is developed, which captures only the first fore-aft tower mode. Subsequent modes are neglected, as well as the out-of-plane blade modes corresponding to the three blades oscillating together in the fore-aft direction. Therefore, this model may only predict the behavior of WTGs accurately in the lower frequency range, below the influence of the neglected modes. A complete description of the model parameters and values can be found in (Gros and Chachuat, 2012).



$$\dot{\Omega}_H(t) = \frac{Q_a(t) - T_G(t)}{I_{DT} + J} \tag{1}$$

$$\ddot{\Phi}_T(t) = \frac{Q_t(t) - \xi^2 M_{rn} h^2 w_t^2 \Phi_T(t) - Q_m(t)}{\xi^2 (M_{bl} h^2 + J_t)}, \tag{2}$$

where Φ_T [rad] stands for the tower fore-aft displacement relative to the vertical axis; Ω_H [rad/s], for the rotor angular velocity; and T_G [Nm], for the generator torque.

The rotor aerodynamic torque is $Q_a(t) = \frac{1}{2}\rho\,\pi R^3 \frac{C_p}{\lambda(t)} V(t)^2$ [Nm], the thrust moment is $Q_t(t) = [\frac{1}{2}(1+C_s)h\rho\,\pi R^2 C_t + C_X]V(t)^2$ [Nm], and the structural moment is $Q_m = Q_{ov} + B_t\dot{\Phi}_T(t)$ [Nm]. Moreover, the wind speed at the hub position is $V(t) = V_\infty - \xi\,h\dot{\Phi}_T(t)$ [m/s], with V_∞ [m/s] the free-flow wind speed, and $\lambda(t) = \frac{R\Omega_H(t)}{V(t)}$ is the tip-speed ratio. The aerodynamic coefficients $C_{p\lambda}(\beta,\lambda)$ and $C_t(\beta,\lambda)$ are defined in look-up tables, as obtained from combined blade element and momentum theory.

Regarding the collective pitch position β [deg], the actuator dynamics relating β to the pitch reference β_R [deg] are approximated as 2nd-order dynamics with limited bandwidth,

$$\ddot{\beta}(t) = K_P[\beta_R(t) - \beta(t)] - K_D\dot{\beta}(t). \tag{3}$$

The focus in this paper is on EST events triggered under above-rated conditions, which typically cause higher structural fatigue. In this scenario, the rotor velocity Ω_H^{r} during normal power production mode is dictated by the WTG design requirements, while the generator torque T_G^{r} is adjusted to meet the rated power value. In particular, this requires that a constant rotor velocity is maintained by pitching the blades so as to control the aerodynamic torque. A set of initial conditions for the EST is given by $Q_a(0) = T_G^{\mathrm{r}}$, $\Omega_H(0) = \Omega_H^{\mathrm{r}}$, $\dot{\Phi}_T(0) = 0$, $\ddot{\Phi}_T(0) = 0$, $\dot{\beta}(0) = 0$, $\ddot{\beta}(0) = 0$.

Note that (1)-(3) is a fifth-order model, but as many as six initial conditions are defined; therefore, the system is over-specified at initial time, which implies that only $T_G(0)$ can be set freely, whereas $\beta_R(0)$ has to be equal to $\beta(0)$ according to (3). Note also that the proposed optimization-based methodology remains applicable under below-rated conditions subject to minor modifications of the initial conditions.

3. Emergency Shut-Down Optimization formulation

The problem of minimizing the tower fatigue during an EST procedure is now cast as an optimal control problem. In order to make the problem amenable to a numerical solution, the optimization horizon is taken finite, with the final time t_{f} taken equal to the time

needed by the blades to reach the feathered position in a standard EST procedure with constant pitch rate of $\dot{\beta}^R = 5.5$ rad/s.

An approximation of the actual rainflow counting (RFC) (Burton et al., 2011) is considered as the cost functional. Since the RFC is independent of T_G and β_R and the model (1)-(3) is affine in the controls, this OCP is singular, which could invalidate the low-order model due to the presence of high frequencies such as bang-bang arcs. To remedy this, a secondary objective that penalizes high-frequencies in the collective pitch dynamics is added, leading to the following regularized cost functional:

$$J = \int_0^{t_\mathrm{f}} |\dot{\Phi}_T(t)|\,dt + \omega \int_0^{t_\mathrm{f}} \ddot{\beta}(t)^2\,dt \approx \int_0^{t_\mathrm{f}} \frac{\dot{\Phi}_T(t)^2}{\sqrt{\dot{\Phi}_T(t)^2 + \varepsilon^2}}\,dt + \omega \int_0^{t_\mathrm{f}} \ddot{\beta}(t)^2\,dt, \qquad (4)$$

with $\omega \geq 0$ the regularization parameter, and $\varepsilon \ll 1$ a numerical perturbation.

The following path constraints are imposed to represent the limitations imposed by the actuators on the pitch position, pitch rate and pitch acceleration, and in order for the pitch angles to be in (a neighborhood of the) feathered position at t_f:

$$\beta^{\mathrm{br}} \leq \beta(t) \leq 90\ [\mathrm{deg}], \qquad \beta(t_\mathrm{f}) \geq \beta_\mathrm{f},$$
$$-\dot{\beta}^{\max} \leq \dot{\beta}(t) \leq \dot{\beta}^{\max}, \qquad -\ddot{\beta}^{\max} \leq \ddot{\beta}(t) \leq \ddot{\beta}^{\max}.$$

The generator torque T_G and power $P_G := T_G \Omega_H$ too are restricted along the path as

$$0 \leq T_G(t) \leq T_G^{\max}, \qquad T_G(t)\,\Omega_H(t) \leq 1.1\,T_G^{\mathrm{r}}\,\Omega_H^{\mathrm{r}}.$$

Finally, the maximum torque that can be reclaimed from the generator typically decreases with the rotor speed due to power electronics restrictions, and no torque can be reclaimed below the so-called cut-in rotor speed Ω^{ci}. A conservative approximation of these limitations is considered next in disjunctive form as

$$T_G(t) \leq \begin{cases} a\,\Omega_H(t)\,[\Omega_H(t) + b], & \text{if } \Omega_H(t) \geq \Omega^{\mathrm{ci}} \\ 0, & \text{otherwise,} \end{cases} \qquad (5)$$

where the constants a and b are determined based on the power electronics of the WTG. Direct incorporation of (5) would make the control problem nonsmooth and may cause standard numerical solution procedure to abort prematurely. To remedy this, a multi-stage formulation (Vassiliadis et al., 1994) of the problem is adopted next, which relies on the observation that the rotor speed $\Omega_H(t)$ decreases monotonically from its rated value Ω_H^{r} at $t = 0$ down to zero at t_f during a typical EST procedure; that is, $\Omega_H(t)$ may cross the cut-in rotor speed Ω^{ci} only once.

A direct numerical procedure is considered to solve the OCP, where the control trajectories are parameterized over 100 stages as (continuous) piecewise affine functions. Because the response of the reduced-order model is non-stiff, the so-called simultaneous approach (Biegler et al., 2002) is well suited. Lagrange polynomials with 4-point Radau collocation are used for the state variables and the resulting large-scale NLP has about 4,800 variables and 4,900 equality/inequality constraints.

4. Optimal EST Procedures: Case Study

A 3 MW WTG is considered, for which a Bladed model was first developed for detailed performance and structural fatigue simulation, as well as a low-order model (1)-(3). The parameter values for the low-order model and the OCP are in (Gros and Chachuat, 2012).

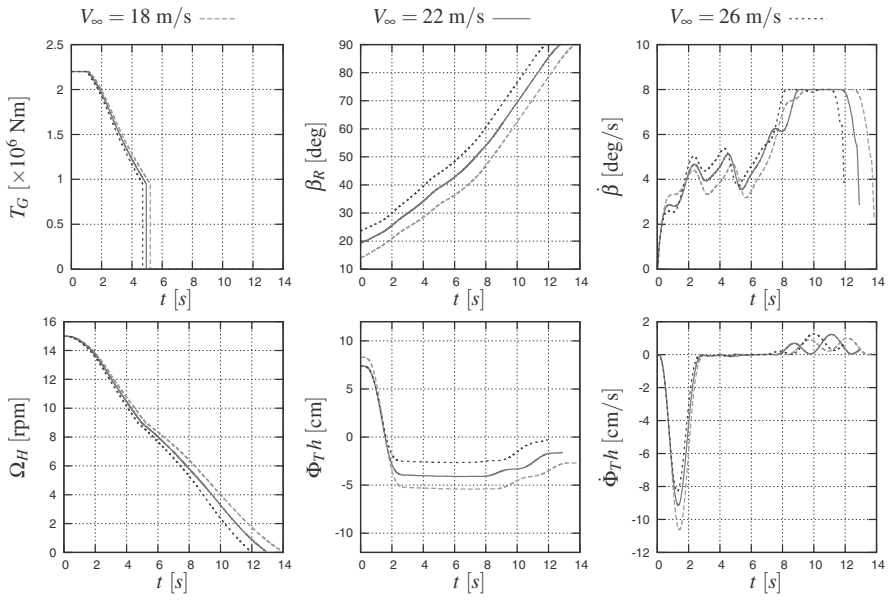


Figure 1. Optimal control and response with regularization $\omega = 10^{-6}$ *for above-rated wind speeds* $V_\infty = 18$*,* 22 *and* 26 m/s*.*

Optimal solutions of the OCP computed for various above-rate wind speeds $V_\infty = 18$, 22 and 26 m/s and a regularization of $\omega = 10^{-6}$ are shown in Fig. 1. While it is clear that the optimal trajectories are quite sensitive to V_∞, it is also seen that the general structure or pattern of these trajectories is conserved across different V_∞ values. The major effect of different wind speed values V_∞ appears to be shifting the optimal collective pitch reference trajectories $\beta_R(t)$. In all cases, the pitch trajectories reach the specified feathered position after a rather regular increase from their respective rated pitched angles. The choice of $\omega = 10^{-6}$ for the regularization yields a good compromise between performance loss and pitch rate ($\dot{\beta}$) aggressiveness across various above-rated wind speeds.

Regarding fatigue reduction, it is seen from the middle and right lower plots in Fig. 1 that the optimal control strategies are particularly efficient at dampening the fore-aft tower displacement. The first compressive peak brings the tower back to nearly vertical position, where it stays during the remaining of the EST horizon. Observe also from the lower right plot that the tower shows small fore-aft oscillations close to the end of the horizon, which are due to a loss of controllability—see below.

4.1. Validation in Bladed Simulation Environment

The Bladed simulation environment is used as a means to validate the optimized EST strategies and compare them with the constant pitch rate (standard) procedures. One such comparison is shown in Fig. 2, where the optimized EST procedures is computed for $V_\infty = 22\,\mathrm{m/s}$ and $\omega = 10^{-6}$. Large reductions in the fore-aft displacement oscillations (left plot) and in the corresponding tower root moment (right plot) are obtained. In terms of the RFC (computed over an extended horizon of 240 s), the fatigue reductions at above-rated wind speeds of 18, 22 and 26 m/s are 45%, 56% and 61%, respectively.

It should be noted that the oscillations predicted by Bladed are larger than those initially predicted by the reduced-order model (compare Fig. 1); such discrepancy is the result of

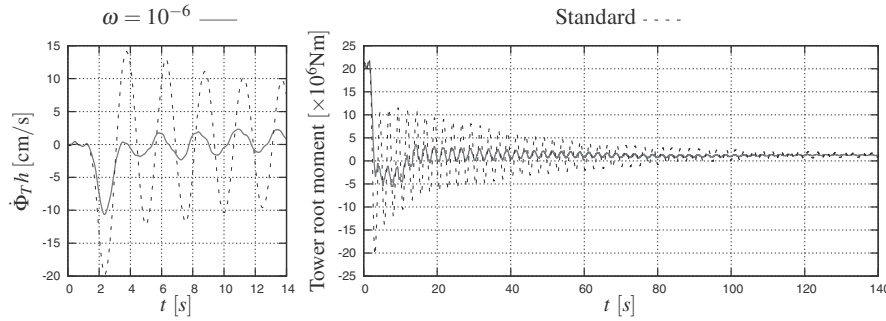

Figure 2. Comparison between constant pitch rate (standard) and optimized EST strategies for $V_\infty = 22$ m/s in the Bladed simulation environment.

the neglected out-of-plan blade modes and higher fore-aft tower modes, as noted earlier. Note also that the residual oscillations can last over several minutes. This is because once the pitch has reached its feathered position and the rotor speed is below its cut-in value, neither aerodynamic nor mechanical damping is possible anymore; that is, the WTG is left essentially uncontrolled.

5. Conclusions and Future Directions

An optimization-based approach has been proposed to tackle the problem of structural fatigue reduction during EST of WTGs. A low-order model has been developed and used for the optimal control problem formulation and solution. The resulting EST strategies have been validated in the Bladed simulation environment, and comparisons with constant pitch rate (standard) EST procedures have revealed that reductions as high as 45-60% in structural fatigue can be obtained at various above-rated wind speeds.

Because EST procedures are subject to large disturbances due to wind speed variation and turbulence, and since the mathematical models carry uncertainty, direct application of the computed optimal control trajectories in open loop may lead to poor performance or violate some operating constraints. Pivotal to the success of an optimization methodology for EST is therefore a closed-loop strategy that adapts the control trajectories in real time using on-line measurements. Such strategies are currently under investigation.

Data-driven causal inference based on a modified transfer entropy

Yidan Shu, Jinsong Zhao*

State Key Laboratory of Chemical Engineering, Department of Chemical Engineering, Tsinghua University, Beijing, China
**Email: jinsongzhao@tsinghua.edu.cn*

Abstract

Causality inference and root cause analysis are important for fault diagnosis in the chemical industry. Due to the increasing scale and complexity of chemical processes, data-driven methods become indispensable in causality inference. This paper proposes an approach based on the concept of transfer entropy which was presented by Schreiber in 2000 to generate a causal map. To get a better performance in estimating the time delay of causal relations, a modified form of the transfer entropy is presented in this paper. A case study on a simulated chemical process is performed to illustrate the effectiveness of this approach.
Keywords: Causal inference, Transfer entropy, Process safety

1. Introduction

Elucidation of the cause-and-effect relationships among variables or events is the central aim of many studies in physical, social, behavioral and biological sciences (Pearl, 2009). In the chemical process industry, knowing the cause-and-effect relationships means knowing the propagation path of fault or disturbance, which is critical for alarm management, fault diagnosis, and incident/accident investigations. As a result, it is of great significance to develop an effective and reliable method of causal inference and root cause analysis.

There exists some techniques that are to some extent similar to causal inference and root cause analysis, like HAZOP analysis (Dunjó, 2010), and signed digraph (SDG)-based methods (Maurya, 2004). But methods that rely on only process knowledge are often difficult to use because of the increasing complexity and size of modern industrial processes. Meanwhile, data-driven methods like cross-correlation function (Bauer, 2008), and transfer entropy (Schreiber, 2000, Bauer, 2007) can overcome such difficulties. However, data-driven methods needs to be improved to avoid mbiguities or false results. This paper is focused on causal inference based on an improved transfer entropy.

2. Introduction to transfer entropy and proposed midification

2.1. Introduction to transfer entropy

Based on the concept of information theory and information entropy (Shannon and Weaver, 1949), Schreiber proposed the concept of transfer entropy in 2000 to measure the asymmetric interactions in a system. Unlike mutual information, transfer entropy is in an asymmetric form, which makes it possible to measure cause-and-effect relationships. To consider time delay, which is common in many practical situations, Bauer in 2007 incorporated h, the prediction horizon, and rewrote the transfer entropy as equation (1).

$$t(x \mid y) = \sum_{x_{i+h}, x_i^{(k)}, y_i^{(l)}} p(x_{i+h}, x_i^{(k)}, y_i^{(l)}) \log \frac{p(x_{i+h} \mid x_i^{(k)}, y_i^{(l)})}{p(x_{i+h} \mid x_i^{(k)})} \tag{1}$$

x and y represent two variables while x_i and y_i represent their values at time i. $x_i^{(k)} = [x_i, x_{i-1}, \cdots, x_{i-k+1}]$ and $y_i^{(l)} = [y_i, y_{i-1}, \cdots, y_{i-l+1}]$. The probability density function (PDF) is estimated by a kernel estimator. In 2010, Yang applied the Bauer's form of transfer entropy equation (1) to validate SDGs. In his work, the prediction horizon was changed to maximize the transfer entropies and the transfer entropies that are large enough will validate the existence of the corresponding SDG arcs that represent the causal relationships between process variables.

2.2. Modification of transfer entropy

In the Bauer's transfer entropy, the reference of future uncertainty's decrease is $x_i^{(k)}$. As a result, as prediction horizon varies, the reference also varies. Such phenomenon seems unreasonable to determine the actual maximized improvement of prediction.

In our modified transfer entropy, the $x_i^{(k)}$ in equation (1) is replaced by $x_{i+h-1}^{(k)}$. As a result, the reference is fixed and doesn't change with h. In our opinion, such modification will make the maximization more reliable and make it possible to estimate time delay with prediction horizon. The modified form of transfer entropy is as below:

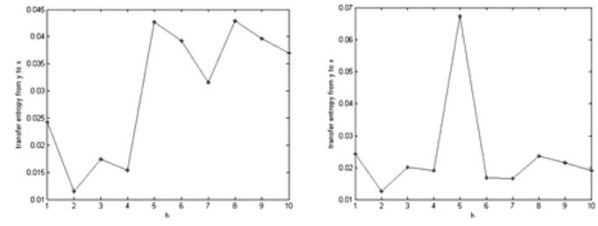
$$t(x \mid y) = \sum_{x_{i+h}, x_{i+h-1}^{(k)}, y_i^{(l)}} p(x_{i+h}, x_{i+h-1}^{(k)}, y_i^{(l)}) \log \frac{p(x_{i+h} \mid x_{i+h-1}^{(k)}, y_i^{(l)})}{p(x_{i+h} \mid x_{i+h-1}^{(k)})} \tag{2}$$

$x_{i+h-1}^{(k)} = [x_{i+h-1}, x_{i+h-2}, \cdots, x_{i+h-k}]$ and other symbols are the same as equation (1).

To illustrate our idea, suppose an auto-regressive model (see equation (3)). y is random and normally distributed at each moment i. x is determined by both y and x itself:

$$x(i) = x(i-1) + y(i-5) \tag{3}$$

We can expect the time delay from y to x to be 5. Both Bauer's form and our modified form of transfer entropy are applied, and let k=l=1 and h be an integer between 1 to 10. Fig. 1 (a) and (b) show transfer entropies as a function of h under both forms.



(a) (b)

Fig. 1 Transfer entropy vs. h under (a) Bauer's form (b) the modified form

From Fig. 1(a) we can see Bauer's form can find two local maximums at h= 5 and h=8 respectively. Moreover, the latter one is a little bit larger than the former one. That means this form cannot find time delay exactly for this example. However, our modified form finds only one maximum at the right h.

3. Causal inference based on the modified transfer entropy

To obtain a causal map based on the time series of process variables, the following four steps are proposed based on the modified transfer entropy.

3.1. Parameter selection

k, l, and the range of h in equation (2) should be decided before calculation. The threshold of the transfer entropy to extract the significant results also need to be chosen.

k is set to be both 1 and 0. When k=1, most transfer entropies will be smaller than those when k=0. The transfer entropies that remain above the threshold can be considered to represent the strong relations. When k=0, the transfer entropies obtained generally represent the weak relations which are still worth considering to build the causal map.

l is set to be 1. If l=0, the equation (2) is meaningless. Larger l will make the calculation more difficult, and generate many transfer entropies with similar large values which makes it hard to extract the significant part.

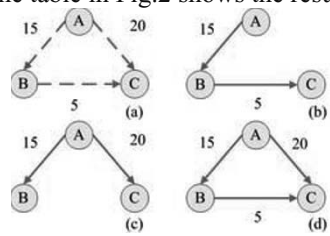
The choice of the range of h depends on the estimation of the actual time delay. The choice of the transfer entropy threshold is worth studying. In our proposed approach the threshold is set to be 0.1 for k=1, and 0.15 for k=0.

3.2. Strong relations extraction

With k=1, the strong relations are expected to be found. Since there exist some relations that may be the combinations of other relations, elimination of such redundant relations is necessary to avoid generation of a messy causal map. However, ambiguity may occur when we try to decide which relation is redundant. For example, for the time delay map Fig.2 (a), the following three causal maps could be all reasonable:

1. Causal chain map (Fig.2 (b)), i.e. A causes B, B causes C. This map is generated based on the fact the causal relation from A to C is redundant.
2. Common cause map (Fig.2 (c)), i.e. A causes B and C simultaneously. Due to the common cause A, it looks as if there exists a relation between B and C.
3. Straightforward causal map (Fig.2 (d)) derived based on the transfer entropy values. It is a coincidence that the sum of the time delays from A to B and from B to C approximately equals the time delay from A to C.

Here we use a strategy based on the assumption that a large transfer entropy implies high degree of significance. More specifically, the causal arcs are added in the order of the values of their corresponding transfer entropies from high to low. The causal arcs with larger transfer entropies are added first. If a causal arc to be added can be regarded as combinations of existing causal arcs, then it is a redundant relation that should be omitted. The table in Fig.2 shows the result of this strategy.



The smallest transfer entropy scenarios	Causal map inferred
from A to C	(b)
from B to C	(c)
from A to B	(d)

Fig. 2 Time delay map and causal maps of the three time-series example (a) Time delay map (b)Causal chain map (c)Common cause map (d)Straightforward causal map

3.3. Weak relations extraction

The transfer entropies with k=0 are also worth considering because they can also predict some information of causal relations. The same process of elimination of redundant relations as above should be performed then.

3.4. Reciprocal causation consideration

For k=0, if two variables have a significant maximized transfer entropy to each other at h=0, their relations may be either that they cause each other or that one is cause to the other with a time delay that is very close to 0, but not vice versa. To decide which assumption is the fact, the transfer entropies of k=1 are referred to once more. If their transfer entropies to each other are similar no matter whether they are above threshold, the former assumption will be considered as the fact, otherwise the latter.

4. Case study

The chemical process with 14 process variables simulated by UniSim Design R390.1 includes two CSTRs in series where cold water and hot water are mixed. All of the control loops are proportional controls. The Process Flow Diagram (PFD) is shown in Fig. 3.

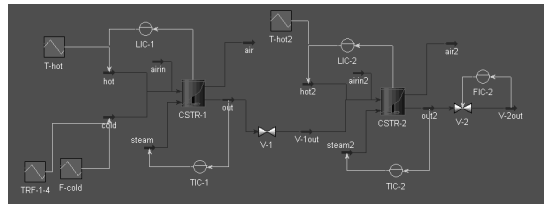


Fig. 3 PFD of the simulated process

200 samples with 0.5 second sampling interval are collected for the case study. A significance threshold of 0.1 is chosen to decide whether a transfer entropy can represent the existence of a cause-effect relationship.

With k=1, the generated causal map is shown in Fig. 4(a) with each node representing a process variable. The labels in the form of (A, B) on the arrows between two nodes indicate the maximized transfer entropy A and the corresponding time delay B. The nodes are named in the way "equipment/stream tag name" – "the variable type abbreviation" (F: flow rate, T: temperature, L: level, H: heat flow).

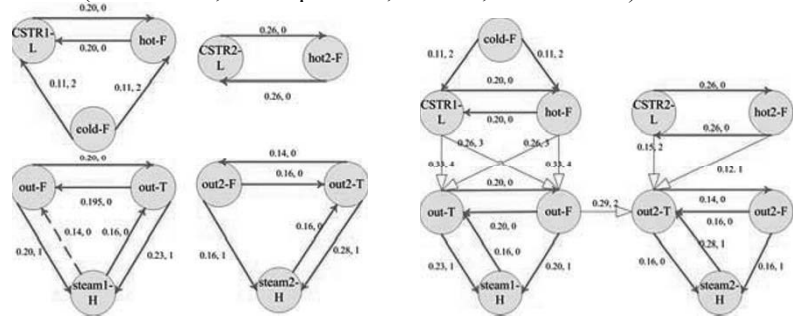

Fig. 4 (a) Strong relations in simulated case (b) Causal map with weak relations added

There are no significant transfer entropy values relevant to the three variables - stream 'hot' temperature, stream 'hot2' temperature and stream 'cold' temperature. The reason is that they belong to input flows and have only weak impact on other variables.

The other 11 variables are divided into 4 clusters in the causal map in Fig. 4(a), which exactly correspond to the 4 control loops. Dotted lines in Fig. 4 means the causal relations are omitted through examination of redundancy.

After step 3.3 and 3.4 are finished, the causal map becomes what is shown in Fig. 4(b). The fine arrows with hollow heads are added after these two steps.

It can be seen that the level of CSTR1 and the flow rate of the stream 'hot', and the level of CSTR2 and the flow rate of the stream 'hot2', make two special variable pairs. The two variables in each of the two pairs have similar transfer entropy to each other when k=1 and h=0, and interact with other variables in the same way. To make the causal map brief, such a variable pair is merged into one single node. The final simplified causal map is shown in Fig. 5.

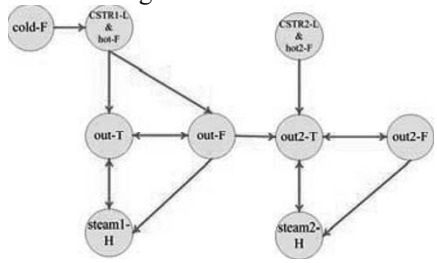

Fig. 5 Final simplified causal map

5. Conclusion

Causal inference is of great value for alarm management, fault diagnosis, and incident investigation. Due to the increasing size and complexity of modern industrial process, data-driven methods of causal inference show its advantage over knowledge-based ones. This paper modifies the Bauer's form of transfer entropy proposed and improves its performance in estimating time delay of causal relations. A causal inference approach based on transfer entropy is also proposed in this paper. A case study on a simulated chemical process is performed and illustrates the effectiveness of the proposed approach. However, some issues still need to be solved. The choice of the threshold should be considered further. Ambiguities and wrong causal relationships cannot be avoided fundamentally. A systematic procedure to bring in process topological knowledge to improve the performance of the data-driven method will be studied in the future.

Data-based Method for Diagnosing Multiple Blockage Locations in a Microreactor with Parallelized Microchannels

Masaru Noda[a] and Nobuhide Sakamoto[a]

[a]*Nara Institute of Science and Technology, 8916-5 Takayama, Ikoma 630-0192, Japan*

Abstract

Microreactors with parallelized microchannels are widely used in chemical industries because a single microchannel processes only a small amount of raw material. Any blockage in parallelized microchannels causes poor uniformity of the residence time distribution among microchannels and thus leads to degraded product quality. To address this issue, we developed a data-based identification method that can cope with blockages in multiple microchannels. The method identifies multiple blockage locations by comparing measured pressure-distribution data with pressure-distribution data calculated by computational fluid dynamic (CFD) simulation when blockage occurs. To avoid a combinatorial explosion of CFD simulations for database construction, the proposed method identifies blocked locations using only pressure-distribution data obtained when a single channel is blocked. The results of CFD simulations showed that the method can accurately identify three blocked locations using fewer pressure sensors than there are microchannels.

Keywords: Microreactor, Diagnosis, Channel blockages, Computational fluid dynamics, Correlation coefficient

1. Introduction

Microreactors have received both industrial and academic attention as a new type of production technology for specialty chemicals that are difficult to produce with conventional reactors. However, blockage in the microchannels of microreactors is a serious problem that limits their practical usage. It is therefore essential to detect and identify blockage locations to ensure more effective and stable microreactor operation.

Kano *et al.* (2007) proposed data-based and model-based blockage diagnosis methods using temperature sensors that identify blockage locations in stacked microchemical processes. Tanaka *et al.* (2011) developed a blockage detection and diagnosis system for parallelized microreactors with split-and-recombine-type flow distributors. This system can isolate a blocked microreactor with a small number of flow sensors. Simulation and experimental results showed that these methods can diagnose a single blockage location using fewer pressure sensors than microchannels.

In previous studies, we proposed a method for detecting blockage locations in a microreactor with parallelized microchannels. The method makes use of pressure sensors when blockages occur in two microchannels simultaneously (Yamamoto *et al.*, 2009, Noda *et al.*, 2010). It identifies the two blockage locations by comparing measured pressure-distribution data with pressure-distribution data calculated by computational fluid dynamic (CFD) simulation before the blockages occurred. The method can easily be extended to apply to cases in which there are three or more

blocked microchannels without incurring any combinatorial explosion of CFD simulations for database construction.

In this paper, we apply the method to a blockage identification problem where blockages occur in three microchannels simultaneously. We used CFD simulation in this study to generate the validation data for our method in case studies.

2. Microreactor

Figure 1 shows the structure of the microreactor used for the study. It is a point symmetrical microreactor consisting of three parts: an inlet manifold for flow distribution, parallelized microchannels for the reaction, and an outlet manifold for mixing. Pressure sensors are set up at all or some of the microchannel inlets. We assume that the total number of sensors and their locations have been given in advance.

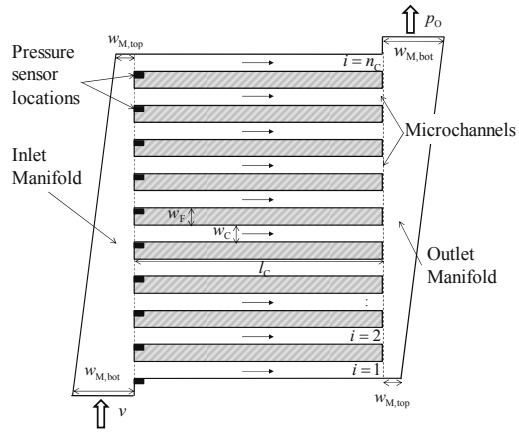

Fig. 1 Microreactor structure

The blockage degree BD_i of microchannel i is defined by Eq. (1), where $f_{B,i}$ and $f_{N,i}$ are the flow rates of microchannel i with and without blockage, respectively (Kano *et al.*, 2007).

$$BD_i = \left(1 - \frac{f_{B,i}}{f_{N,i}}\right) \times 100 \ [\%] \tag{1}$$

3. Identification method of blockage locations

The pressure drop distribution in a microreactor changes when a blockage occurs. Figure 2 shows an example of the pressure drop distribution when blockages simultaneously occur in three microchannels ($BD_1 = 15\%$, $BD_2 = 35\%$, $BD_8 = 35\%$) in a microreactor with ten microchannels.

As the figure shows, the pressure distribution has certain patterns with regard to blockage locations. Therefore, the locations can be identified by comparing the measured pressure distribution data with pressure distribution data prepared before the blockages occurred. However, to construct a database for identifying multiple blocked channels, it is necessary to calculate a large amount of pressure distribution data for all multiple channel combinations under various degrees of blockage. This calculation must be done by using CFD simulation, which is a very time-consuming process.

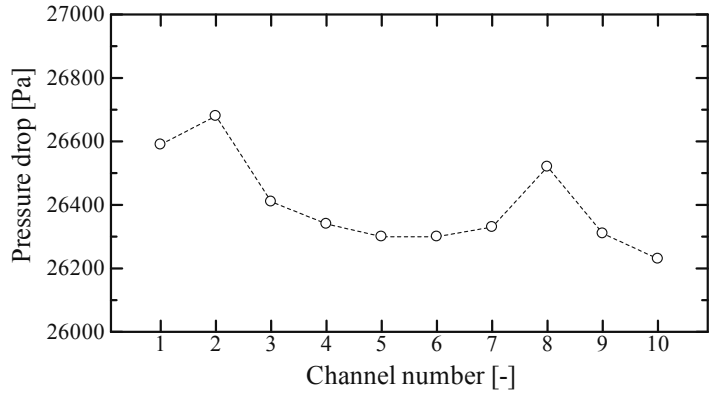

Fig. 2 Example pressure distribution data when blockage occurs in three microchannels

To avoid this combinatorial explosion of CFD simulations, we propose a method for identifying multiple blockage locations by using only pressure distribution data obtained when a single channel is blocked. In the example described here, the three blocked microchannels are identified through the following steps.

(1) Calculate the pressure difference data vector $\Delta\hat{P}_{B,i}$ defined by Eq. (2). Here, $\hat{P}_{B,i}$ is the pressure data vector at sensor locations when x% (>0) blockage occurs in microchannel i, which is calculated by CFD simulation. $\widetilde{P}_N$ is the pressure data vector measured at sensor locations under normal conditions.

$$\Delta\hat{P}_{B,i} = \hat{P}_{B,i} - \widetilde{P}_N \quad (i \in I) \tag{2}$$

Any blockage degree can be selected for x because the direction of the pressure difference vector between normal and abnormal conditions changes very little with regard to blockage degree.

(2) Measure the pressure difference data vector $\Delta\widetilde{P}$ defined by Eq. (3). Here, $\widetilde{P}_B$ is the actual pressure data vector measured at sensor locations. $\widetilde{P}_N$ is for normal conditions and $\widetilde{P}_B$ is for abnormal conditions.

$$\Delta\widetilde{P} = \widetilde{P}_B - \widetilde{P}_N \tag{3}$$

(3) Calculate the orthogonal projection vector $\Delta\overline{P}_{i_1,i_2,i_3}$ of $\Delta\widetilde{P}$ to the projection plane spanned by vectors $\Delta\hat{P}_{B,i_1}, \Delta\hat{P}_{B,i_2}$ and $\Delta\hat{P}_{B,i_3}$ $(i_1, i_2, i_3 \in I)$ by Eq. (4), where $\langle\cdot,\cdot\rangle$ denotes the inner product and $\|\cdot\|$ denotes the 2-norm.

$$\Delta\overline{P}_{i_1,i_2,i_3} = \alpha_{i_1}\Delta\hat{P}_{B,i_1} + \alpha_{i_2}\Delta\hat{P}_{B,i_2} + \alpha_{i_3}\Delta\hat{P}_{B,i_3} \tag{4}$$

$$\begin{bmatrix} \alpha_{i_1} \\ \alpha_{i_2} \\ \alpha_{i_3} \end{bmatrix} = \begin{bmatrix} \left\| \Delta\hat{P}_{B,i_1} \right\|^2 & \left\langle \Delta\hat{P}_{B,i_1}, \Delta\hat{P}_{B,i_2} \right\rangle & \left\langle \Delta\hat{P}_{B,i_1}, \Delta\hat{P}_{B,i_3} \right\rangle \\ \left\langle \Delta\hat{P}_{B,i_1}, \Delta\hat{P}_{B,i_2} \right\rangle & \left\| \Delta\hat{P}_{B,i_2} \right\|^2 & \left\langle \Delta\hat{P}_{B,i_2}, \Delta\hat{P}_{B,i_3} \right\rangle \\ \left\langle \Delta\hat{P}_{B,i_1}, \Delta\hat{P}_{B,i_3} \right\rangle & \left\langle \Delta\hat{P}_{B,i_2}, \Delta\hat{P}_{B,i_3} \right\rangle & \left\| \Delta\hat{P}_{B,i_3} \right\|^2 \end{bmatrix}^{-1} \begin{bmatrix} \left\langle \Delta\tilde{P}, \Delta\hat{P}_{B,i_1} \right\rangle \\ \left\langle \Delta\tilde{P}, \Delta\hat{P}_{B,i_2} \right\rangle \\ \left\langle \Delta\tilde{P}, \Delta\hat{P}_{B,i_3} \right\rangle \end{bmatrix}$$

(4) Identify blocked microchannels i^*_1, i^*_2, and i^*_3 by using Eq. (5), whose microchannels have the highest correlation between $\Delta\tilde{P}$ and $\Delta\overline{P}_{i_1,i_2,i_3}$.

$$(i_1^*, i_2^*, i_3^*) = \arg\max_{i_1,i_2,i_3 \in I} \frac{\left(\Delta\tilde{P} - \Delta\tilde{P}^m\right)^{\mathrm{T}} \left(\Delta\overline{P}_{i_1,i_2,i_3} - \Delta\overline{P}^m_{i_1,i_2,i_3}\right)}{\left\|\Delta\tilde{P} - \Delta\tilde{P}^m\right\| \left\|\Delta\overline{P}_{i_1,i_2,i_3} - \overline{P}^m_{i_1,i_2,i_3}\right\|} \tag{5}$$

Here, all elements of $\Delta\tilde{P}^m$ and $\Delta\overline{P}^m_{i_1,i_2,i_3}$ are the means of all elements of $\Delta\tilde{P}$ and $\Delta\overline{P}_{i_1,i_2,i_3}$, respectively.

4. Case study

The proposed method was applied to a blockage diagnosis problem for a microreactor with 10 microchannels. Table 1 summarizes the geometric parameters in Fig. 2 and the microreactor's operating conditions. Four pressure sensor configurations (Conf. A–D) were implemented for use in different case studies.

Conf. A: $n_S = 10$, $S = \{1, 2, 3, 4, 5, 6, 7, 8, 9, 10\}$
Conf. B: $n_S = 6$, $S = \{1, 3, 5, 6, 8, 10\}$
Conf. C: $n_S = 5$, $S = \{1, 3, 5, 7, 9\}$
Conf. D: $n_S = 4$, $S = \{1, 4, 7, 10\}$

Pressure sensors were set up at the inlet of the microchannels $i \in S$. The sensors' measurement accuracy was assumed to be 10 Pa, which was determined in accordance with the best measurement accuracy of commercial MEMS pressure sensors.

In the case study, the following blockage diagnosis problem was considered to assess the proposed method's effectiveness.

$$BD_1 = 15\%,\ BD_2 = 35\%,\ BD_8 = 35\%$$

Table 1 Geometric parameters and operation conditions of microreactor

Name	Parameter	Value	Unit	Name	Parameter	Value	Unit
Number of channels	n_C	10	-	Widths of manifold	$w_{M,top}$	5.0	mm
Channel width	w_C	100	μm		$w_{M,bot}$	1.4	mm
Channel depth	z_C	100	μm	Inlet velocity	v	0.01	m/s
Channel length	l_C	20	mm	Outlet pressure	p_O	101.3	kPa
Width of fin	w_F	284	μm	Viscosity	μ	0.1	Pa·s

Simulation results are summarized in Table 2, in which the combinations of identified numbers of blocked channels are shown. The proposed method correctly identified the blocked microchannels #1, #2, and #8 when there were five or more sensors. These results demonstrate that a small database with pressure distribution data for the blockage in a single microchannel can correctly identify multiple blockage locations in a microreactor when the number of pressure sensors is more than half of the number of microchannels.

Table 2 Simulation results

Sensor configuration (n_s)	A(10)	B (6)	C (5)	D (4)
Identified blockage locations	1, 2, 8	1, 2, 8	1, 2, 8	1, 5, 8

5. Conclusion

A data-based identification method that can cope with blockages in multiple microchannels was proposed. To avoid a combinatorial explosion of CFD simulations for database construction, the proposed method identifies blocked locations by using only pressure distribution data when a single channel is blocked. The results of CFD simulations showed that the method can accurately identify three blockage locations using fewer pressure sensors than there are microchannels. In this study we focused on a case in which three microchannels were blocked, but our method can easily be extended to apply to cases in which there are four or more blocked microchannels without incurring any combinatorial explosion of CFD simulations for database construction.

Dept. of Civil and Managegement Engineering, Nagoya Institute of Technology, Nagoya 466-8555, Japan

Abstract

In this paper, the security improvement approaches for process plant instrumentation and process information systems are proposed. By dividing control and information systems into plural zones considering process dynamics under the proposed framework, higher possibility of cyber-attacks detection and operational accident prevention can be attained. Based on this framework, accidents caused by cyber-attacks are evaluated as a form of FTA created from detectability and reachability matrices made from process, operation and control (management) constraints. An example also illustrated to understand the proposed approach.
Keywords: plant security, hazard management, plant safety, design methodology

1. Introduction

Current Industrial Control Systems (ICS: from sensors to SCADA, MES) are connected to Internet for many purposes such as information exchange for business oriented plant operations and remote maintenance. The open system movement, though, shows great promise for certain benefits through COTS (commercial off the shelf) products, it also causes various risks as the results of open architectures and network technologies. Recently, a very specific threat for process plants has come in reality. Stuxnet is acknowledged as the first malware, which attacked continuously to a uranium enriching plant in Iran, targeting specific Programmable Logic Controllers (PLCs). This malware has been spread out all over the world to many process plants with and without Internet connection. As the most serious effect from Stuxnet, demonstration by followers might be occurred with high possibility over automatically operated critical infrastructures. In this situation, ICS require highly reliable security and safety services with urgent priority.

In this paper, the authors discuss about a new protection profile for process plant that covers not only safety but also security. Under this profile, even if some invasion to the ICS is succeeded, plant operators might be able to handle the attacks with intangible and autonomous ICS. Design methodologies of secured process plant and PIS (Plant Information Systems) are also discussed with an illustrative example.

2. Characteristics of ICS security problem

The serious security holes of personal computer systems are frequently reported, and security patches thereto are distributed almost every day. In some cases, the security patches make uncertain troubles from conflicts among installed applications. Full security patches, therefore, are rarely applied to ICS for maintaining their security. For

the ICS security, particular approaches are necessary in addition to ones for information systems.

2.1. Schemes for enhancement of ICS Security

Evaluation of security assurance level of ICS is discussed in ANSI/ISA99. Security zones and conduits shown in Fig. 1 are important concepts in ISA99 (Uehara, 2011). The security of the system is evaluated based on the zones and their interfaces. The firewalls between zones must not have the same vulnerability. In this standard, however, safety is not discussed at all. For the process plants, the zone design approach to improve safety should be discussed with security of ICS.

2.2. Schemes for enhancement of ICS Safety

The design approaches of Safety Instrument Systems (SIS) are described in IEC61508 (IEC61511 is the standard for process industry). Safety integrity and reliability are evaluated using Hazard and operability studies (HAZOP), layers of protection analysis (LOPA), risk graphs, FTA and so on. However there are very few papers that consider the threats of the cyber attaches (NRC, 2010). Although, the effects of single failure are discussed in these approaches, attacks of cyber terrorists cause multiple failures. They invade the system via Internet and/or malwares and steal, manipulate and conceal process and control information.

Cyber terrorists can attack the plural layers in IPL (cf. 2, 3, 4, 6, 7 layers in Fig. 2).Especially, when emergency shutdown system in IPL4 that is constructed with PLC, is attacked, service of the plant can be stopped immediately. Against such undesirable shutdown, a fail-safe system shown in Fig. 3 is necessary. This additional logic system is attached to check the trigger conditions of the manipulation (It is not necessary to check the all conditions). The manipulation is activated only when the both outputs are identical. The design scheme of SIS should be reconsidered from security perspective.

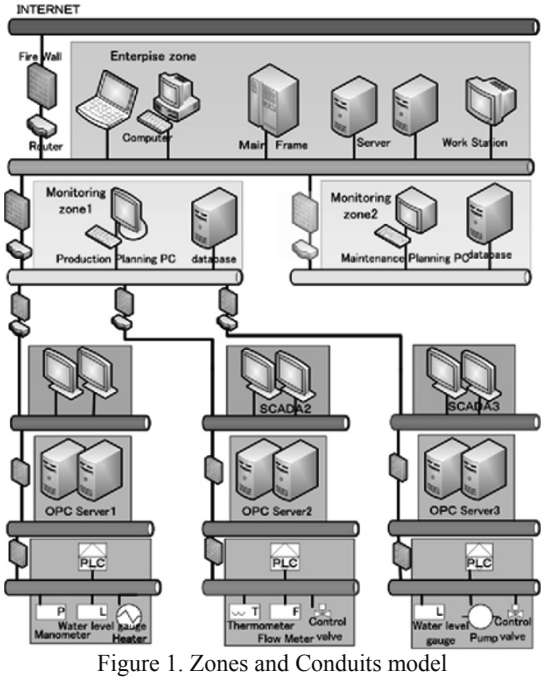

Figure 1. Zones and Conduits model

Figure 2. Independent Protection Layers

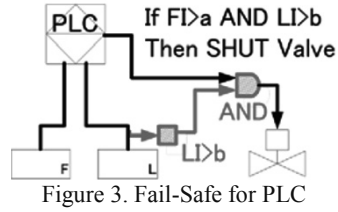

Figure 3. Fail-Safe for PLC

3. Fault Tree Analysis for threats of cyber terrorism

Fault tree is very popular method to evaluate risks. Because it can deal with multiple failures, it can be applied to evaluate the threats of cyber terrorism. Attacks of cyber terrorists are parts of causes of accidents. Manipulation sequences by terrorists are similar to sets of mal-operation. Concealment of their manipulation is similar to a set of sensor malfunctions. In safety assessment, they are evaluated based on human factors and equipment failures. In security problems, the probability of their occurrence is not independent. Cyber terrorists combine the causes to ensure their attacks. The countermeasures against cyber terrorism must appear in FTA to evaluate their efficiency. Invalidation of a countermeasure is one of the conditions, which are combined by AND, to occur a trouble state in FTA. Countermeasures are activated after the detection of abnormality. If the trigger information is concealed, countermeasure is invalidated. The effects of concealment must be considered as well as manipulation.

How to construct Fault Tree for evaluation of security threats were discussed in our previous papers (Shindo, 2000, Toyoshima, 2011, Yogo, 2011). In this paper, a systematic, qualitative and quantitative scheme is proposed to evaluate the effects of manipulation and concealment by cyber terrorists. The efficiency of the scheme to divide the plant instrument into plural zones is evaluated on the view of invalidation of cyber-attacks.

4. Effects of manipulation and concealment in a zone

The main threats of cyber terrorists are all sorts of accidents (i.e. explosion and contamination of drinking water) and/or sabotage against service continuity (i.e. power outage and water outage). In industrial plants, they are caused by manipulations of valves and/or switches. If actual process data can be observed by operators, such intentional manipulation should be detected because of spontaneous delay in process dynamics and some countermeasure can be applied before said manipulation affects. Terrorists, therefore, conceal their manipulations to disable countermeasures.

In industrial plants, many controllers are utilized. If they are divided into plural zones and the same scheme cannot be applied to invade the zones, some zones can survive against cyber-attack. As the result, possible manipulations are limited in the invaded zones. If plural manipulation is necessary to activate multiple accidents in other zones simultaneously, the probability of accident can be reduced.

Although the signals from the sensors in the invaded zones can be forged, the controller in the surviving zones may be affected by the said manipulation. When certain cyber-attack is detected, field devices and local signals such as glass gauges of tanks should be checked. The controllers in the invaded zones are switched into local backup controllers as shown in Fig. 4 or turned into manual operation mode. If the dynamics of the controller is slow, the local backup might not be necessary. When the detection is succeeded immediately, the controllers can be recovered from the attacked state. Even if the state of the invade zones becomes dangerous, certain manual sequence to shut down the plant is safely adopted.

The detection in the surviving zone also affects controllers. The controllers in the surviving zones manipulate valves based on the sensed signals. If the manipulation is manual, the action of operator based on the sensor can be considered as a controller. If the caused manipulation is a cause of an accident, the risk of the control in surviving zones should be considered.

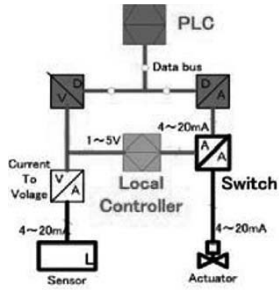

Figure 4. Backup controller

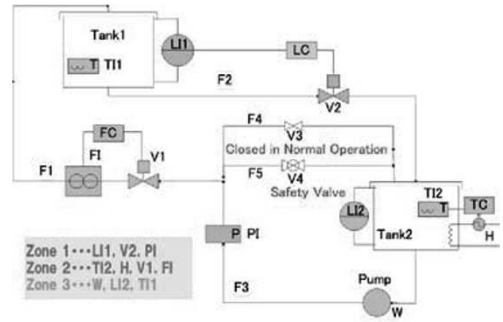

Figure 5. Two tank system for Example

In this paper, the effects of zones on detection and risk reduction of cyber-attack are discussed. A simple plant shown in Fig. 5 is utilized to illustrate the evaluation scheme of effects of zones. It has 10 process variables and 10 sensed variables. Manipulated variables are 6. Two of them are local valves, which cannot be operated by cyber attackers. One is a remote operable valve, which is not connected with a controller. Three of them are actuators of controllers. They are divided into three zones as shown in Fig. 5.

The relationships between the variables are expressed using Boolean matrices as shown in Table 1. They are square matrices, whose rows and columns contain all variables. All of their diagonal elements are one. Tables from 2 to 4 show a part of the matrices.

Matrix P in Table 1 shows the process dynamics. Matrix C in Table 2 shows control actions. It can express not only controller but also manual operations based on the observation. The columns M_{23} in Table 3 correspond to the manipulated variables in the invaded zone (zones 2 and 3 in this case). The columns of A_{23} in Table 4 correspond to the information which can be forged by cyber-terrorists. These matrices are arranged according to the selection of invaded zones. S_1 is the diagonal matrix to express the effects of concealment. The diagonal elements corresponding to the invaded sensors are zeros. O_1 is the matrix to extract the surviving sensors.

Detectability matrix and reachability matrix are defined by eq. (1) and (2), respectively.

$$D_{23}(m) = \sum_{k=1}^{m} O_1 \, (S_1 \cdot P \cdot C)^{k-1} S_1 \cdot P \cdot M_{23} \quad (1)$$

$$R_{23}(\mathrm{n}) = \sum_{k=1}^{n} (P \cdot C)^{k-1} P \cdot A_{23} \quad (2)$$

If non-zero elements appear in each column of the detectability matrix, it can be judged that the effects of the manipulation can be detected under concealment by cyber attackers. If manipulation cannot be detected, all elements of the column corresponding to it remain zero even when the order of detectability matrix (i.e. *m* in eq. (1)) is larger than the size of variables.

Table 5 shows the detectability matrices in two cases. $D_{23}(26)$ shows that manipulation of heater cannot be detected when zones 2 and 3 are invaded. $D_2(3)$ shows every manipulation in zone 2 can be detected in three steps of propagation. In this case, the manipulation of heater can be detected in the temperature change of the other tank, T1. It is easy to calculate the detectability matrices for all cases of invasion by cyber attackers. It can be confirmed that only the case, in which zone 2 and zone 3 are invaded and heater is manipulated, is undetectable. Needless to describe, if all zones are invaded, any manipulation under concealment cannot be detected from sensed information. In order to detect the heater manipulation in such a case, the temperature analog signal must be duplicated and be transferred to zone 1.

Table 6 shows reachability matrix R_{23}. It shows the effects of forgery in invaded zones. While forgery of T1i doesn't affect others, T2i can affect as similar to H. The change of T2i can cause heater manipulation by its controller. If operator manipulation is described in controller matrix, C, the effect of the operators' countermeasures against the forged situation can be considered.

5. Conclusion

Evaluation method of security zoning for Industrial Control Systems is proposed by defining detectability matrix and reachability matrix. This approach shows an example of the cooperation of information engineers and process engineers for security improvement of control systems.

Abstract

HAZOP is the most commonly used process hazard analysis tool in industry, a systematic yet tedious and time consuming method. The aim of this study is to explore the feasibility of process dynamic simulations to facilitate the HAZOP studies. We propose a simulation-based methodology to complement the conventional HAZOP procedure. The method systematically generates failure scenarios by considering process equipment deviations with pre-defined failure modes. The effect of failure scenarios is then evaluated using dynamic simulations -in this study the K-Spice® software used. The consequences of each failure scenario are summarized using a sensitivity measure, which forms the basis for ranking the significance of failure scenarios. The ranking then reveals the most critical process parameters as well as equipment in a system. The methodology is successfully highlighted using part of gas-reinjection process model as case study.

Keywords: HAZOP, Dynamic Simulation, Process Control, Process Model, Safety, gas-reinjection

1. Introduction

Due to increasing public awareness, legal demands (such as Seveso II directive) for safety systems and many severe accidents within the oil, gas and chemical industry, much research has been invested in developing effective hazard and safety analysis methodologies. One of the most commonly used process hazard analysis for risk assessment is the hazard and operability (HAZOP) analysis. The HAZOP method systematically covers the entire process by taking a deviation, which is generated by a combination of a relevant guide word (e.g. MORE OF, LESS OF, …) with a key process parameter (e.g. Flow, Temperature, etc.) to identify possible causes and consequences in a given section of a plant (Cameron et al. 2005). Based on a qualitative risk assessment of the identified causes and consequences of a hazard (e.g. using the ALARP principle), recommendations are then made by HAZOP team to improve the base case design (and or retrofit/upgrade the existing plant). One of the drawbacks of the HAZOP method is that it is time-consuming and purely depends on human experience and the knowledge of the multidisciplinary HAZOP team. These and other drawbacks motivated the development of computer-aided HAZOP methods and accompanying software tools to facilitate carrying out HAZOP analysis in industry.

Research in the area of computer-aided HAZOP accounts for approximately 40% of the publications in the last decade as reported in 2010 by (Jordi et al. 2010).
Most computer-aided HAZOP methods uses expert systems based on qualitative reasoning engines, logic representation and symbolic manipulation type artificial intelligence techniques. Examples of such methods include QUEEN, HAZOPexpert, STOPHAZ, functional HAZOP among others (Jordi et al., 2010; Enemark-Rasmussen, 2011). It is noted that most of these methods require the translation of a P&ID of plant into an appropriate HAZOP model (as needed by the expert system in question) and an extensive database, which consists of known facts, rules and characterization of process equipment on basis of type of operation and process variables. This information base draws on knowledge from experiences and studies of process deviations, causes and consequences of these deviations and hence needs to be adapted or extended for the specific application. Industry acceptance of such HAZOP software is rather low, due to need for new skills and expertise in learning the HAZOP modelling language.
In this contribution, our aim is to develop a methodology that provides support for incremental improvement of the HAZOP studies by using readily available dynamic models. The premise is two-fold: (i) dynamic models are increasingly used in the chemical industry –most if not all projects in the oil and gas industries use dynamic models for verifying design capacity and evaluating instrumentation, control and automation strategies. These models are available for hazard and operability analysis at no additional cost, (ii) the dynamic models are based on laws of conservation for mass, energy and momentum and a set of constitutive equations such as physical properties calculations. This provides objective credible and scientifically sound decision making in HAZOP analysis. The methodology is explained below and highlighted using the gas-reinjection process as a case stud -commonly used in offshore oil and gas industry.

2. Dynamic simulations based Methodology for HAZOP studies

The simulation methodology used for operability and safety analysis (Enemark-Rasmussen, 2011) uses a combination of failure mode effect analysis and HAZOP procedures as described by (Skelton, 1997). Generation and dynamic simulation of failure scenarios allows the user to follow the changes in the critical process variables when a failure scenario is introduced in equipment. The analysis was carried out following the steps in the methodology, as seen in Figure 1 and Figure 2:

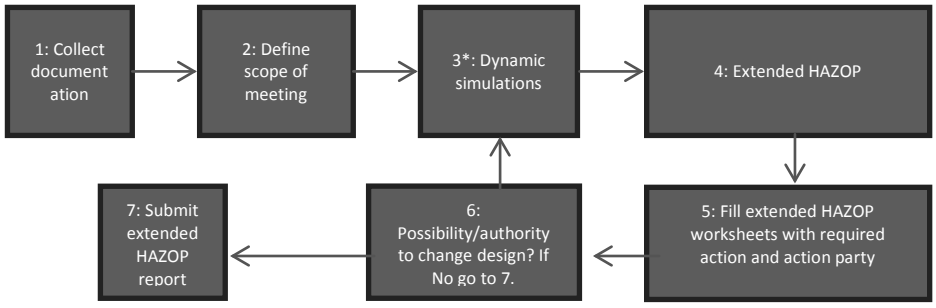

Figure 1: Extended HAZOP methodology using dynamic simulations

2.1. Scenario generation

The system is described by the simplified differential state equations (1) which are based on the conservation of mass, energy and momentum equations. The variables

defining the state of the system are the critical process parameters, *x*, the time, *t*, and the variable equipment settings, θ.

$$\frac{df}{dx} = f(x,t,\theta) \; and \; y = g(x,t,\theta) \tag{1}$$

A failure scenario is thus defined as a deviation, *i*, of the process equipment variable, θ_i, resulting in a failure mode of the process system, g_i. A failure scenario is mathematically simulated using the state equation (1) by varying the nominal values of the parameters of equipments (e.g. valve) according to the failure (e.g. valve fails to close or fails to open).

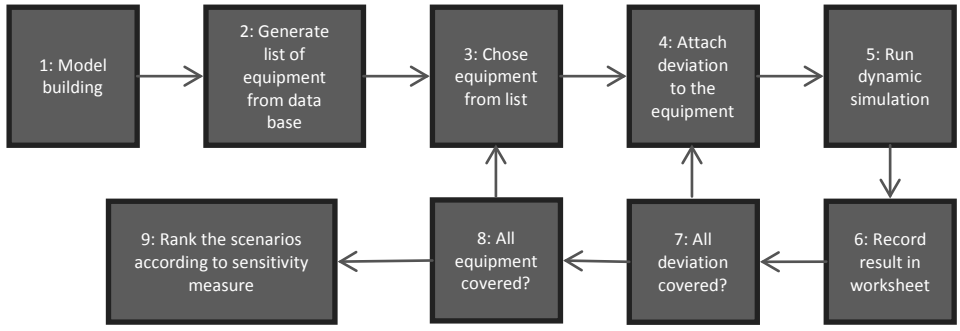

Figure 2: Detailed structure of the dynamic simulation step used in the methodology

2.2. Failure scenario ranking

The significance of the consequences of the failure scenarios are ranked based on sensitivity analysis (SA) given in equation (2) (Sin et al., 2009). The normal operation value (e.g. Pressure) at a given position and time in the process is defined by y(θ) and the failure scenario value at the same position and time is defined by y(θ-Δθ) both generated by the dynamic simulation of the failure mode, $f_i(\theta_i)$.

$$If \; \theta > \theta_i \Rightarrow SA = \frac{\Delta y}{\Delta \theta} = \frac{y(\theta) - y(\theta - \Delta\theta)}{\Delta \theta} \; and \; If \; \theta < \theta_i \Rightarrow SA = \frac{\Delta y}{\Delta \theta} = \frac{y(\theta + \Delta\theta) - y(\theta)}{\Delta \theta} \tag{2}$$

2.3. Process equipment deviations

The deviations or malfunctions included at this stage is limited to the most common process equipment used in the upstream oil and gas industry, such as separators, valves, piping and process control. Deviations are defined in the range zero to one by equations or by logical meaning. As example, plugging is defined by the admittance equation, $A_v^{new} = A_v^{normal}(1 - plugging \; fraction)$, where the admittance, A_v, is proportional to the flow through the pipe and the flow coefficient, C_v. Deviations such as fully closed/fully open are logic-based, and receive values of zero or one.

The following type of deviations considered for the process equipments in the case study: Fully closed, Fully open, Plugging low, Plugging high, Fail high, Fail low, Fouling low, Fouling high, Rupture/leakage, Power failure, Deterioration and wear. This list can be extended if necessary for different equipments or scenarios.

2.4. Summary of results: ranking of failure scenarios

The results obtained during simulations of the failure scenarios are recorded in a pre-generated worksheet which includes scenario number, j = 1…N, failure mode, f_i, values for both θ and θ_i, normal operation and failure values of the critical process parameters as well as the sensitivity measurement used for ranking.

3. Results and discussions Case study of gas re-injection process

To validate the methodology a case study of an offshore gas re-injection process is investigated. Process instrumentation and flow diagram is given in Figure 3.

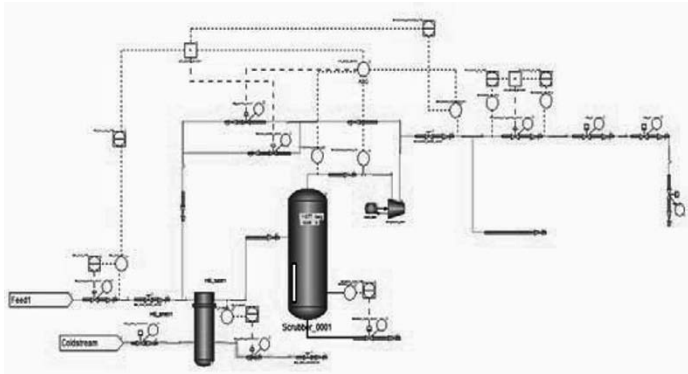

Figure 3: Process instrumentation and flow diagram for gas re-injection process

The K-Spice® software uses built-in functionality to introduce equipment deviations, in the software called equipment malfunctions. After introducing an equipment deviation, the behavior of critical process variables is displayed over time at mass or energy transfer points or other locations of interest, such as production outlets. Each failure scenario is simulated over enough time to capture any changes that might occur during the transient phase when going from normal to failure operation conditions. The system typical reaches peak values within a short time span, before the control systems react to counter e.g. pressure increase. For each failure scenario simulation any peak values are recorded together with the stabilized process parameter values to be used for sensitivity measurement ranking. The results of each failure are recorded as shown in Table 1.

Table 1: Failure scenario result from Gas feed control valve fully closed.

Scenario	**Failure scenario**				**T [°C]**	**u [kg/h]**	**P [barg]**	**Sensitivity measure (SA)**			**Consequences**
J = 1...N	Failure mode f_i	Parameter (θ)		$y_i(\theta)$	Normal value			$\frac{\Delta T}{\Delta \theta}$	$\frac{\Delta u}{\Delta \theta}$	$\frac{\Delta P}{\Delta \theta}$	
		Default	Failure		Failure value						
1	Gas_feed control valve1 fully closed	0.715	0	Recycle loop	76.5	0	189.3	107	0	264.8	No flow in system.
					0	0	0				
		0.715	0	Compressor	79.8	244110	189	112	341413	264.3	
					0	0	0				
		0.715	0	Reinjection P2	76.2	209385	169.6	107	292846	237.2	
					0	0	0				
		0.715	0	Reinjection P1	76.2	34725	169.6	107	48566	237.2	
					0	0	0				
		0.715	0	Gas feed	70	244133	120	0	341445	0.0	
					70	0	120				
		0.715	0	Sea Water outlet	37.7	697475	15.5	10	975456	-0.6	
					30.2	24	15.9				

In Table 2 the five highest ranked scenarios are displayed for Temperature, Flow and Pressure parameters based on the quantitative sensitivity measure obtained by forward or backward differentiation (equation 2). Using the methodology, 68 failure scenarios were identified and ranked based on the sensitivity ranking. The most severe failure was found to be: the re-injection control valve failed closed. This resulted in a pressure peak

above design values at the compressor and pressure build-up at gas feed inlet. Other high ranked failure scenarios resulted in loss of re-injection and possible damage to equipment due to pressures reaching above design pressure.

Table 2: Failure scenarios ranked by sensitivity measure of critical process parameters

Sc	Temp ranking Failure mode f_i	SA $\frac{\Delta T}{\Delta\theta}$	Sc	Flow ranking Failure mode f_i	SA $\frac{\Delta u}{\Delta\theta}$	Sc	Pres ranking Failure mode f_i	SA $\frac{\Delta P}{\Delta\theta}$

4. Conclusion and perspectives

The methodology based on dynamic simulations captures the strengths of the conventional HAZOP by being systematic in approach. It uses rigorous equipment and deviation models to generate and simulate failure scenarios. The outcomes of the simulations are recorded, which quantitatively indicate the deviations in the critical process parameters. Using the sensitivity measure, the failure scenarios are ranked and the significant ones are identified. In this way, the methodology reduces the time needed and complements the skills of the analysis team in HAZOP. The advantage of the methodology is two folds: (i) no additional skills required to use our method as HAZOP teams consist of design and control engineers familiar with the process simulations and, (ii) no need for HAZOP model building as the method *reuses* dynamic process models already available for use in the oil & gas industry. From practical experiences, it is the opinion of the authors that much time and resources can be saved with the use of dynamic simulation methodology as input to the HAZOP meeting by prioritizing the focus area for discussion in the HAZOP team. The method requires a regularly updated process model prior to use in simulations and proper selection of points in the process for recording as such the results still depend on user's process insight.

Abstract

Many chemical processes are constructed within very compact areas due to the limitation of resources including land and cost although many of their units are dangerous and vulnerable to accidents such as fire or explosion. There have been many researches to make chemical processes safer by modifying the layout of process to ensure the safety distance among hazardous equipment. Even the safety among units is secured, however, this situation can get worse if the process site is near residential areas or the workspace of employees is located in the site because of the risk to human, which is usually not concerned for process layout. In this study, quantitative risk to human as well as the risk of equipment itself is considered to give more reliable layout of chemical processes. Among various quantitative risk approaches, modified individual risk index has been adopted. Individual risk counts for the risk that a person near the dangerous environment can take. With this index, optimal process layout is designed by minimization of cost and land area to consider the limitation of resources, also. The proposed methodology can provide the guideline to designing safe layout of chemical process concerning the various safety distance measures including equipment-equipment distance, equipment-employees distance and equipment-the public distance.

Keywords: Process layout, Individual risk, Safety distance, MILP

1. Introduction

In 2005, there was fire and explosion at the refinery of BP Products North America in Texas City which claimed 15 deaths and more than 170 injuries. In 1998, an explosion at the LPG filling station in Bucheon, Gyeonggi province of Korea caused 1 death and 96 injuries. Apart from the direct cause of the accident, high casualties of both accidents arouse from the existence of dangerous equipment or device near the people.

Above accident cases show that the proper safety distance between process areas and public or worker residential areas is crucial to minimize the effects of accident and the damages to human. There were not many researches, however, about the safe layout of hazardous facilities considering public residence or workspace of employees from the early part of process design. Previous researches about the process layout optimization include 2-dimensional layout of processes using heuristic rules (Suzuki, 1991) and MILP modeling for multi-floor layout optimization (Patsiatzis, 2002). Researches considering safety factors and accident scenarios also have been carried out. Dow Fire & Explosion Index was used to evaluate effective radius and damage costs of accident and to optimize process layout by MILP (Patsiatzis, 2004), and scenario-based optimization using statistical method for toxic chemical release was implemented for

layout (Diaz-Ovalle, 2010). These approaches have some limitations due to the subjectivity of indices and the uncertainty of scenarios.
In this study, mathematical modeling for process layout optimization is used together with the consideration of process safety to secure safety distances, especially to human. Optimal layout of process is arranged by satisfying the separation distances and minimizing costs. To ensure the minimum effect of accident, following three types of distances must be considered: distance between equipment; distance between equipment and workspace (e.g. control room); distance between equipment and process boundary (i.e. public area). The first one is determined from previous researches about the safety distance between equipment. The second and third types of distance were calculated to meet the allowable limit of individual risk for worker and public.

2. Individual Risk

A risk index is a comprehensive, integrated representation of accident frequency and consequence. Among various risk indices, IR (Individual risk) is an effective measure for quantifying the risk from chemical process equipment to human, since it is the risk to a person in the vicinity of a hazard and includes the nature, the likelihood, and the time period of the possible injury to the individual (CCPS, 1988).
The basic calculation of risk is usually done by the product of frequency and consequence of accident that came from various quantitative risk analysis methods like Fault Tree Analysis, but IR reflects more elements.
To get IR index (Franks, 2007), first the frequency of fatality of a person at the location of interest *i*, considering the accident frequency, fatality rate, weather effect and directional effect is calculated for all the accident scenarios about the event outcome *j*.

$$FoF_i = \sum_j f_{eo,j} \cdot p_{fatality,i,j} \cdot p_{weather,i,j} \cdot p_{direction,i,j} \quad (1)$$

Then, fraction of time and probability of presence of people are multiplied to give IR for the group of people *k* at the location *i*.

$$IR_{i,k} = \theta_k \cdot p_{location,i,k} \cdot FoF_i \quad (2)$$

For certain allowable limit, IR can be used as constraint of layout optimization problem. In this study, we use IR limit to estimate the minimum safety distance of equipment.

3. Process Layout Optimization based on Risk Analysis

The optimization of process layout was carried out through two sections: calculation of IRs and safety distances of process equipment and cost optimization of process under distance constraints.
In risk boundary section, target process is analyzed and related hazards are identified to select appropriate accident scenario. Then, frequency and consequence analysis (FA and CA) for selected scenario are performed and IR of equipment is calculated. We can obtain the safety distances of equipment that satisfy the allowable limit of IR since IR can be expressed as a function of distance from the equipment.
The layout optimization section employs typical constraints of layout problem of MILP form such as dimension and orientation, non-overlapping of equipment and separation distances (Patsiatzis, 2004). In this study, however, there are three types of separation distance constraints not just one: (1) distances between equipment, ED_i (Prugh, 1988) (2) equipment – workspace distances, $RD_{work,i}$, calculated from IR of equipment to worker (3) equipment – process boundary distances, $RD_{pub,i}$, calculated from IR to public people. The process is economically optimized under these constraints by

minimization of cost including pipeline, land and equipment cost. Therefore, the objective function is expressed in three terms:

$$minimize \sum_i \sum_{j \neq i} C_{ij} D_{ij} C_{pipe} + C_{land} \sum_k AR_k Q_k + \sum_i E_i \quad (3)$$

Fig. 1 summarizes the overall procedure described above.

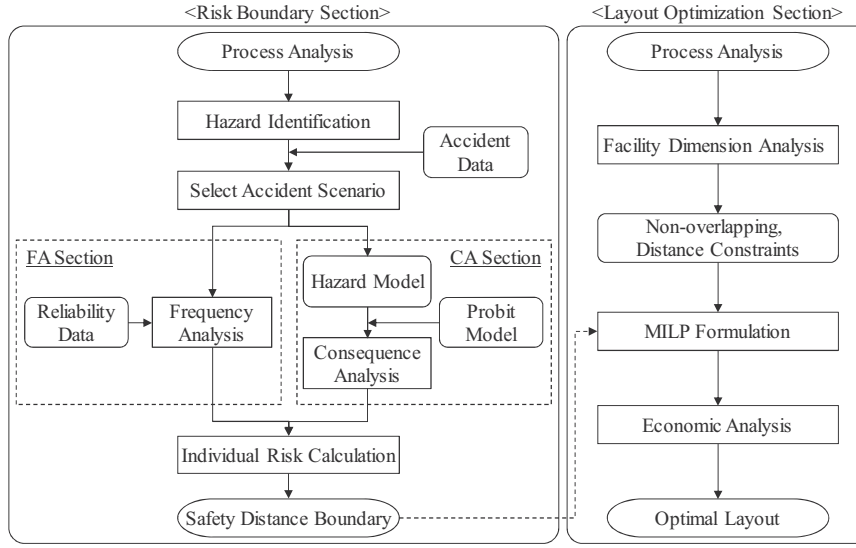

Figure 1. Overall procedure for layout optimization from risk analysis

4. Case Study

The proposed methodology is applied to a DME (dimethyl ether) filling station as an example. DME is one of the promising next-generation fuels, which has been researched as the substitute of LPG or diesel. Since the equipment required for filling station are vulnerable to fire or explosion, appropriate layout is necessary to ensure the safety for human and process itself.

4.1. Problem Description for DME Filling Station

In its filling station, there are four main units after the loading section: compressor, storage tank, pump and dispenser. Connectivity among them is shown in Fig. 2. Besides them, a control room is considered for workspace.

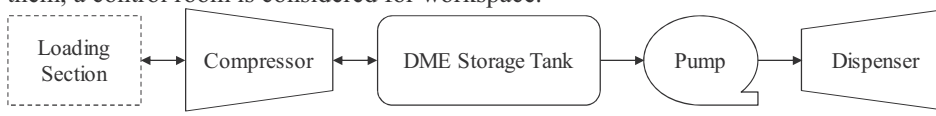

Figure 2. Scheme of DME filling station

Here, we optimize the layout of DME filling station to minimize the total cost under following assumptions:

- Worst-case accident scenarios (θ_k =1, $p_{location,i,k}$ =1)
- No directional and meteorological effects ($p_{weather,i,j}$ =1, $p_{direction,i,j}$ =1)
- Square process site and rectangular equipment
- Rectilinear pipeline connections between units

Operation condition of each unit was obtained from that of the LPG filling station since DME has similar physical properties with it and DME-LPG mixture can utilize the existing LPG facilities. To compare the economic result, various combinations of storage tank sizes with the same total capacity are considered.

4.2. Calculation of Safety Distances

From the accident records of LPG filling station in Korea (1987~2003), 3 major types of accident – flash fire, BLEVE (boiling liquid expanding vapor explosion) and VCE (vapor cloud explosion) – were considered to evaluate the accident effect. Then, risk indices are obtained with the frequency analysis using K-RDB (Korea Reliability DataBase) and the consequence analysis from probit analysis. Allowable limit of risk index (IR) is 10^{-3} for workers in control room and 10^{-4} for public people outside the process area. Safety distances that meet these criteria are listed in Table 1 for equipment.

Table 1. Minimum separation distances

Equipment		From workspace		From boundary		Between equipment
		$RD_{work,i}$ [m]	IR ($<10^{-3}$)	$RD_{pub,i}$ [m]	IR ($<10^{-4}$)	ED_i [m]
Storage tank	5ton	26	0.000942	39	0.000072	7.7
	10ton	31	0.000974	49	0.000093	
	15ton	37	0.000956	56	0.000096	
	20ton	40	0.000988	62	0.000083	
Pump		15	0.000659	17	0.000042	8.8
Compressor		18	0.000420	19	0.000042	9.6
Dispenser		25	0.000882	29	0.000086	8

4.3. Process Layout Result

Five combinations of storage tanks with total capacity of 20ton were optimized using CPLEX solver in GAMS and one of the layout results is shown in Fig. 3. Storage tanks are located near the center of the process site for all cases because they are the most hazardous equipment. Control room is on a corner to minimize the risk from other units while it does no harm to public.

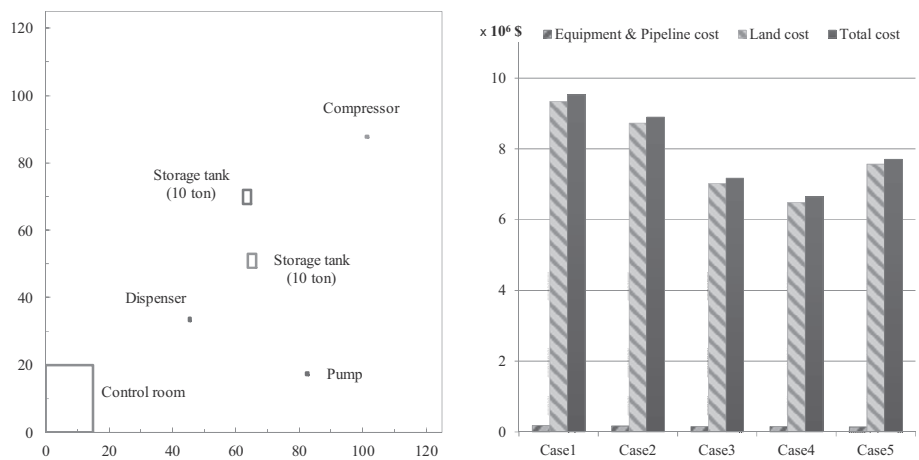

Figure 3. (left) Layout result of Case4 (right) Cost comparison of cases

Land area and costs of each case are compared in Table 2 and Fig. 3. For all cases, land cost affects the total cost much more than the cost of equipment and pipeline, and therefore, Case4 which requires the smallest land area shows the lowest total cost.

Table 2. Layout optimization result

	Case1	Case2	Case3	Case4	Case5
Combination	5ton x4	5ton x2 & 10ton	5ton & 15ton	10ton x2	20ton

5. Conclusion

In this work, optimization of chemical process layout considering the inherent safety of the process was proposed. The risk of process equipment to human was divided into two categories, i.e. risk to workers and risk to public, and assessed through individual risk (IR) index approach based on the accident frequency and consequence analysis. Then, optimization of process layout minimizing the cost under safety distance constraints comes from IR value was carried out by mixed-integer linear programming (MILP). As an example case, layout of a DME filling station was optimized with the consideration of risk to workers in control room and people outside the process boundary.

With this method, economic feasibility of chemical process can be enhanced by a proper layout while ensuring the safety for human in the early stage of process design. In addition, land area required to satisfy the economic and safety constraints could be estimated. If the consideration of safety devices available for equipment were added, the reliability of resulted process layout would be improved.

Optimal channel design and sensor placement in flow distributors for detecting blockage of parallelized microreactors

Osamu Tonomura, Atsushi Nishida, Lin Wang, Shnji Hasebe

Dept. of Chemical Engineering, Kyoto University, Nishikyo, Kyoto 615-8510, Japan.
E-mail: tonomura@cheme.kyoto-u.ac.jp (O. Tonomura)

Abstract

When the production capacity of micro chemical plants is increased by numbering-up approach, it is important to realize the uniform flow distribution among the parallelized microreactors. In addition, a blocked microreactor needs to be identified as early as possible to achieve the stable long-term operation of micro chemical plants. In this research, a system that can detect a blocked microreactor by using just two flow sensors is developed. The performance of the developed system is maximized by adjusting the channel size and sensor placement in the flow distributors. The effectiveness of the developed system and the optimal design result is demonstrated by computational fluid dynamics simulation.

Keywords: microreactor, flow distributor, design, sensor placement, blockage detection.

1. Introduction

Microreactors engage the attention of researchers and engineers in the pharmaceutical and chemical industries. Microreactors can achieve the high yield and selectivity of a product owing to their advantages of rapid mixing, high heat transfer, and precise residence time control (Hessel et al., 2005). The numbering-up approach, which means the parallelization of microreactors, is effective at increasing the production capacity of microreactors and opens up the possibility of a direct transfer from laboratory scale to production scale. However, some difficulties are left behind. When the numbering-up approach is applied to micro chemical plants (MCPs), it is important to realize the uniform flow distribution among the parallelized microreactors, which are connected by flow distributors. The flow maldistribution is caused by the inadequate design of the flow distributors and deteriorates the performance of MCPs. In addition to the flow uniformity, it is necessary to take measures against blockage, which is the most recognized trouble with MCPs. For example, Bayer et al. (1999), who developed a continuous radical polymerization process having micro pre-mixers, mentioned that poor mixing conditions cause blockage in a reactor. Ju et al. (2006) applied a stainless steel microchannel reactor for the continuous synthesis of zeolite NaA, and they found that aging the synthesis solution was a key procedure for avoiding blockage of the microchannel. In these literatures and others, one of the critical operation problems was blockage in microreactors, which negatively affects the flow distribution in the whole MCPs with numbering-up structure. Therefore, a blocked microreactor needs to be detected as early as possible to achieve the stable long-term operation of MCPs. However, it is not practical to install the sensors in all the microreactors from the viewpoint of cost or space. Therefore, the goals of this research are to develop a flow

distributor suitable for MCPs and to propose a blockage detection method with the limited measurement.

2. Flow Distribution in Parallelized Microreactors

This section shows the basic structure and characteristics of MCPs with parallelized microreactors. The characteristics of a specific flow distributor developed by Tonomura et al. (2008) are also analyzed through computational fluid dynamics (CFD) simulations.

2.1. Split-and-recombine-type flow distributors (SRFDs)

A schematic diagram of a MCP with externally parallelized microreactors is shown in Fig. 1. The parallelized section where microreactors are running in parallel is connected to a distribution section and a confluence section. The distribution section carries out a function of distributing a reactant flow among the parallelized microreactors. The distributed flows pass through microreactors and are collected into one flow at the confluence section. A lack of uniformity in the flow distribution lowers the MCP's performance.

Flow distributors, which are used at the distribution section in Fig. 1, are typically classified into two types: manifold-type and bifurcation-type. Unlike such flow distributors, Tonomura et al. (2008) have developed split-and-recombine-type flow distributors (SRFDs). Figure 2 shows an example of SRFDs, in which one flow is divided into four flows. The SRFD consists of channels having a length of L [mm] and a width of d [mm]. It is assumed that $L_1 = L_4 = L$ and $L_2 = L_3 = \alpha L$. α is introduced to achieve the uniform flow distribution among the parallelized microreactors under a normal operating condition and determined by CFD simulation. u_{in} [m/s] is the averaged flow velocity at the inlet, and u_k [m/s] (k is channel number) is the averaged flow velocity at the outlet of each channel. The outlet of SRFD is opened to atmosphere. In this research, the commercial CFD software "COMSOL Multiphysics® 3.4" is used to estimate the flow distribution of water (293 K) in the SRFD. The normalized flow velocity u^*_k, which is given by u_k/u_{in}, is used to evaluate the flow distribution.

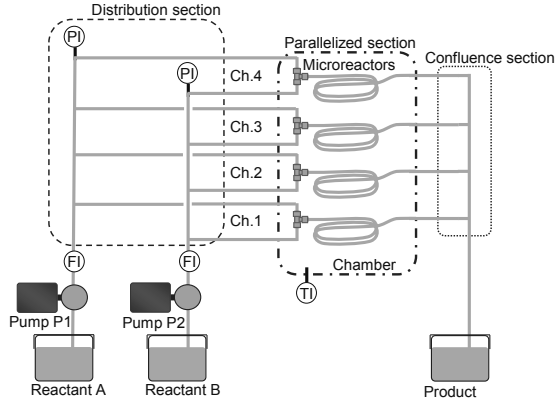

Figure 1 A MCP with parallelized microreactors.

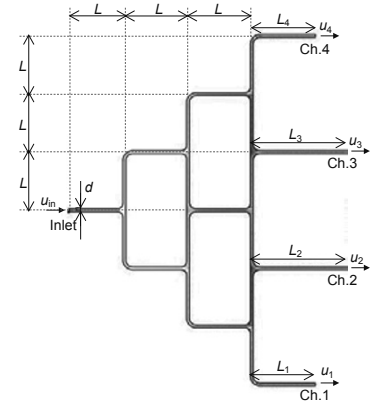

Figure 2 A developed SRFD.

2.2. Design modification of SRFD

It is preferable that the uniform flow distribution in the SRFD is maintained even when the inlet flow velocity or the material properties of the fluid change. The effects of

design parameters on the flow distribution are investigated by using CFD simulation. Table 1 shows the representative simulation conditions for SRFDs. When a circular channel having L = 10 mm and d = 1.0 mm is adopted, u_{in} = 0.2 m/s corresponds to inlet volumetric flowrate V_{in} = 10 mL/min. Figure 3 shows the results of CFD simulation. The vertical axis denotes the differences between two normalized flow velocities, u^*_2 and u^*_1, and the flow distribution is highly uniform when each plotted point in Fig. 3 is located near zero. The uniform flow distribution is achieved independently of L/d, when Reynold number (Re) is less than 100. At higher Re, the difference in flow velocity between Ch. 2 and Ch. 1 becomes large. In such a case, the SRFD needs to be re-designed so as to realize the uniform flow distribution. The alternative approach is to use flow controllers. However, the installation of flow controllers in all the channels requires high cost and extra space.

Figure 3 indicates that the difference between u^*_2 and u^*_1 is reduced at higher Re, according as L/d becomes large. An increase in L/d usually leads to a larger pressure drop of flow in the SRFD (ΔP_{SRFD}). To further improve the uniformity in the flow velocities without increasing ΔP_{SRFD}, the modified SRFD (mSRFD) where the channel width of Ch. 0 is enlarged, as shown in Fig. 4, is proposed in this research. CFD simulation result of mSRFD (L/d = 20) is added to Fig. 3, and it is clarified that mSRFD gives a more uniform flow distribution in the wide range of Re.

Table 1 Representative simulation conditions for SRFDs.

L/d	L [mm]	d [mm]	α	u_{in} [m/s]	Re
5	10	2.0	1.80	0.05	100
10	10	1.0	1.75	0.2	200
20	10	0.5	1.78	0.8	400
40	40	1.0	1.67	0.2	200

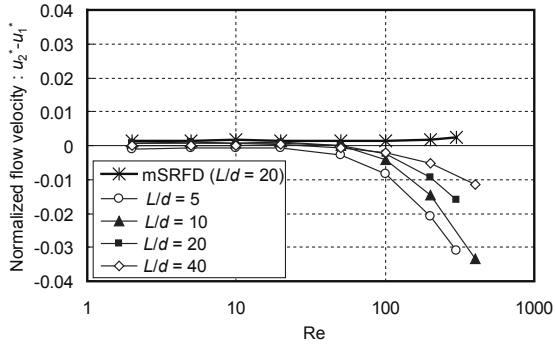

Figure 3 CFD simulation results.

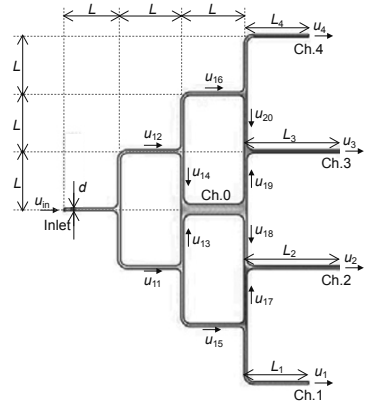

Figure 4 A modified SRFD.

3. Blockage Detection in Parallelized Microreactors

Blockage is the most recognized problem in MCPs, because the diameter of microchannels is less than 1 mm. A process monitoring system that can detect blockage is indispensable for effective and stable operation of MCPs. In this research, just two flow sensors are embedded in SRFDs, and a blockage diagnosis system (BDS) is

developed to identify a blocked microreactor among the parallelized microreactors. In addition, the performance of the developed system is maximized by adjusting the channel size and sensor placement in the flow distributors.

3.1. Blockage diagnosis system

Reactants are supplied to MCPs at a constant flowrate. MCPs have a symmetric structure and are designed beforehand so that flow distribution is uniform. Under these assumptions, the developed BDS uses the ratios of flow velocity (or flowrate) differences between normal and abnormal operating conditions at one sensor to those at the other sensor. In this research, two sensors are located in SRFDs. The procedure for building BDS is as follows: (1) obtain flow velocity data under normal operating conditions, (2) obtain flow velocity data under blockage in each microreactor, (3) calculate the flow velocity difference between normal and abnormal operating conditions at two sensors, and (4) calculate the ratio of flow velocity differences. After blockage is detected, the blockage location is identified through the following procedure: (1) calculate the flow velocity difference between normal and abnormal operating conditions at two sensors, (2) calculate the ratio of flow velocity differences, and (3) identify the microreactor that has the smallest difference between the prepared ratio and the actual ratio as a blocked reactor.

3.2. Application to four parallelized microreactors

The performance of the developed BDS is evaluated with its application to four parallelized microreactors, which are connected to SRFD. Through the system development, the results of flow velocity measurements are plotted in the two dimensional Δu_{15} and Δu_{16} space (Fig. 5). In this figure, ΔP_{MR} and ΔP_{mSRFD} represents the pressure drop of microreactors and mSRFD, respectively. The ratios of flow velocity differences under the blockage in microreactor connected to Ch.i (i = 1, 2, 3, 4) correspond to square, diamond, triangle, and circle, respectively. As each point deviates from the origin, the total flowrate in the process becomes large. Figure 5 shows that the

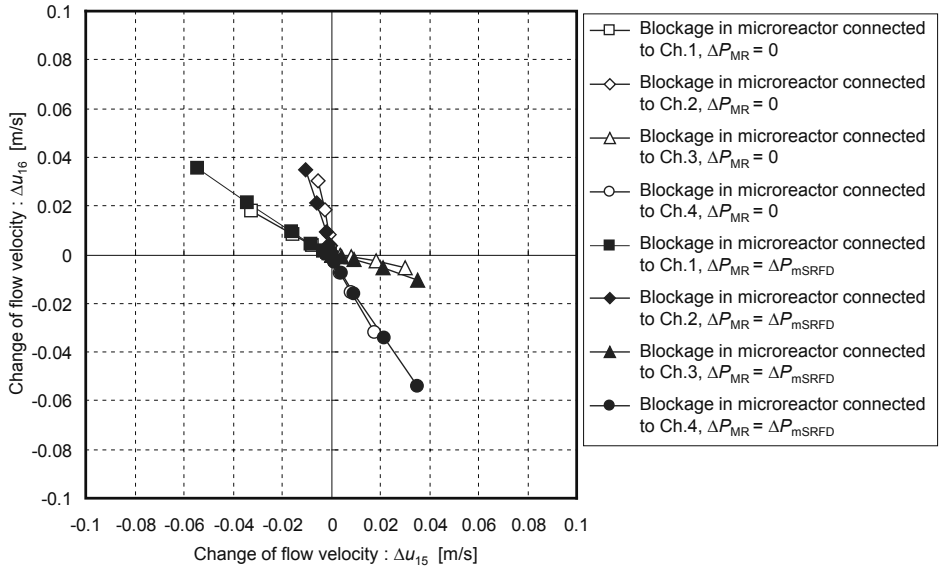

Figure 5 Blockage diagnosis results (Flow sensors are located at u_{15} and u_{16}).

ratio of two flow velocity differences remains unchanged even when total flow rate of the process varies, without reference to ΔP_{MR}. In addition, it is clarified that the blockage location is successfully identified on the basis of the ratios of two flow velocity differences. These simulation results suggest that the developed BDS has robustness to changes in the total flowrate and ΔP_{MR}.

3.3. Optimization of channel size and sensor placement

Flow distribution in MCPs with/without blockage can be estimated by CFD model or pressure balance (PB) model (Amador et al., 2004). In this research, an optimal channel design and sensor placement problem is solved on the basis of PB model, which requires less computational time than CFD model. Channel diameters and sensor placement are determined to maximize the adjacent angles between lines in Fig. 5 within constraints on the total flowrate, the flow uniformity under normal operating condition, the number of available sensors, the number of parallelized microreactors and their pressure drop, and the channel size boudaries. As a result of optimization by using gPROMS®, the maximum angle is obtained when the diameters of horizontal and vertical channels of the SRFD are 2.8 mm and 2.1 mm, respectively, and the two sensors are located at channels of u_{17} and u_{20}. The effectiveness of the optimal design result is confirmed by CFD simulation.

4. Conclusions

The flow uniformity in SRFDs, which have three or more bifurcation points and one or more junction points, was examined through CFD simulation, and the design of SRFDs is modified to achieve a uniform flow distribution in the wide range of Re. In addition, the blockage detection and diagnosis system that can identify a blocked microreactor by using a small number of flow sensors was developed, and its effectiveness was demonstrated numerically. The results showed that the developed system has high robustness to changes in the fluid properties and the microreactor characteristics such as pressure drop. In addition, the performance of the developed system was maximized by adjusting the channel size and sensor placement in the flow distributors. The developed system will be applicable to various types of microchemical plants with parallelized microreactors.

Abstract

Multiphase is an inherent nature of many batch processes, which should be taken into consideration to achieve efficient process monitoring. Although there have been several methods for phase identification, yet process information, especially process dynamic information, is not fully utilized. In this paper, an automatic phase identification method is proposed, which not only captures the differences in variable cross-correlations, but also explores the changes in process dynamics and model-explained variance. Accordingly, better phase identification, deeper process understanding and more efficient fault detection results are obtained. The practical application to an injection molding process verifies the effectiveness of the proposed method.

Keywords: multivariate statistical modeling, batch processes, multiphase, principal component analysis, process monitoring

1. Introduction

In today's manufacturing industry, batch processes play an important role in producing low-volume and high-value-added products. In order to achieve consistent quality and operation safety, the multivariate statistical process monitoring (MSPM) methods have attracted great research interests. Among them, multiway principal component analysis (MPCA) (Nomikos and MacGregor, 1994; Nomikos and MacGregor, 1995) is the most popular method in batch process monitoring. Nevertheless, since MPCA takes the entire batch data as a single object, the multiphase nature of many batch processes cannot be well modeled. For better monitoring, it is desired to model each phase separately.

In batch processes, different phases may have different features, while the process characteristics within the same phase are usually similar. Based on such finding, various types of phase identification and modeling methods have been proposed (Yao and Gao, 2009). Specifically, sub-PCA identifies phases by revealing the changes in cross-correlations among variables (Lu *et al.*, 2004); while, alternatively, the data distribution information also provides indications on phase division (Yao *et al.*, 2011). Nevertheless, these methods ignore the information about process dynamics, which certainly reduces the accuracy of phase identification. The multiphase PCA (MP-PCA) method (Camacho and Picó, 2006) is capable to provide a dynamic model. In spite of that, MP-PCA detects phase switch points based on model predictions, which may not lead to satisfactory phase division results consistent with the changes in process characteristics.

To overcome such shortcomings, an automatic phase identification method is proposed in this paper, not only capturing the differences in variable cross-correlations, but also exploring the changes in process dynamics and model-explained variance. As a result,

* To whom correspondence should be addressed:

Tel: 886-3-5713690, Fax: 886-3-5715408, Email: yyao@mx.nthu.edu.tw

more accurate and more stable phase identification results are obtained, on the basis of which process analysis is conducted to enhance the understanding of the batch operation, while more efficient monitoring is achieved.

2. Methodology

2.1. MPCA

After arranging the batch process data into a two-dimension matrix $\mathbf{X}(I \times JK)$ and normalizing the data, MPCA decomposes **X** as following:

$$\mathbf{X} = \mathbf{T}\mathbf{P}^T = \sum_{m=1}^{JK} \mathbf{t}_m \mathbf{p}_m^T \tag{1}$$

where *I*, *J* and *K* are the total numbers of batches, variables, and sampling intervals within each batch; $\mathbf{T}(I \times JK)$ and $\mathbf{P}(JK \times JK)$ are the score matrix and the loading matrix, respectively; $\mathbf{t}_m(I \times 1)$ are principal component (PC) vectors orthogonal to each other; and $\mathbf{p}_m(JK \times 1)$ are orthonormal loading vectors projecting data into score space and contains variable correlation information. Algebraically, $\|\mathbf{t}_m\|$ is equal to the *m*th largest eigenvalue λ_m of the matrix $\mathbf{\Sigma}=\mathbf{X}^T\mathbf{X}$, and $\mathbf{p}_m$ is the corresponding eigenvector.

2.2. Automatic phase identification

In batch processes, process variables are not only cross-correlated with one another at each sampling interval, but also autocorrelated over time. Since MPCA treats the entire batch trajectories as a single object, the loading matrix **P** extracts both the cross-correlations among variables and the dynamic correlations between different sampling intervals. Moreover, the amount of variance accounted for by each PC as function of time also provides insight into the process operation. In this paper, these two types of information are combined to provide reliable phase identification results.

Without losing generality, it is reasonable to assume that the matrix **X** is organized as $\mathbf{X} = \left[\tilde{\mathbf{X}}^1 \quad \tilde{\mathbf{X}}^2 \quad \cdots \quad \tilde{\mathbf{X}}^k \quad \cdots \quad \tilde{\mathbf{X}}^K \right]$, where $\tilde{\mathbf{X}}^k(I \times J)$ is a time-slice data matrix containing all measurements at the *k*th sampling interval in different batches, and $k = 1, \cdots, K$. Hence, the loading matrix **P** of the MPCA model has the structure as $\mathbf{P} = \left[(\tilde{\mathbf{P}}^1)^T \quad (\tilde{\mathbf{P}}^2)^T \quad \cdots \quad (\tilde{\mathbf{P}}^k)^T \quad \cdots \quad (\tilde{\mathbf{P}}^K)^T \right]^T$, where the portion-loading matrix $\tilde{\mathbf{P}}^k(J \times JK)$ containing all rows in **P** corresponding to the *k*th time interval. Consequently,

$$\tilde{\mathbf{X}}^k = \mathbf{T}(\tilde{\mathbf{P}}^k)^T = \sum_{m=1}^{JK} \mathbf{t}_m (\tilde{\mathbf{p}}_m^k)^T , \tag{2}$$

where the vector $\tilde{\mathbf{p}}_m^k(J \times 1)$ is the *m*th column in $\tilde{\mathbf{P}}^k$, containing all elements corresponding to the *k*th time interval in $\mathbf{p}_m$. To reveal the changes in process correlation structure along operating time, the explained variance of each PC with respect to time can be derived as following. At each time interval *k*, the variance can be summarized as:

$$(\sigma_{\text{time}}^k)^2 = \text{trace}\left(\frac{(\tilde{\mathbf{X}}^k)^T \tilde{\mathbf{X}}^k}{I-1}\right) = \sum_{m=1}^{JK} \text{trace}\left(\frac{(\tilde{\mathbf{X}}^k)^T (\mathbf{t}_m (\tilde{\mathbf{p}}_m^k)^T)}{I-1}\right) = \sum_{m=1}^{JK} (\sigma_{\text{time},m}^k)^2 , \tag{3}$$

where $(\sigma^k_{\text{time},m})^2$ is the extracted variance at time interval k by the mth PC. Thus, the explained variance of the mth PC at the kth time interval is obtained in terms of ratio as:

$$EVT^k_m = \frac{(\sigma^k_{\text{time},m})^2}{(\sigma^k_{\text{time}})^2} = \frac{\text{trace}((\tilde{\mathbf{X}}^k)^T(\mathbf{t}_m(\tilde{\mathbf{p}}^k_m)^T))}{\text{trace}((\tilde{\mathbf{X}}^k)^T\tilde{\mathbf{X}}^k)}. \tag{4}$$

Such explained variance EVT^k_m (m=1, ..., JK) and the portion-loading matrix $\tilde{\mathbf{P}}^k$ at each sampling interval k are then combined into a process feature matrix $\mathbf{F}^k$, where

$$\mathbf{F}^k = \left[\tilde{\mathbf{p}}^k_1 \cdot EVT^k_1 \quad \tilde{\mathbf{p}}^k_2 \cdot EVT^k_2 \quad \cdots \quad \tilde{\mathbf{p}}^k_{JK} \cdot EVT^k_{JK}\right], (k = 1, 2, \cdots K). \tag{5}$$

Hence, $\mathbf{F}^k$ not only summarizes the static and dynamic variable correlation information, but also reflects the process characteristics contained in the model-explained variance. In the meantime, $\mathbf{F}^k$ takes the different importance of each PC into consideration. Such feature matrices should be similar to each other for the time intervals within the same phase; while in different phases, the feature matrices are significantly different. Therefore, it is a natural idea to identify the phases by clustering $\mathbf{F}^k$ ($k = 1, 2, \cdots K$).

The K-means algorithm has been adopted for phase identification based on sub-PCA (Lu *et al.*, 2004). However, it suffers a major shortcoming: the total number of the clusters is usually subjectively determined by the user. To overcome such shortcoming, the X-means clustering algorithm (Pelleg and Moore, 2000), which automatically estimates the number of clusters, is adopted for phase identification in this paper.

2.3. Process analysis and monitoring

After phase identification, the model-explained variance with respect to variable can be used for process analysis in each phase. Supposing matrix $\breve{\mathbf{X}}^c_j$ contains the entire trajectory information of the jth process variable measured in phase c, the percentage of variance accounted for by each PC as function of variable is expressed as

$$EVP^{c,j}_m = \frac{\text{trace}((\breve{\mathbf{X}}^c_j)^T(\mathbf{t}_m(\breve{\mathbf{p}}^j_m)^T))}{\text{trace}((\breve{\mathbf{X}}^c_j)^T\breve{\mathbf{X}}^c_j)}, \tag{6}$$

where c, j, m are the indices of phase, variable and PC, respectively. The utilization of $EVP^{c,j}_m$ in process analysis will be illustrated in the next section.

For online monitoring, one should first determine which phase the new data belong to. Since each operation phase occupies a certain time span in the cycle duration, the current phase can be identified by checking which time span the current sample falls in. Then, various types of modeling methods, such as phase-MPCA (Dong and McAvoy, 1996), batch dynamic PCA (Chen and Liu, 2002), etc., can be adopted to build the phase models. Since the process characteristics are more stable within each phase, the phase models can provide better monitoring results. For illustration, in the following case study, phase-MPCA models are built for process monitoring.

3. Application results

Injection molding, a well-established technique, which is widely applied in the polymer processing industry, is utilized to verify the effectiveness of the proposed method. The normal operation conditions are same as the ones described in (Yao *et al.*, 2011).

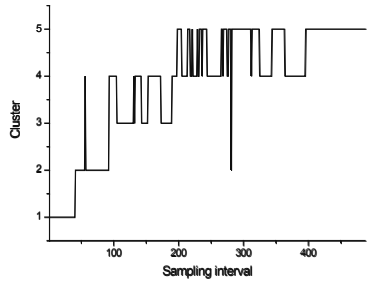

Fig. 1 Phase identification based on sub-PCA

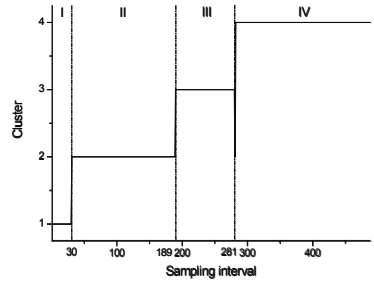

Fig. 2 Phase identification based on the proposed automatic identification method

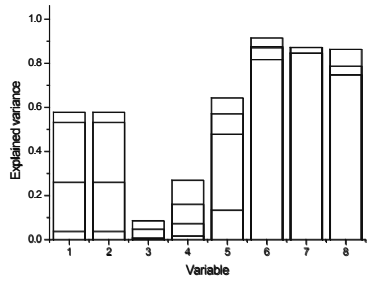

Fig. 3 Cumulative percent of the explained variance with respect to variable in phase 1

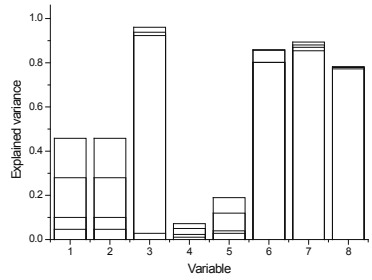

Fig. 4 Cumulative percent of the explained variance with respect to variable in phase 2

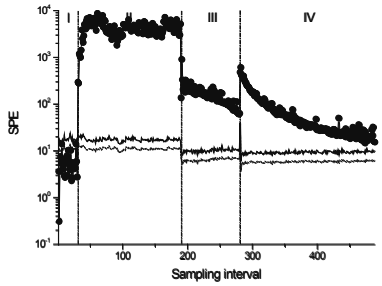

Fig. 5 SPE control chart based on the conventional MPCA model

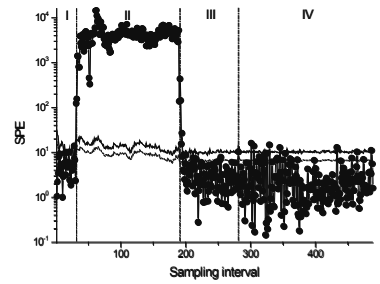

Fig. 6 SPE control chart based on the phase models

For comparison, phase identification is conducted based on sub-PCA and the proposed method, respectively. Fig. 1 and Fig. 2 show that the proposed method provides a clearer and more stable identification. Such results are expectable, since sub-PCA only focuses on the changes in static cross-correlation structure among variables, while the proposed method better utilizes process dynamic information. The identified phases correspond to filling, packing and holding, plastication, and cooling steps, respectively, well reflecting the process characteristics.

After phase identification, more process features can be explored with the model-explained variance with respect to variable in each phase. In Fig. 3 and Fig. 4, the lowest line in each bar indicates the percent explained by the first PC, the second lowest

line represents the cumulative percent explained by the first two PCs, and so on and so forth. It is observed that the first PC mainly consists of three bands of barrel temperatures throughout the whole cycle duration, while the other PCs have varying contributors in different phases. Such observation is reasonable. In the injection molding process, the barrel temperatures are continuously controlled. Therefore, the phase effects are not obvious in these variables. Because of closed-loop control, these variables are tightly correlated to each other and relatively independent to other variables. This explains why they barely share the first PC with other variables.

The monitoring results of an abnormality in the packing pressure are plotted in Fig. 5 and Fig. 6. Such fault only affects the second phase. However, Fig. 5 shows that the conventional MPCA keeps alarming in all the last three phases, making the diagnosis more difficult. In contrast, the phase models provide a more accurate monitoring result.

4. Conclusions

Multiphase is an inherent nature of many batch processes, which should be carefully considered in process modeling and monitoring. Up to the present, most existing methods for batch process phase identification ignore the dynamic information contained in process data. In this paper, an automatic phase identification method is proposed, which involves more process information. On the basis of more accurate and more reliable phase division, more efficient monitoring and deeper process understanding is achieved. The effectiveness of the proposed method is verified with the application to an injection molding process.

Data driven fault detection using multi-block PLS based path modeling approach

Manoj Kandpal, Prem Krishnan, Lakshminarayanan Samavedham *

National University of Singapore

Abstract

Early detection of process faults (while the plant is still operating in a controllable region) can save billions of dollars and enhance safety by minimizing the loss of productivity and preventing the occurrence of process mishaps. This has encouraged researchers to develop methods for improved monitoring of industrial units. This work is based on a pathway modeling approach using multi-block PLS as the mathematical machinery. The proposed approach is a multivariate data analysis procedure which divides the process data into different blocks, determines relationships among the blocks, which are then used for fault detection. In the developed methodology, an extension of multi-block PLS, a special modification of the PLS technique is realized by incorporating the H-Principle in the algorithm. This renders it different from PLS as the analysis is done in steps, maximizing the product of size of improvement of fit and associated precision at each step. The T^2 statistic is primarily used as an indicator of normalcy or fault in the system. This new technique is illustrated via application to two industrial-scale, high-fidelity simulated systems namely the Tennessee Eastman Process (TEP) and a Depropanizer Process (DPP).

Keywords: Fault Detection, Multi-Block PLS, Path Modeling, H-Principle.

1. Introduction

Significant advances in sensing technology, computer processing power and cheaper data storage have all meant that process data can be obtained, stored, analyzed and put to good use (for controller design, process improvement, fault detection and diagnosis etc.). With processes becoming more complex & tightly integrated and increased concerns over safety and environmental impact, the need to monitor and operate processes by leveraging on knowledge about their current state through the data they generate has become exigent. Just to put things in context, the size of data available for analysis has increased dramatically from a mere 1000 × 20 in the 1970's to 500000 ×1000 in this decade (Kettaneh, Berglund et al. 2005).

Various modeling methodologies have been developed for achieving efficient monitoring and control system for such processes. These methodologies are broadly divided into three types: quantitative model-based methods; qualitative model-based methods; and process history based methods (Venkatasubramanian 2003). The last type concerns with the transformation of large amounts of historical data into a particular form of knowledge representation that will enable proper detection and diagnosis of abnormalities. Availability of vast amounts of plant data has encouraged researchers to develop and improve process history based methods, such as PCA, PLS, CA, etc., for better operation and control of such industrial units. The present work deals with monitoring of faults in industrial chemical processes, using the multi-block PLS modeling approach and the H-Principle concept developed by Höskuldsson and is tested on three case studies. The various terms and abbreviations used in this work are based

on standard terms used in chemometrics literature and in the work of Höskuldsson *et al.*(Höskuldsson 1992), unless otherwise stated.

2. Methodology

2.1. H-Principle

The methodology, suggested by Hoskuldsson (Höskuldsson 1992), is similar to PLS where at each step the method maximizes the following measure,

$$[(\text{Size of improvement of fit}) \times (\text{associated precision in terms of variance})]$$

$$\text{i.e. } \boldsymbol{max}(\Delta\, fit) \,/\, (\Delta\, variance)$$

For two blocks, X and Y, the improvement in fit for given t is,

$$E = \left(\frac{1}{t^T t}\right) t\, q^T, \quad \text{such that,} \quad Q = Y^T t$$

Also, size of fit is, $\quad tr(E^T E) = \left[\frac{|Y^T t|^2}{t^T t}\right]$

The H-principle suggests that these two terms should be balanced as follows:

$$\max \left[\frac{|Y^T t|^2}{t^T t}\right] \times \frac{\left[1/|\sum|\right]}{t^T t} = \max \frac{w^T X^T Y Y^T X w}{|\sum|}$$

Assuming that $|\sum|$ is constant, the solution is to choose w as the eigenvector associated with the leading eigenvalue of the eigenproblem,

$$X^T Y Y^T X w = \lambda w \qquad \text{(similar to PLS)}$$

For a system with four blocks, we maximize the fourth block's (X_4) loading vector q_4 s.t. $|w_1|=1$; where, w_1 is calculated from

$$X_1^T X_2 X_2^T X_3 X_3^T X_4 X_4^T X_3 X_3^T X_2 X_2^T X_1 w_1 = \lambda w_1$$

This weight vector, 'w_1', is used to obtain the scores for the first block which are in turn used for detection purposes.

2.2. Multiblock PLS

In chemometrics, data from industrial and laboratory systems are typically of varied nature and come from different sub-systems. In such cases it is a better option to treat such data as being composed of multiple blocks rather than a single one. The technique applied to the case studies is also very useful in reducing the number of variables required for the monitoring scheme as only data related to variables in the first block is required to facilitate detection. The division into blocks can be done either on the basis of the nature or source of data. Several researchers have worked on multi-block PCA/PLS methodology for monitoring the operating performance of large continuous processes, such as the low-density polyethylene reactor (MacGregor, Jaeckle et al. 1994) and for various other chemical processes (Reinikainen and Höskuldsson 2007; Kohonen, Reinikainen et al. 2008) similarly. The flowchart for the general multi-block process employed is summarized in figure 1.

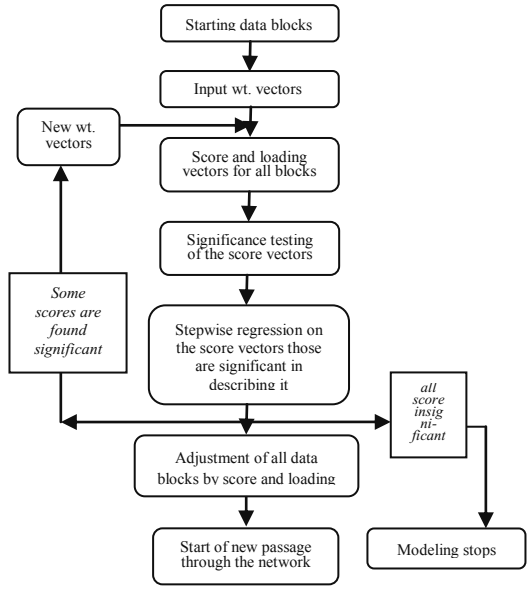

Figure 1. Multiblock PLS

3. Case studies

To test the developed methodology, we grouped the variables into blocks on the basis of the source of variable, i.e. based on orientation and arranged in a linear fashion such as

$$X_1 \rightarrow X_2 \rightarrow \ldots X_n$$

3.1. Depropanizer process (DPP)

The process schematic for DPP, as provided by EnVision System Ltd., is shown in figure 2. The unit comprises of a fractionation tower, a condenser, reflux drum and the reboiler, comprising a total of 36 variables that are monitored. The simulation data is collected for a total of 15 faults over a period of three hours for each of the normal and fault conditions and the samples are recorded at a regular interval of 12 seconds. A total of 901 samples were collected for the normal operating region as well as the faults with each fault being introduced at the 51st sample. The normal operating data was divided into training (initial 60% of the samples) and testing datasets (remaining 40%).

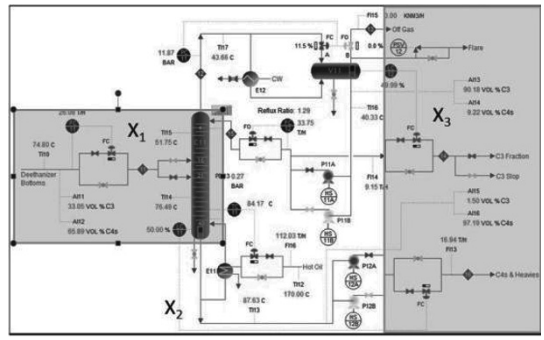

Figure 2. Block representation of DPP

3.2. Eastman's Tennessee plant 52 variables

For the second case, we consider the well-known TE process as described by Downs et al (Downs and Vogel 1993). The process includes a total of 52 variables. Data is available for 20 different faults. The data set for the process was obtained from the *Multiscale Systems Research Laboratory (Braatz 2010)* and was divided into 4 blocks (similar to DPP in figure 2) on the basis of source of data as shown in Table 1 and arranged in a linear manner. The variables were divided such that blocks X_1, X_2, X_3 and X_4, have 19,10, 10, 13 variables respectively.

3.3. Eastman's Tennessee plant 25 variables

For this case study, we considered the study of only 25 variables and placed them in the 4 blocks respectively. These 25 variables are chosen from 16 important variables as reported by Chen et al (Chen and McAvoy 1998) plus additional variables in the path. The total set included 18 CVs and 7 MVs (Table 2).

TE 52 variables				**TE 25 variables**			
Block 1	Block 2	Block 3	Block 4	Block 1	Block 2	Block 3	Block 4
XMV 1-4 XMV 10 XMEAS 1-4 XMEAS 6-9 XMEAS 23-28	XMV 5-6 XMV 11 XMEAS 5 XMEAS 10-13 XMEAS 20 XMEAS 22	XMV 7-9 XMEAS 14-21	XMEAS 29-41	XMV 1-3 XMV 10-11 XMEAS 1-3 XMEAS 6	XMEAS 7-9 XMEAS 21	XMEAS 11-14 XMEAS 22 XMV 7	XMEAS 15-19 XMV 8

Table 1: Variables for different block in TE process

4. Results and discussions

Statistical methods of PCA, CA and our proposed technique were applied to the test problems. The detection is done using T^2 and Q statistics limits at 99% and 95% confidence interval. For this work, the best result from both these measures has been taken and corresponding detection rates (DR) and false alarm rate (FAR) have been reported in Table 2-3.

4.1. Depropanizer process (DPP)

The results show that both T^2 and Q stat were able to detect faults; however, Q stat for PCA (not shown) appeared to have larger false alarm rates (0.102 – 0.2653) for all the faults. Otherwise, the false alarm rate in all other methodologies were almost nil, thus only detection rates have been shown (Table 2). The result shows that the proposed methodology was able to perform better in 10 out of the 15 cases.

Fault No.	PCA	CA	Multi-block PLS
F1	0.9918	0.9894	0.9941
F2	0.9977	0.9988	1.0000
F3	0.9977	0.9988	0.9988
F4	0.9965	0.8931	0.9988
F5	0.9965	0.9871	0.9988
F6	0.9977	0.9988	0.9941
F7	0.9918	0.9671	0.9906
F8	0.9883	0.9871	0.9918

Fault No.	PCA	CA	Multi-block PLS
F9	0.9977	0.9988	1.0000
F10	0.9977	0.9988	1.0000
F11	0.9977	0.9882	1.0000
F12	0.9977	0.9401	0.9271
F13	0.9918	0.9802	0.9941
F14	0.9883	0.953	0.9800
F15	0.9977	0.953	0.9671

Table 2: Detection rates for the faults in DPP

It can be noted that these fault were not too difficult to detect, with detection rates exceeding 92%.

4.2. Tennessee Eastman Process

The methodology was tested on the two case studies carved out from the TEP data. Table 3 gives an estimate of all the detection and false alarm rates using the 25 variable case study and Table 4 shows how the methodology will perform in different scenarios.

No.	PCA		CA		Multi- Block		**No.**	PCA		CA		Multi- Block

F_{11}	0.2375	0.8750	0	0.1750	0.0250	0.4288							

Table 3. Detection and false alarm rates using 25 variables

Increase in detection rates usually implies increasing false alarm rates. Thus the use of methods depends on the type of performance we expect or accept. For example, in case of fault detection using all variables, if low FAR (< 10%) and low detection rate (> 80 %) are prefererd, the number of faults detected by PCA , CA and multi-block methods would be 4, 8 and 9 respectively; thus, multi-block method looks more promising. If the limit for FAR and detection rate were chosen as (< 10%) and (> 90%) respectively, the number of faults detected by the methods are found to be 4, 6 and 5 respectively. In this

case, CA seems to perform better. If the FAR limit is higher (< 20%), the results are 8, 6 and 9 favoring the use of multi-block methods.

FAR	DR	For 25 variables			For all 52 variables		
		PCA	CA	Block	PCA	CA	Block
<10	>99	3	0	0	3	3	3
< 10	> 95	4	3	**5**	5	6	6
<10	>90	4	**6**	5	6	6	6
< 10	> 80	4	8	**9**	**10**	7	7
< 20	> 90	8	6	**9**	**9**	6	6

Table 4. Comparison of cases for 25 and 52 variables

5. Conclusions

The developed methodology is able to detect faults with high reliability. It outperformed CA and PCA in the DPP case study. The methodology, along with PCA and CA, was also able to detect all but 5 faults (fault 3, 5, 15, 16, & 19) with good DR & low FAR in the 25-variable TEP case study. These five faults are difficult to detect even with all 52 variables. From Table 3, it can be seen that the multi-block method was able to detect more number of faults for three important scenarios in both the TEP case studies. PCA, despite giving the best detection rates with its Q statistic, also suffered from higher FARs. The performance of CA was found to be somewhere in between PCA and the multi-block methodology. The multi-block methodology was found to be more effective with lower number of variables in TEP (Table 4) leading us to believe that choosing the right variables in each of the blocks is an important factor. To this end, an optimization scheme can be applied to find out the best possible set of variables to be placed(based on post-analysis of data and using the results in an online monitoring scheme) in different blocks such that maximum effective detection is possible with minimum error. Further work would involve applying this new approach on other large scale simulated processes as well as on real time data from industrial processes.

Optimisation of a Power Plant Utility System Using Process Integration

Mkhokheli Ndlovu, Thokozani Majozi

Department of Chemical Engineering, University of Pretoria, Lynnwood Road, Pretoria 0002, South Africa

Abstract

This paper looks into the optimisation of a power plant utility system. The system consists of a boiler and a cooling tower which constitute a comprehensive utility system. These two systems, although complementing each other in real operations, have been treated separately in published literature, thus creating a false dichotomy between the boiler and cooling water systems. Such individual treatment of the system components gives suboptimal results. In this work, a holistic method of analysis and optimisation of the comprehensive utility system in presented. Nonlinear programming (NLP) models are formulated first for each system and these are then combined to give the comprehensive utility system model. In the mathematical models nonlinear equations are extensively used in the mass and energy balances and in calculating performance in terms of thermodynamic parameters which include enthalpy, entropy and efficiency. The comprehensive utility system model is solved using a specially formulated performance index as an objective function; which is a function of both the heat removed in the cooling tower and the electricity produced in the power plant. The model accurately predicts that the steam turbine efficiency decreases with increasing cooling tower effectiveness. The results further show that better performance of the utility system is achieved (1.7 % improvement in the performance index) when the system is modeled as a single utility system as opposed to treating the system's components separately.

Keywords: Optimization, process integration, cooling tower, boiler, rankine cycle

1. Introduction

1.1. Background

Process integration is no longer a new subject, having started from the pioneering work of Linnhoff and Flower (1978) in the 1970's, who developed systematic procedures for the optimisation of both grassroots and retrofit designs. Their work led to the development of pinch analysis, which was later extended to the optimisation of mass integration networks by El Halwagi and Manousiouthakis (1989). The success of the principles then developed led to a number of applications in the chemical and allied process industries and even in nontraditional chemical industries. The traditional industries include refineries and power plants, which use huge volumes of water and electricity. The cost of producing and delivering water of suitable quality and electricity has increased over the years, thus affecting the economic viability of such process plants. The result has been a continued pursuit of improving the efficiency of these industries. Kim and Smith (2001) recently realised the importance of combined heat and mass transfer and presented a technique for optimisation of a cooling water system comprising a cooling tower and its associated heat exchanger network. They showed

that improved system performance is obtained from a complete system analysis as opposed to focusing on the individual components of the cooling water system. In this work, a holistic method for the optimisation of a power plant utility system is presented, following the principles of Process Integration.

1.2. Problem Definition

Figure 1 below shows a standard Rankine cycle for power production. This is a basic cycle consisting of four main components; the boiler, the turbine, the condenser and the boiler feed water pump. The standard cycle is different to the Rankine cycles found in modern power plants, where additional components are usually added as a means of enhancing the performance of the cycle, e.g. reheat and regenerative cycles. Such advanced cycles are not considered in this paper; however the treatment of such systems follows the same principles presented in this work. Also shown in the figure is the cooling water system which supplies water used as cooling medium in the condenser. The water system consists of the cooling tower, and the circulating system including the water pump.

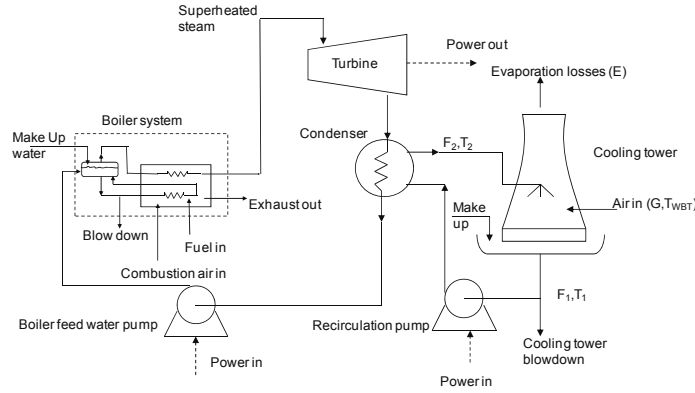

Figure 1: Standard Rankine cycle for power generation

The above figure combines two utility systems, the boiler and the cooling tower, which constitute a comprehensive utility system. These two systems, although complementing each other in real operations, have been treated separately by a number of researchers, e.g. Rodriguez et al (2001), Dincer et al. (2001), Zubair et al. (2003) and Gutierrez et al. (2010). Thus a lot of work has been done previously on optimising the standard Rankine cycle and similarly on optimising the cooling tower system. However no such work is available for the comprehensive system and it is this realisation that led to this work - the focus being to develop an integrated model for the optimisation of the complete system as shown in Figure 1.

2. Mathematical model formulation

The comprehensive utility system was modeled by first developing individual models for the Rankine cycle and for the cooling tower systems and later combining these to give a single integrated system model. The mathematical models formulated in the work have a form:

$$\min Z(x), x = [x_1, x_2, ...x_n]^T \in R^n \quad (1)$$

or

$$\max Z(x), x = [x_1, x_2, ...x_n]^T \in R^n \quad (2)$$

subject to the constraints:

$$g_j(x) \le 0, j = 1,2.....,m$$
$$h_j(x) = 0, j = 1,2.....,r \quad (3)$$

where $Z(x)$, $g_j(x)$ and $h_j(x)$ are scalar functions of the real column vector $x^{\mathbf{T}}$ and x is the vector of optimisation variables. The constraints in the model were the mass, energy and momentum balance equations and these together with the performance indices presented below as objective functions where solved in both the GAMS® and Matlab® programming environments.

2.1. Steam Turbine Model

The steam turbine model used in this work is an adaptation of the model by Rodriguez et al. [2001]. The objective was to maximize the thermal efficiency:

$$\eta_{th} = \frac{\text{Cycle Net Work}}{\text{heat supplied from external sources}} \quad (4)$$

Table 1 below shows the optimisation results from the steam turbine model for a specified circulating water flowrate of 15 kg/s with turbine inlet conditions of 500°C and 186 bar.

Table 1: Optimization results – single condensing steam turbine model

Final value of $Z(x^*)$,%	35.9
Number of iterations	48
Variables	64
Equations	69
Turbine Outlet Pressure (bar)	0.057
Condenser Heat Duty (kW)	-23230

2.2. Cooling Tower Model

The cooling tower model follows the formulation of Kim and Smith (2001). The model gives, the cooling water return flowrate and temperature, evaporation loss and outlet air temperature for a specified cooling tower height and inlet conditions. These parameters are functions of the air wet bulb temperature, cooling tower return temperature and the air and water flowrates:

$$T_1 = f(F_2, T_2, G, T_{WBT}) \quad (5)$$
$$F_1 = f(F_2, T_2, G, T_{WBT}) \quad (6)$$
$$E = f(F_2, T_2, G, T_{WBT}) \quad (7)$$

These parameters are defined in Figure 1. The objective was to maximise the cooling tower effectiveness defined as:

$$\eta_{eff} = \frac{Q_{ACT}}{Q_{MAX}} \quad (8)$$

where Q_{ACT} is the actual heat removed and Q_{MAX} is the maximum possible heat removed by the cooling tower. Figure 2 below shows the cooling tower model validation using

the experimental data of Bernier (1994). Also shown in Figure 2 is the predicted cooling tower performance in graphical form.

Cooling Tower Model Validation				
Case	*1*	*2*	*3*	*4*
Water flowrate (kg/s)	0.2	0.3	0.398	0.495
Air flowrate (kg/s)	0.67	0.656	0.664	0.658
CW inlet temperature (°C)	36.7	32	29.3	27.9
CW outlet temperature (°C)	19.8	20.4	20.7	20.8
Model Result CW Inlet Temperature	36.7483	32.0287	29.3418	27.9832
Model Result CW outlet temperature(°C)	19.500	20.00	20.24	20.52
Error (%) in CW Inlet Temperature	0.13	0.09	0.14	0.30
Error (%) in CW Outlet Temperature	-1.5	-1.9	-2.2	-1.35

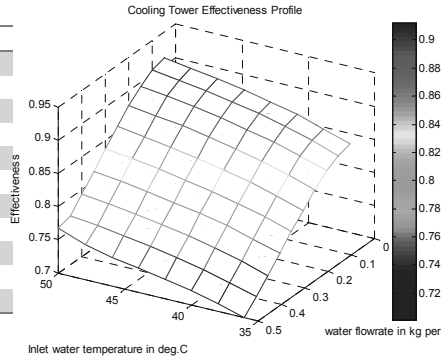

Figure 2: Cooling tower model validation and predicted performance

The model results show that high effectiveness in the cooling tower is obtained when the inlet conditions are high temperature and low flowrate.

2.3. Comprehensive system Model

The comprehensive utility system model was obtained by combining the above two models and was solved using different objective functions which were functions of both the steam turbine thermal efficiency and the cooling tower effectiveness. For the work presented in this paper, the following comprehensive system performance index (PI) was used:

$$PI = \frac{\text{Heat rejected to atmosphere by cooling tower}}{\text{Net power generation}} \tag{9}$$

The objective of the optimisation was to minimise the above performance index.

3. Results and Discussion

Figure 3 and Table 2 below show the performance of the comprehensive system.

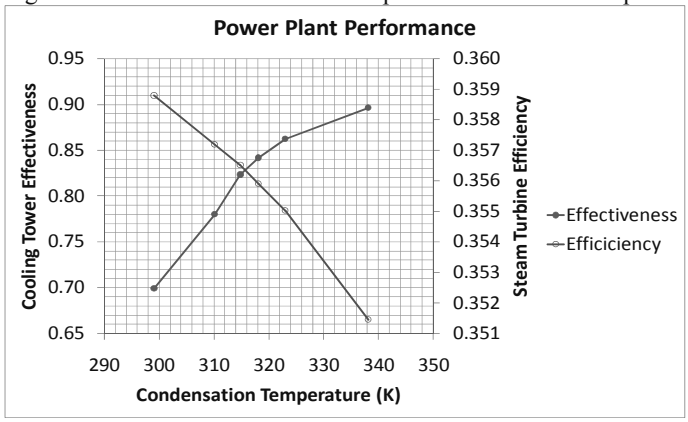

Figure 3: Comprehensive utility system performance

The data shows the effect of treating the system as a single integrated utility system as opposed to individual system component models. The comprehensive system model accurately predicts that the steam turbine efficiency decreases with increasing cooling tower effectiveness (Figure 3), a situation which is well borne out in practice as an increase in the cooling tower effectiveness occurs when conditions at the inlet of the cooling tower are high temperature and low flowrate. Consequently, the resultant high cooling tower inlet temperature translates to a high condensation temperature in the Rankine cycle and hence a reduction in the steam turbine efficiency. The results also showed that the comprehensive system PI increases with the condensation temperature. The cooling tower experimental data of Bernier (1994) was combined with data from the steam turbine model to give a comprehensive system dataset which was used as a basis for the analysis. Table 2 below shows the values of the performance index for different data sets.

Table 2: Optimisation results of the comprehensive utility system

Dataset	1	2	3	4
Individual system optimisation	1.7094	1.7094	1.7094	1.7094
Comprehensive system optimisation	1.6806	1.6840	1.6795	1.6803
% Change in comprehensive system performance index (PI)	-1.7%	-1.5%	-1.7%	-1.7%

As seen from the table, the overall system performance improves by an average of 1.7% when the system is treated as an integrated unit.

4. Conclusion

This paper presented the optimisation results of a comprehensive utility system found in power plants. The main conclusion from the work is that better performance of the system is achieved when the system is modeled as a single utility system as opposed to treating the system components individually.

Abstract

Appropriate discretization is a key point of simultaneous strategies for dynamic optimization. Inappropriate discretization mesh may cause slow convergence, or even failure in the solution of the resulting NLP problem. Based on the observation that the level of power change of HTR-PM and mesh configuration is related to each another, the current paper proposes a simplified MFE strategy to discretize and solve efficiently the dynamic optimization problems arising from frequent HTR-PM load transition. The strategy develops offline and online phases to generate at low cost the appropriate discretization meshes for problems corresponding to any level of power change. The example of online optimal operation of HTR-PM demonstrates that the performance for real-time applications is significantly improved.
Keywords: High-Temperature gas-cooled Reactor (HTR), Dynamic Optimization, Moving Finite Element (MFE), Simplified MFE, Power-change adaption

1. Introduction and motivation

High-temperature gas-cooled reactor (HTR) is one of the promising nuclear power technologies, that is expected to be inherently safe and capable of integrating with advanced hydrogen, electricity, and process heat production (Idaho National Laboratory, 2009). The Shidaowan HTR plant built in Shandong, China will be the first commercial HTR plant in the world. The 200 MWe plant (two reactor modules, each with 250 MWt) will drive a single steam turbine at about 40% thermal efficiency. Modular design of HTR is of great difference from traditional light water reactors. Power change, unit shutdown, and load balance between modules could be frequent and significant.

HTR pebble bed module (HTR-PM) has a lumped parameter DAE model (Li et al., 2008) with 1,019 algebraic equations and 62 differential equations, based on which an optimization problem is formulated to ensure smooth and quick response to load transition. The simultaneous approaches that discretize both the state and control profiles using the collocation of finite elements are expected to solve the problem efficiently, as they directly couple the solution of the DAE system with the optimization problem. On the other hand, the element mesh has a great influence on the convergence and efficiency of the solution to the dynamic problem. The resulted nonlinear programming (NLP) problem after discretization may converge slowly, or even fail, due to inappropriate element meshes.

*This work was supported by the 973 Program of China(2012CB720500) and the NSF Program of China(61104134). E-mail address: zjshao@iipc.zju.edu.cn

The strategy of moving finite elements (MFE) (Russell and Christiansen, 1978; Biegler, 2010) treats the length of elements as a part of NLP variables. The variable elements allow the catching of breakpoints in the optimal control profile and the changes in the active set, and the error estimate at non-collocation points is imposed to guarantee discretization accuracy. However, the MFE strategy leads to a more constrained and difficult NLP. Furthermore, the NLP needs to be solved for each instance of the dynamic optimization problem. Therefore, the MFE strategy can be too expensive for online applications. Simplified strategies need to be developed, especially for the family of problems with similar scenarios.

2. Opportunity: Observation of element meshes for the optimization of HTR-PM load transition

For the frequent load transition of HTR-PM, a family of optimization problems arises with the same objective of control performance and based on the same process model and operating requirements, aims to provide fast and smooth power transition:

$$\begin{aligned} &\min_{z(t),y(t),u(t),p} \int_0^{t_f} \left[(x(t)-x_{sp})^T Q(x(t)-x_{sp}) + (\Delta u(t))^T R \Delta u(t)\right] dt \\ &s.t.\ \frac{dz(t)}{dt} = f(z(t), y(t), u(t), p) \\ &\quad c(z(t), y(t), u(t), p) = 0 \\ &\quad g(z(t), y(t), u(t), p) \le 0 \\ &\quad z(0) = z^0,\ t \in [0, t_f] \end{aligned} \tag{1}$$

where $z(t)$ and $y(t)$ are the differential and algebraic variables, respectively; controlled variables $x(t) \in z(t) \cup y(t)$ include the power ratio (w.r.t. full power (FP)) of the reactor, outlet helium temperature, outlet pressure of the steam header, and outlet temperature of the steam generator; manipulate variables $u(t)$ include the feedwater flowrate, helium flowrate, control rod reactivity, and turbine valve opening; and p is the time-independent parameters. Additionally, x_{sp} is the set points of $x(t)$, and Q and R are weight matrices. Note that the power operation ratio limit is $\pm 2.5\%$ FP/min. The constraints in (1) describe the system dynamics, operational path constraints, initial value, and time horizon of the optimization problem.

The simultaneous approach that uses Radau collocation on finite elements discretizes (1) into the following NLP problem (Kameswaran and Biegler, 2006):

$$\begin{aligned} &\min_{z_{ij}, y_{ij}, u_{ij}, p} \sum_{i=1}^{NE}\sum_{j=1}^{K} (x_{ij}-x_{sp})^T Q (x_{ij}-x_{sp}) + \\ &\qquad \sum_{i=1}^{NE}\sum_{j=2}^{K} (u_{ij}-u_{i,j-1})^T R (u_{ij}-u_{i,j-1}) + \sum_{i=1}^{NE-1} (u_{i+1,0}-u_{i,K})^T R (u_{i+1,0}-u_{i,K}) \\ &s.t. \sum_{k=0}^{K} \dot{\ell}_k(\tau_j) z_{ik} - h_i f(z_{ij}, y_{ij}, u_{ij}, p) = 0 \\ &\quad c(z_{ij}, y_{ij}, u_{ij}, p) = 0, i = 1..NE, j = 1..K \\ &\quad g(z_{ij}, y_{ij}, u_{ij}, p) \le 0, i = 1..NE, j = 1..K \\ &\quad z_{i+1,0} = z_{i,K},\ i = 1..NE-1 \\ &\quad z_{1,0} = z^0 \end{aligned} \tag{2}$$

where *NE* is the number of finite elements; in each element $t \in [t_{i-1}, t_i]$ ($0 < t_1 < ... < t_{NE} = t_f$), *K* is the number of Radau points, $\dot{\ell}(\tau)$ ($\tau \in (0,1]$) is the derivative of Lagrange interpolation polynomial, and $h_i = t_i - t_{i-1}$ is the element length.

We appoint four groups of power change demands, ranging from 10% FP to 40% FP. Figure 1 presents the appropriate element meshes that lead to the successful solution of the corresponding optimization problems. As shown in the figure, with the increasing level of power change, placing more elements at the beginning of the time horizon is necessary. Additionally, the similar placement of mesh points can be observed for the same level of power change. Therefore, if the MFE strategy can be parameterized with the level of power change of HTR-PM, the appropriate element mesh for any optimization problems arising from load transition can be obtained quickly after the power change demand is provided.

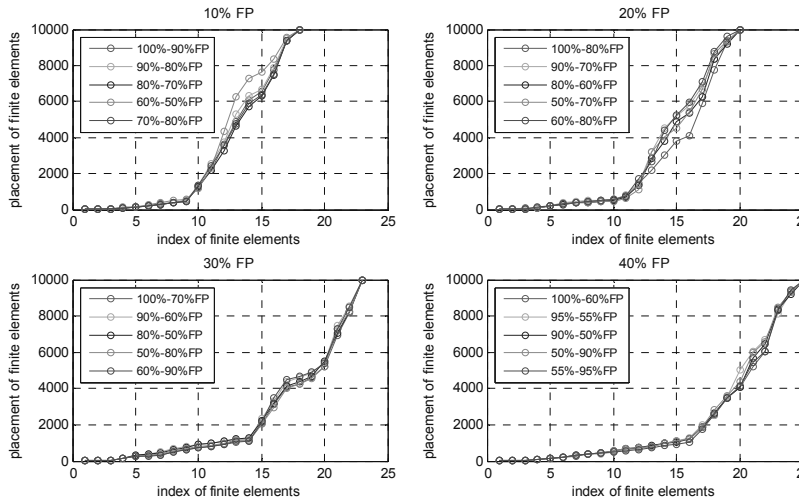

Figure 1. Mesh configuration corresponding to different levels of power change

3. Simplified MFE with power change adaption strategy

The strategy is composed of offline and online phases. The offline phase is a time-consuming but robust bi-level algorithm, which solves optimization problems for different levels of power change demands, and adjusts the element meshes to guarantee discretization accuracy. The discretization error estimate is given by:

$$e = \max\{\| \dot{z}(t_{i,nonc}) - h_i^{opt} f(z(t_{i,nonc}), y(t_{i,nonc}), u(t_{i,nonc}), p) \| \mid i = 1..NE\} \tag{3}$$

where $t_{i,nonc}$ are the non-collocation points in each element. This phase can be terminated when enough meshes have been obtained for each typical level of power change demand. Below is the more detailed description of the bi-level algorithm.

Element Mesh Generation:

For the given initial mesh $\bar{h}$, initialize the placement of mesh points $h^{opt} \leftarrow \bar{h}$, discretization error $\varepsilon^{rd} \leftarrow +\infty$; give the amplitude of mesh point disturbance d, tolerence on discretization error ε_c.

1. Upper-level: Generate an element mesh for dynamic optimization:

- Disturb placement of mesh points by uniform distribution $h_i^{opt} \leftarrow U[h_i^{opt} - d, h_i^{opt} + d]$.
- Adjust the mesh to match the given time horizon $h_i^{opt} \leftarrow t_f \cdot h_i^{opt} \Big/ \sum_{i=1}^{N_{\max}} h_i^{opt}$.

2. Lower-level: Solve problem (2) using mesh h^{opt}.
3. Check error estimate (3) at the solution:

- If $e \le \varepsilon_c$, save mesh h^{opt}, and the algorithm can stop while enough meshes, say 50 meshes, are obtained; otherwise, if $e \le \varepsilon^{rd}$, update $\varepsilon^{rd} \leftarrow e$.
- Go to step 1.

Note that different from the MFE strategy, which solves problem (2) together with the following error estimate:

$$\begin{cases} \| \dot{z}(t_{i,nonc}) - h_i f(z(t_{i,nonc}), y(t_{i,nonc}), u(t_{i,nonc}), p) \| \le \varepsilon_c \\ \sum_{i=1}^{NE} h_i = t_f, h_i \ge 0 \end{cases} \tag{4}$$

the simplified MFE does not involve solving such a more constrained and difficult NLP. Instead, the simplified MFE exploits a derivative-free method to look for meshes for accurate discretization.

Let *M* denote the set of the obtained meshes. The online phase takes advantage of *M* to generate at low cost the discretization mesh for the current power change demand *p*. A straightforward way is to use regression methods. A profile can then be obtained, which represents the configuration of the newly generated element mesh. Let *config* denote the configuration, the placement of the mesh points can be calculated by *config(index)*, where *index = 1..NE* is the index of mesh points and *config(NE)* = t_f.

4. Numerical results

For power changes ranging from 10% FP to 50% FP, the offline phase of the simplified MFE strategy generates five groups of element meshes with 50 meshes for each group, by solving the related dynamic optimization problems. Figure 2 shows the configuration of these meshes.

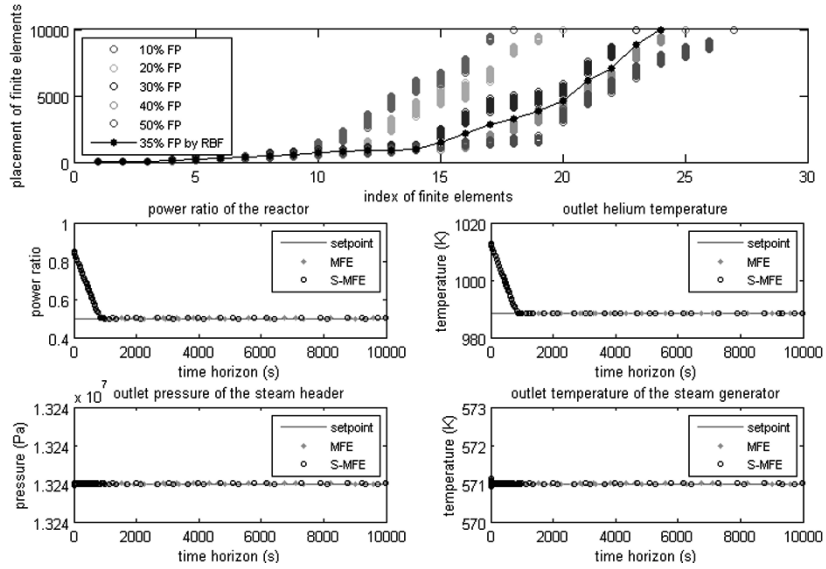

Figure 2. Online generated element mesh and optimization results

The online phase is triggered when a power change demand comes, for example, a demand that changes the load of HTR-PM from 85% FP to 50% FP. In this numerical experiment, the MATLAB toolbox function *newrbe*, which is an implementation of RBF interpolation method, is applied for regression. The configuration of the resulting element mesh is illustrated in the first plot of Figure 2, and the placement of the mesh points is obtained subsequently.

This newly obtained mesh is used to solve the dynamic problem. The resulting profiles of the controlled variables are presented in other plots of Figure 2. All the variables reach their set points as desired, and the operation ratio limit is satisfied. These plots also present the profiles using the MFE strategy. Apparently, solutions from these two strategies are almost the same.

Table 1 lists the solution-related data of both strategies, where columns #var, #eq, and #ineq are the numbers of variables, equality constraints, and inequality constraints of the resulting NLP problem, respectively. The primial-dual interior-point method code IPOPT (Wächter and Biegler, 2006) v3.8.1 is used as the NLP solver. Column *accuracy* is the error estimate according to (3). The results are obtained on a PC with 3.16GHz Core 2 processor and 4GB of RAM running Windows XP. The results indicate that the MFE strategy takes 21 times longer to solve the problem.

Table 1. Numerical results by simplified MFE and MFE strategies

Strategy	*NE*	#var	#eq	#ineq	accuracy	CPU (sec)
Simplified MFE	24	60466	59962	708	6.83736e-4	61.203
MFE					9.36438e-4	1373.969

5. Conclusion

The current paper presents a simplified MFE strategy to solve efficiently the dynamic optimization problems arising from HTR-PM load transition. By taking advantage of the relationship between the level of power change of HTR-PM and the configuration of element mesh, which leads to the successful solution of the dynamic problem, the simplified MFE can generate discretization meshes quickly for problems corresponding to any level of power change. Numerical results demonstrate that the simplified MFE strategy obtained the same optimization results as the MFE strategy, but with much faster online performance.

A methodology to forecast the price of commodities

Davide Manca

Dipartimento di Chimica, Materiali e Ingegneria Chimica "Giulio Natta"
Politecnico di Milano, Piazza Leonardo da Vinci 32, 20133 Milano, Italy

Abstract

A feasibility study of a new plant or even of a revamped one bases the forecast for incomes and outcomes on a discounting back approach. This means that both prices and costs of commodities are assumed constant for long periods. The paper tries to solve the "discounting back" problem that sees a coming apart between the dynamics of real market prices/costs (subject to fluctuations, volatility, and the "supply and demand" law) and the constant prices/costs assumed in conventional feasibility studies. The manuscript presents and discusses a methodology to model the time evolution of prices and costs of commodities.

Keywords: Market and demand fluctuations; Feasibility study; Price and cost forecast; Commodities; Plant design.

1. Introduction

Both the design from scratch and the revamping of a chemical plant are based on some kind of off-line optimizations where a suitable economic potential is maximized (Douglas, 1998; Manca and Grana, 2010). Such economic potential accounts for the positive contributes coming from products (and byproducts), and for the negative terms of capital and operating expenses (respectively known as CAPEX and OPEX) that include also the cost of raw materials.

To be effective, the economic assessment of the design procedure calls for an updated evaluation of both equipment and commodity costs. On the equipment side, there are tools, such as the Guthrie's formulas (Guthrie, 1969) and the cost indexes (*e.g.*, Marshall and Swift; Nelson-Farrar; Chemical Engineering, CEPCI; Vatavuk, VAPCCI), that allow evaluating up-to-date values of the CAPEX terms. On the OPEX and commodities side, the discounting back approach of feasibility studies simplifies excessively the economic assessment due to the lack of tools to forecast the prices/costs of products/byproducts and utilities.

The commodity market dictates the oscillations of both raw and product materials according to the "supply and demand" law. Unfortunately, conventional feasibility studies base the forecast for incomes and outcomes on the discounted-back approach. This means that the prices/costs of commodities and utilities are assumed constant for long periods with the reference point being usually the date when the economic assessment is performed. This calls for a further issue about the availability or estimation of updated values of prices/costs of commodities and utilities.

Going back to the discounted-back issue, it is rather evident the significant limitations of this approach that neither accounts for price/cost volatilities nor contemplates features such as market oscillations and fluctuations. The paper focuses on the price/cost of commodities and on possible modeling of their dynamics. Once this procedure is proposed, analyzed, modeled, and validated, it can be implemented to accomplish improved and more realistic feasibility studies of the designed plant (this

last feature is out of the scope of the paper).

2. The Methodology

The feasibility study of a chemical plant is based also on buying costs of raw materials and on selling prices of products. It is rather limiting assuming the price/cost of commodities either constant or characterized by a straight-line trend. These coarse approximations may play a role in the short-term forecasts but become unreliable when long-term economic assessments must be performed. Actually, during the life-cycle of a chemical plant (that can last a few tens of years) there may happen bull-and-bear periods, *i.e.* positive and negative economic situations. For instance, the price of crude oil in the 2006-2011 five-year period has seen large and sudden fluctuations from as high as 140 US$/bbl to as low as 30 US$/bbl in few months. These edgy fluctuations cannot be modeled by a simply averaged trend line. Conversely, a detailed analysis of the time series of commodity prices/costs is mandatory to extract the pieces of information that are required by the detailed statistical assessment of an improved feasibility study of a chemical plant.

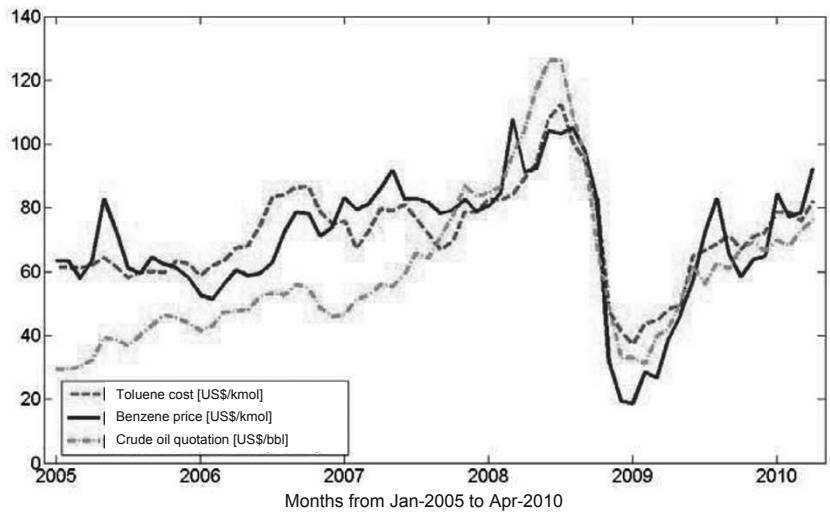

Figure 1: Prices of benzene, toluene, and crude oil in the 2005-2010 five-year period.

2.1. The Reference Component

Instead of tracking the dynamic evolution of prices and costs of each commodity of a chemical process, it is worth adopting an Archimedean approach based on the relative comparison of components respect to a reference one. By doing so, the price/cost of commodities will be referred to the price/value of a reference component and the economic dynamics of these commodities will be a suitable function of the time series of the quotation of the reference component. The reference component must be chosen according to the market field of the chemical plant. It should be a key component for either the chemical process or the sector where the plant operates. The availability of frequent and updated values of the reference component is a further recommended feature. For instance, as far as the Oil&Gas sector is concerned, an appropriate key component is crude oil.

Being the raw material and precursor of a number of chemical processes, crude oil is a

good candidate to the role of reference component. In addition, its price is well-known, largely available, and periodically updated on the main trading markets. Finally, crude oil, besides being a reference component for all its derived commodities, plays a similar role also respect to industrial utilities such as steam and electric energy.

2.2. The Process

As far as the process is concerned and for the sake of simplicity, let us focus on a well known and extensively discussed chemical process such as the hydrodealkylation (HDA) of toluene to benzene (Douglas, 1988; Luyben *et al.*, 1998; Manca and Grana, 2010). All the main components involved in the HDA, such as methane, hydrogen, benzene, toluene, and biphenyl (representative of the aromatic heavier byproducts) at some extent depend economically from the crude oil quotation. For further sake of simplicity, we will focus on the main components of the process, *i.e.* toluene (raw material) and benzene (the final product) to describe and discuss the proposed methodology to forecast the price/cost of commodities. Figure 1 shows the significant dependence of benzene price and toluene cost (on a monthly basis) from the crude oil reference quotation in the Jan-2005, Apr-2010 period.

2.3. The Correlation Role

To assess numerically the economic dependence between the commodities price/cost and the reference component quotation, it is worth considering a statistical index such as the covariance that measures the interaction intensity between the stochastic variables X and Y:

$$\sigma_{X,Y} = \mathrm{cov}(X,Y) = E\left[(X-\mu_X)(Y-\mu_Y)\right] \tag{1}$$

$\sigma_{X,Y}$ allows understanding if there are any correlations between the fluctuations of X and Y respect to their expected (*i.e.* average) values μ_X, μ_Y. To understand better the interaction between X and Y variables, the correlation index measures in a non-dimensional way the interaction between these variables:

$$\mathrm{corr}(X,Y) = \frac{\mathrm{cov}(X,Y)}{\sqrt{\mathrm{var}(X)\,\mathrm{var}(Y)}} = \frac{\sigma_{X,Y}}{\sigma_X \sigma_Y} \tag{2}$$

where $\mathrm{corr}(X,Y) \in -1,\ldots,+1$. Therefore, two variables are completely correlated if $\mathrm{corr}(X,Y) = +1$, anticorrelated if $\mathrm{corr}(X,Y) = -1$, and they are not dependent if $\mathrm{corr}(X,Y) = 0$. As a matter of fact, $\mathrm{corr}(X,Y)$ allows assessing quantitatively the dependence of the commodity prices/costs from the quotation of the reference component. Therefore, the higher the correlation index (between each single commodity price/cost, Y, and the reference component quotation, X) the better the identification of the reference component and, eventually, the better the functional dependency of prices/costs of commodities from the quotation of the reference component.

With reference to the diagrammed values of Figure 1, the following correlation indexes: $\mathrm{corr}(CO,T) = 0.8119$, $\mathrm{corr}(CO,B) = 0.7231$, where CO is crude oil, T is toluene, and B is benzene, show a high dependency degree (as expected) of benzene and toluene from the crude oil fluctuations of market quotations.

2.4. Time Dependence

Once the dependence of commodity prices/costs from the quotation of the reference component has been assessed, it is necessary to determine if there are any time delays between those time series. Possible time delays play, indeed, a role in the definition of the functional dependency between X and Y series. Correlograms can be of real help

in quantifying the time shift between such series. Correlograms are diagrams that report the correlation index of two time series X and Y as a function of the progressively increasing time shift introduced between them. For the sake of clarity, the correlogram of toluene costs respect to crude oil quotations for the monthly values of the 2005-2010 five-year period allows pointing out that the price of toluene mainly depends on the price of crude oil at the same month and at the previous one.

A further step towards the definition of the functional dependence of the commodity prices/costs from the reference component quotation consists in understanding if there are any autocorrelations for each time series of the prices/costs of commodities. In other words and with reference to the HDA plant and specifically to the toluene cost (the same can be done for the benzene price), the question is about the dependence of the toluene cost from previous values (*i.e.* prior months) of the toluene cost. How many previous values should be accounted for? What is the memory degree of the toluene cost respect to its previous quotations? The fast decreasing trend of autocorrelation bars (after the first month time shift) shows that there are not any seasonal or other peculiar trends. The negligible values of the autocorrelation index, for time delays of 4-5 months, show that the toluene cost loses any memory of the past after such a time interval. Same considerations can be drawn for the benzene price.

2.5. Dynamic Model

Both the correlograms and autocorrelograms (respectively of $X-Y$ and $Y-Y$ time series) play a major role in the definition of the functional dependence of the commodities price/cost. The objective is indeed to identify a functional time-dependence of the price/cost of each commodity from its previous value(s) and that/those of the quotation(s) of the reference component. In econometric terms, we are speaking of mixed autoregressive models based on two variables (*i.e.* X and Y). In general, a mixed autoregressive model with p delays of the dependent variable, Y, and q delays of the independent variable, X, is defined as an Autoregressive Distributed Lag model (Stock and Watson, 2003) and denoted as $ADL(p,q)$. According to the results produced by the correlograms and autocorrelograms analysis, the dynamic price/cost models for the HDA commodities assume the rather simple structure $ADL(1,0)$ and specifically:

$$P_{T,i} = a_{T,0} + a_{T,1}P_{CO,i} + b_{T,1}P_{T,i-1} \quad P_{B,i} = a_{B,0} + a_{B,1}P_{CO,i} + b_{B,1}P_{B,i-1} \tag{3}$$

where P is the price/cost of commodities, a and b are some appropriate linear regression coefficients, and subscript i refers explicitly to the monthly quotation of either the commodity or the reference component. The rather simplified linear model of equation (3), based on only one contribute from both the dependent and independent variables (respect to the actual price/cost), is chosen first of all to keep the things as simple as possible (while satisfying the findings of the correlation analysis) but also to avoid overfitting problems produced by possible overparameterizations of the identification model. The evaluation of the regression parameters a and b of equation (3) goes through a linear regression procedure based on a multidimensional unconstrained optimization algorithm. With reference to the experimental data, gathered from the market monthly quotations of Jan-2005, Apr-2010 period (*i.e.* 64 values for benzene, toluene, and crude oil), it is a good operating rule to run the identification procedure (*i.e.* the linear regression) on a subset of data (we chose 50 values), leaving the remaining ones to the cross validation procedure (*i.e.* 14 values).

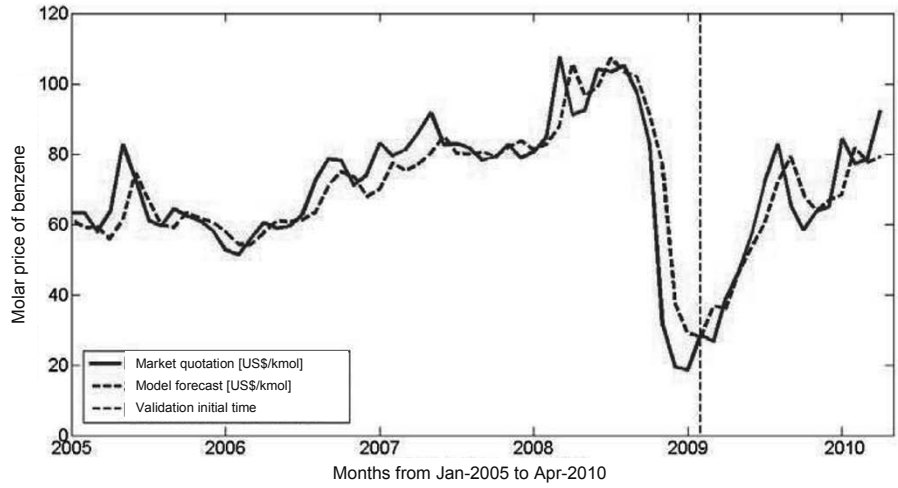

Figure 2: Comparison between market quotations and model forecasts for the price of benzene.

Figure 2 shows a comparison of the price of benzene between the effective market quotations (straight line) and the model forecasts (dashed line). There is a good agreement in the dynamic model of benzene price. The discrepancies between the market model values are due to the stochastic variability of prices and costs that cannot be accounted for by the deterministic model of equation (3). Same results and considerations can be drawn for the toluene cost.

Conclusions

Once the dynamic model of the commodity prices/costs has been determined and validated respect to past market values, it can be used for predictive purposes. The predictive feature of the dynamic model allows implementing a new approach to the feasibility study of industrial plants. For sure, the *ADL* model cannot be used in a deterministic way but a stochastic contribute, based on Monte Carlo methods, must be accounted for and implemented to obtain a suitable distribution of future price/cost of commodities. This feature allows dismissing the classical "discounting back" approach in favor of the dynamic tracking of both commodities and operating expenses to forecast through a stochastic approach the fan of alternatives (*i.e.* statistical distributions) for more consistent feasibility studies of the designed plant. Forthcoming papers will deal with the cost modeling of utilities and specifically of electric energy (again related to a proper reference component) and on the methodology to cope with the stochastic predictions of both commodity and utility prices/costs based on regressive models equal/similar to those reported in equation (3).

Numerical study of mixed-feedstock pyrolysis

Ka Leung Lam, Adetoyese O. Oyedun, Chi Wai Hui

Department of Chemical and Biomolecular Engineering, The Hong Kong Unviersity of Science and Technology, Clear Water Bay, Kowloon, Hong Kong

Abstract

In light of the processing difficulties and constraints in pyrolysing certain types of bulk feedstock alone, a mixed-feedstock pyrolysis approach is proposed in this work. The pyrolysis progress of some common biomass and plastic materials were first studied by common thermal analysis techniques and were then modelled. Using a mix of wood and polyethylene as an example, the proposed approach was evaluated with the aid of two models – a particle pyrolysis model and a CFD rotary kiln model. Based on the evaluation of three areas - heat transfer, secondary reaction and reactor operation, the proposed approach can possibly be used to cope with certain processing difficulties and constraints by enabling a more uniform heating across a cross-section plane, promoting secondary reaction for biomass pyrolysis volatiles, increasing the solid retention time and reducing the extend of char deposition on the reactor wall.

Keywords: modelling, CFD, pyrolysis, mixed-feedstock, kiln

1. Introduction

Pyrolysis is the thermal conversion of organic matter at elevated temperature in the absence of oxygen and yields combustible gas, pyrolysis tar and char. It is a complex process with the outcomes governed by the choice of feedstock and the processing conditions such as the heating profile, solid and vapour residence time, and feedstock size. A considerable amount of work has been on the study of those relations, and the physical and chemical processes involved. For the design, scaling up and optimization of pyrolysis processes, not only the understanding of feedstock characteristics is important, but also the practical consideration of processing efficiency is essential.

On an operational level, one categories of feedstock that has been investigated extensively is plastics. Generally, there exists great difficulties in pyrolysing plastic feedstock because of, for examples, difficulty in loading the feedstock, accumulation of char residue on reactor surface, difficulty in handling the residue and poor heat transfer [1]. It partly attributes to the fact that molten plastic has a low thermal conductivity and a very high viscosity. Another type of commonly investigated feedstock is biomasses. The tar from biomass pyrolysis, in contrast to those produced from plastics, are generally oxygenated, corrosive and unstable, so it is challenging to upgrade the liquid or separate useful chemicals out [2].

2. Problem Statement

For mixed-feedstock pyrolysis studies in the literature, it is common to focus on the possible synergetic effects between certain feedstocks from a chemical interaction prospective using milligram size well-mixed fine powder samples. This numerical study focuses on a macroscopic reactor level to evaluate on the possible processing benefits for a proposed mixed-feedstock pyrolysis approach.

3. Methodology

3.1. Overview

This work evaluates on the proposed mixed-feedstock pyrolysis approach using two mathematical models developed on separate platforms.

3.2. Experimental study

Thermogravimetric analysis (TGA) and differential thermal analysis (DTA) were used for the kinetic study and modelling of the pyrolysis of some biomass (wood and bamboo) and plastic feedstocks (polyethylene and polystyrene). It also serves as a direct approach to observe the pyrolysis progress under constant heating rate condition.

3.3. Numerical study

3.3.1. Modelling particle pyrolysis

Based on the kinetic parameters obtained from the experiment, a pyrolysis model has been developed to describe transiently the pyrolysis progress of a bed of shrinking particles with heat transfer interaction. The model is built on MATLAB® platform. The detail description of similar particle pyrolysis models has been given in earlier works [3-4]. Wood and polyethylene are used as the mixed-feedstock in this study. The shrinking factor (δ) for wood is estimated from the pyrolysis of wood piece with a bench-scale pyrolysis unit.

Particle shrinking model
$\frac{dV}{dt} = -V_0\frac{d\alpha_T}{dt}(1-\delta)$

3.3.2. Modelling pyrolysis reactor environment with CFD

Without the necessity of shreding the feedstock into fine powders, rotary kiln is capable of handling bulk piece of feedstock and is the subject of study in this work. ANSYS ICEM CFD was used to construct the geometry and the mesh of a cross-section of a kiln. The solid bed was defined as a number of discrete bulk spherical particles that are isolated by void space in between. The unstructured triangle mesh composing of over 300000 elements was then introduced to ANSYS FLUENT 12.0 for developing a model to simulate on the heat transfer and volatiles evolving phenomena for the bed of bulk pyrolysis feedstock during a particular short time interval and to make some qualitative comparisons. Build-in volume of fluid (VOF) phase model and standard k-epsilon turbulence flow model were utilized. To simplify the model, physical process is the main focus and chemical reaction during the short time interval is neglected.

4. Result & discussion

4.1. Thermogravimetric analysis (TGA) result

Thermogravimetric analysis serves as a fundamental technique to study the pyrolysis behaviour and pyrolysis kinetics of different feedstock. The profiles in figure 1 indicate a distinct difference in the pyrolysis behaviour between biomass and plastic. This forms a key basis of the proposed mixed-feedstock approach.

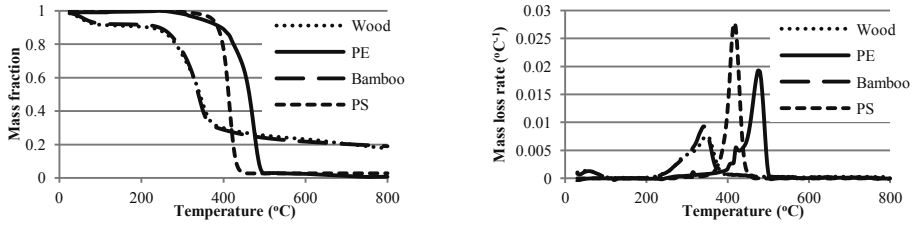

Figure 1 TG profile and DTG profile for the pyrolysis of different feedstocks at 10°C/min

4.2. Evaluation on the proposed mixed-feedstock pyrolysis approach

4.2.1. Overview and scenario

A mixed-feedstock pyrolysis approach is proposed and illustrated by figure 2. By assuming a constant heating for a 1:1 mix of wood and polyethylene particles in the particle pyrolysis model, a volatile evolving profile is obtained to give a basic idea of the pyrolysis volatile generation situation. Table 1 summarizes the simulation results, which will be discussed in the next few sections. In this approach, biomass and plastic feedstock are mixed and pyrolyzed in a rotary kiln reactor. The progress can basically be divided into five zones. In zone A, the mixed-feedstock is being heated up slowly. The moisture and extractives of the biomass is gradually releasing and it marks a minor mass loss. In zone B, polymer melting occurs and results in shrinkage of the solid bed. In zone C, major pyrolysis process for biomass feedstock occurs giving out a lot of volatiles. Further down to zone D, as the temperature increases, plastic pyrolysis contributes to another major mass loss. In zone E, further devolitization of the biomass feedstock is ongoing at this higher temperature zone. The pyrolysis char leaves the kiln at the end. This approach is evaluated in the following sections from three prospective.

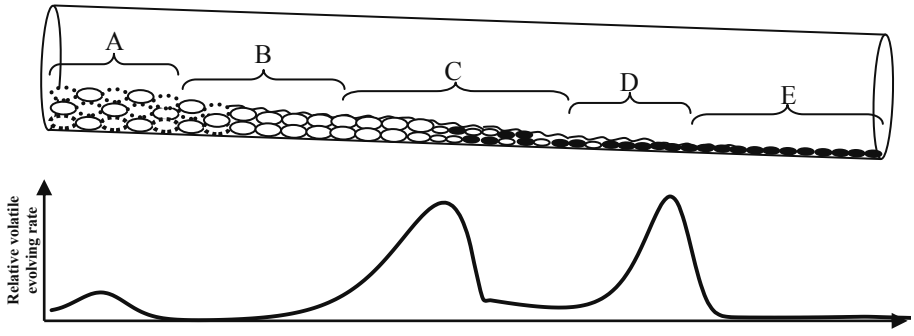

Figure 2 Illustration of a mixed-feedstock pyrolysis approach and its volatile evolving profile

Table 1 Summary of simulation results from the particle pyrolysis model

Feedstock	Relative major mass loss positions	Final volume fraction
Wood	-	0.8678
PE	-	0.0640
1:1 wood-PE mix	0.47 for wood, 0.73 for PE	0.5616

4.2.2. Heat transfer prospective

Heat transfer performance is one of the key considerations for the operation of a pyrolyzer. To achieve an uniform heating for the solid bed material in a rotary kiln, it is essential to have thorough mixing of particles in the transverse plane [5]. This is especially important when there is a significant variation in the size of the particles. A phenomenon referred as segregation occurs in which smaller particles tend to concentrate at the core and received less heating. Because of the fact that the main pyrolysis of biomass occurs at a lower temperature than that of plastic, it is possible that the evolving pyrolysis volatiles from the earlier pyrolysis of biomass material helps make the temperature of the solid bed more uniform. From the simulation shown by figure 3, the heating to the overall bed zone provided by the evolving volatiles from the bottom of the kiln is greater than by without any evolving volatiles. It tends to make the temperature in the transverse plane more uniform.

Figure 3 Contours of temperature for the transverse kiln bed (Left: with evolving volatiles, Right: without evolving volatiles)

4.2.3. Secondary reaction prospective

The pyrolysis volatile generation situation within a short time interval is studied and shown in figure 4. It is observed that the presence of a viscous molten plastic that fill up the void space of the solid bed increases the residence time of the primary pyrolysis products in the solid bed. A longer residence time of primary pyrolysis products in a high temperature zone usually favours secondary reaction. Given sufficient residence time, thermodynamically more stable compounds tend to be formed [6]. It can be an advantage for biomass pyrolysis because of the fact that the primary pyrolysis products, also referred as tar, formed are generally oxygenated, corrosive and unstable. Breaking down these undesirable compounds, formed mainly at zone C's temperature range in figure 2, to gas fraction or more stable compounds is beneficial for later product upgrading and the operation of the reactor.

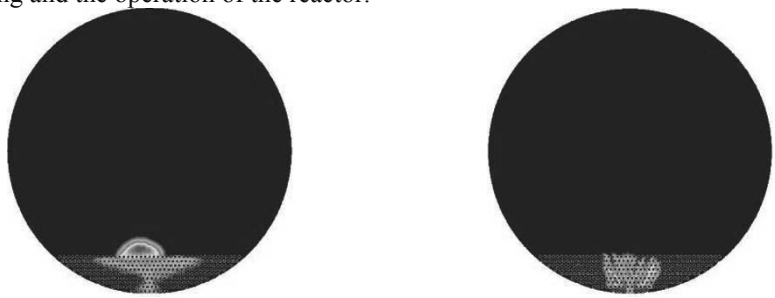

Figure 4 Contours of tracked volatile generated from the bottom of the solid bed (Left: void space not filled, Right: void space filled by molten polyethylene)

Possibly, the approach not only increases the vapour residence time within the solid bed zone, but also enables a different volatile evolving position compared to single feedstock pyrolysis. As observed in figure 2 and table 1, majority of volatiles generated from biomass pyrolysis evolve in the middle of the kiln and therefore, these volatiles have to travel for a longer time in the high temperature zone before condensing and it results in a more severe secondary reaction. On the other hand, the volatiles from plastics pyrolysis tend to be produced near the end of the kiln for faster removal.

4.2.4. Reactor operation prospective

The final residue volume from the pyrolysis of individual feedstock and mixed-feedstock were studied and presented in table 1. Obviously, a mixed-feedstock would yield a char residue with the volume between that of pyrolysing the feedstock alone. From the operation point of view for a rotary kiln, a great reduction in the solid bed size approaching the end of the kiln would generally reduce the solid residence time. The introduction of biomass feedstock is possible to counteract that. In addition, the presence of bulk biomass feedstock reduces the extent of direct contact of viscous molten plastics with the kiln surface to minimize coking from plastic pyrolysis.

5. Conclusion

A mixed-feedstock pyrolysis approach is proposed and evaluated in this work. The proposed approach is found to allow a more uniform heating in the transverse plane, promote secondary reaction for reducing undesirable tar formation from biomass pyrolysis, increase the solid residence time and reduce the extend of char deposition on the reactor wall. These processing improvements can possibly cope with the existing processing difficulties and constraints in single-feedstock pyrolysis.

Nomenclature

α, γ	extent of reaction	α_T	overall mass loss fraction
$\alpha_{T,f}$	final total mass loss fraction	t	reaction time (s)
T	temperature (K)	k	rate constant (s^{-1})
n	order of reaction	A	pre-exponential factor (s^{-1})
E	activation energy (J/mol)	$\bar{R}$	universal gas constant (J/mol-K)
ω	mass loss contribution	H	heat of reaction (J/kg)
C_p	specific heat capacity (J/kg-K)	λ	thermal conductivity (W/m-K)
r	radius of a discrete layer (m)	ρ	density of feedstock (kg/m^3)
T_R	particle surface temperature (K)	T_{bulk}	bulk temperature (K)
V	particle volume (m^3)	δ	shrinking factor
h	convective heat transfer coeff. (W/m^2-K)	i	mass loss reaction i
j	non-mass loss reaction j	f	feedstock c char

Generating operating procedures using a micro genetic algorithm

Rafael Batres

Toyohashi Tech, Hibarigaoka, Tempaku-cho, Toyohashi 441-8580, Japan

Abstract

This paper explores the use of the so called micro genetic algorithms coupled with variable-length chromosomes and a seeding scheme based on tabu search. The problem is to find the sequence of actions that have to be executed in the shortest time possible, but also in a way that minimizes the possibility of situations that may endanger the plant personnel and plant facilities. The proposed approach was tested on the generation of the optimum sequences for startup and shutdown of a mixing vessel similar to the equipment used in the synthesis of acrylic acid. The results show that the proposed method outperforms the traditional GA algorithm both in terms of the quality of the solution and computational effort.

Keywords: operating procedures, micro genetic algorithms, tabu search

1. Introduction

A significant number of serious incidents occur in the process industry during shutdown or startups operations (IChemE, 2006). However, contrasting to industrial applications of scheduling algorithms, the generation of operating procedures is left to expert engineers and plant personnel (Batres, 2002).

The generation of operating procedures can be described as a planning problem where the objective is to find an ordered sequence of plant actions to take the process from an initial state to a goal state. In general, the sequence of actions needs not only to be carried out in the shortest time possible, but also in a way that minimizes the possibility of situations that may endanger the plant personnel or cause damages to the plant.

Existing work for determining operations sequences in the presence of quantitative safety constraints are based on mixed-integer dynamic optimization (MIDO) which combines dynamic optimization with discrete variables for a N_2,O_2,CH_4 mixture changeover. Such approach is useful in situations where a globally optimal solution is not required and one can settle for plan feasibility. In another work, Asprey *et al.* (1999) proposed a two-layer method that combined simulated annealing (SA) and the artificial-intelligence search-method A* to generate startup sequences for a mixing problem. Despite the fact that the two-layer method has the ability to generate a global optimal solution, it does so at the expense of a high number of function evaluations.

This paper investigates an approach based on micro genetic algorithms (μGAs) to generate startup and shutdown operating procedures. μGAs are characterized by a small population size which is restarted several times while keeping the very best fit individual. Krishnakumar (1989) found that μGAs converge faster to the near-optimal solution.

Another aspect of the proposed approach is the use of variable-length chromosomes. Variable-length chromosomes have been applied with success in artificial intelligence planning. In a planning problem, the objective is to find an ordered sequence of actions that achieve a goal given an initial state provided that templates for those actions are

available. For example, Westerberg and Levine (2001) use variable-chromosomes to represent feasible but not necessarily optimum plans. Their GA implementation extends traditional algorithms by incorporating an extra shrinking operator that deletes a randomly selected action from the parent chromosome. Brie and Morignot (2005) describe a genetic algorithm that besides the shrinking operator it also uses an operator for enlarging a chromosome (by inserting new actions) and an operator that modifies a parameter of a randomly selected action. In these two implementations, the respective algorithms are applied to the so-called blocks-world problem.

2. Problem definition

We adopt time optimality as a performance criterion. Therefore, the problem for generating operating procedures for startup or shutdown can be written as follows:

$$\begin{aligned} \text{Min} \quad & A\int_{t_0}^{t_f} dt + B\left\|\boldsymbol{x}_f - \boldsymbol{x}(t_f)\right\| \\ \text{subject to} \quad & \dot{\boldsymbol{x}}(t) = f(\boldsymbol{x}(t), \boldsymbol{u}(t)) \\ & \boldsymbol{x}(t_0) = \boldsymbol{x}_0 \\ & \boldsymbol{x}(t_f) = \boldsymbol{x}_f \\ & \boldsymbol{g}(\boldsymbol{x}) \leq 0 \\ & \boldsymbol{u}(t) \in U,\ U = [u_1, u_2, \ldots, u_n]^T \end{aligned} \tag{1}$$

where $\int_{t_0}^{t_f} dt$ is the time that the system takes to get from the initial state to the final state, $\boldsymbol{x}_0$ and $\boldsymbol{x}_f$ are vectors that represent the initial state and final state respectively, $\boldsymbol{u}(\mathrm{t})$ is a vector that represents a set of operations performed at time $\boldsymbol{t}$, $\boldsymbol{g}(\boldsymbol{x})$ is a vector of inequalities representing process, safety and other constraints, U represents a set of predetermined operations such as specific valve positions, and A and B are constants. When $A = 0$ the problem is reduced to finding the sequence of operations that result in a feasible trajectory.

The system under study is a mixing vessel that belongs to the kind of equipment normally used in the synthesis of acrylic acid. The mixing vessel is a stirred-tank with three inlet valves and one outlet valve. There is one inlet valve for the admission of propylene, one for air, and another for steam. The outlet valve is for the discharge of the mixture. The inlet valves can be operated in a bang-bang fashion or with multiple valve positions. The outlet flow is regulated with a local controller that keeps the pressure constant during startup or shutdown. In the startup operations, the vessel is initially filled with air and the final state is determined by a specified molar composition of the steam-air-propylene mixture outside the flammable region. Conversely, the shutdown operations have the goal of transferring the system to a state that is 100 % air by mass.

As a safety requirement, the valve operations should not take the process through the flammable range. Therefore, a feasible trajectory for the mixing vessel is that in which the final state is reached and the valve operations are carried out to avoid the flammable range. The initial, intermediate, and final states are all expressed in terms of mass fraction.

3. Methodology

The methodology consists of the following steps:

Step 1. Generate a random population.

Step 2. Use tabu search to find a *good* feasible solution and insert it to the population.

<<< Inner loop>>>>

Step 3. Evaluate the fitness of each member of the population.

Step 4. Use crossover and mutation operations to generate a new population.
Step 5. Select the best individual.
Step 6. If the stopping criteria of the inner loop are achieved then go to Step 7. Otherwise go to Step 3.
Step 7. If the stopping criteria of the outer loop are achieved then finish. Otherwise continue with Step 8.
<<< Outer loop>>>>
Step 8. Create a new random population and transfer the best individual from the previous population obtained at Step 6.
Step 9. Restart the inner loop by going to Step 3.

3.1. Procedure for obtaining the good feasible solution

Obtaining a good solution is carried out by formulating the problem as an AI planning problem in which the objective function considers the *distance* of the path from the initial state to the current node and the distance of the path from the current node to the goal. It was found that the Chebyshev distance performs best among other distance approaches considered. Therefore, the objective function is formulated as:

$$f(\boldsymbol{y}_n, n) = w(n)D\exp\left(\max_i\left|y_{n,i} - y_{n,i}^{goal}\right|\right) + E\max_i\left|y_{n,i} - y_{n,i}^{start}\right| + P(\boldsymbol{y}_n, n) \quad (2)$$

where $\boldsymbol{y}_n$ is a state vector containing the mass fractions that resulted from executing an operation, n is the number of operations in list R which is less or equal to the final number of operations that reach the goal state, $w(n)$ is an exponential decay function that reduces its value as the solution progresses towards the goal state, $y_{n,i}$ is the i^{th} component of $\boldsymbol{y}_n$ and represents the mass fraction of component i, y_i^{start} represents the mass fraction at the initial state, y_i^{goal} represents the mass fraction at the goal state, and P is a penalty function that is active when the flammability constraint is violated and whose value decreases as the solution reaches the goal state. The neighborhood used in the tabu search is obtained from a random selection of different combinations of valve positions and the *operator time duration* (the time duration for which a combination of valve positions is maintained). P is given by

$$P(\boldsymbol{y}_n, n) = F\left(1 + q(\boldsymbol{y}_{n-1}, \boldsymbol{y}_n)\right)\left(1 - \frac{n}{N}\right) \quad (3)$$

where $q(\boldsymbol{y}_{n-1}, \boldsymbol{y}_n)$ is the maximum difference between the gas concentration and the flammability envelope for all the concentrations that fall in the flammability region as part of the path that results from moving from state *k-1* to *k*. If moving from state *k-1* to *k* results in a path that is on all its segments outside the flammability region $q(\boldsymbol{y}_{n-1}, \boldsymbol{y}_n) = 0$. The flammability region is approximated by an eighth-degree polynomial. Tabu search is used as the optimization algorithm to obtain the good feasible solution.

3.2. Objective function of the inner loop

The objective function of the inner loop is implemented as a penalty function with a positive term added when the flammability constraint is violated.

$$f(n) = w_1 t_{total} + w_2\varphi + av + bq \quad (4)$$

where t_{total} is the total time that takes from the initial state to the last state, φ is a function of the difference between the last state and the goal which also takes into account the difference between the last state and the goal; v and q are penalty functions that are zero if no violation occurs and positive otherwise; and w_1 and w_2 are weights. w_1 is linearly decreased as the iteration progresses.

3.3. Chromosome structure

Each gene in the chromosome represents an operation defined in terms of the three valve positions and the operator time duration. Each operation is indexed and stored in an operation pool before the actual optimization begins. For example the chromosome shown in Fig. 1 has two genes with index 59 each of which represents an operation in which the steam valve is fully closed, the propylene valve is 10% open, the air valve is fully open, and these positions are kept during 30 seconds.

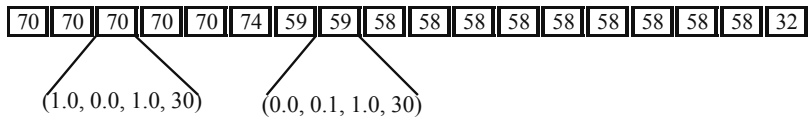

Figure 1. Example of a chromosome

3.4. Crossover and mutation

In addition to traditional crossover and mutation, the growth, shrink and parameter-change mutation (Brie and Morignot, 2005) were implemented. The shrink mutation consists of picking one random point in the chromosome of the parent and then removing the operation at that specific point. The growth mutation is carried out by selecting a random point in the chromosome of the parent and then inserting one operation from the operation pool at that point. The operation from the operation pool is also selected at random. The parameter-change mutation is similar to the traditional mutation, except that the operation from the operation pool has the same valve positions as the mutation target but different time duration.

4. Numeric experiments

All the experiments were carried considering a 50 ℓ tank with a pressure of 1 atm and a temperature of 500 K. The maximum flow rates of each inlet stream were set to 0.1 kg/s. The operator time duration was set for 15, 21, or 30 seconds. Valve positions were considered as completely-open, completely-closed, or 10% open. In the startup case, the initial state was 100 % air by mass, and the goal state was 10% steam by mass, 15% of propylene by mass and the balance was air. Other goal states were explored but this one resulted the most challenging in terms of the number of local minima. In the shutdown case, the initial and goal states were selected as the inverse of those of the startup. In order to evaluate the repeatability of the results, 10 runs were carried out for each experiment. Subsequently, the average and best values were compared with a traditional GA that is initialized with randomly generated populations. Both methods were implemented in Java using JDK 6. The experimental results were obtained on a 3.2 GHz Intel Xeon computer with 8GB of RAM and Windows 7.

The traditional GA contained a population of 100 individuals. The termination criterion for the traditional GA was defined based on a maximum number of generations after exploratory runs showed that convergence for the traditional GA stabilized at 250 generations. For the μGA, the population consisted of 5 individuals. The termination criteria for the inner and outer cycle were set to a maximum of 40 generations and 20 epochs respectively.

Figure 2 compares the process trajectories for the startup case. The operation profiles of the trajectory obtained with the proposed method are shown in Figure 3. Table 1 summarizes the results of the numerical experiments. It can be observed that the proposed method generates operating procedures that take less amount of time to reach the

goal. The results also show that the proposed method presents better repeatability. It can also be noted that the proposed method is more efficient in terms of computation time.

Table 1. Average and best values for startup and shutdown. Best values are in parenthesis.

		Startup Operations		Shutdown Operations	
		Traditional GA	Proposed method	Traditional GA	Proposed method
Computation time [s]		609.3321 (636.2360)	80.5708 (76.1150)	1288.0815 (1308.5160)	255.9522 (251.8470)
Total operations time [s]		523.0909 (498)	481.2 (450)	1575.9 (1731)	1515.0 (1515.0)
Final State	Steam [kg/kg]	0.1012 (0.1008)	0.1017 (0.1005)	0.0321 (0.0064)	0.0011 (0.0011)
	Propylene [kg/kg]	0.1498 (0.1494)	0.1505 (0.1505)	0.0029 (0.0005)	0.0009 (0.0009)
	Air [kg/kg]	0.7490 (0.7498)	0.7478 (0.7490)	0.9650 (0.9931)	0.9980 (0.9980)
Mean squared concentration error		0.0021 (0.0009)	0.0038 (0.0012)	0.0476 (0.0094)	0.017 (0.017)
Fitness		188.1390 (198.9356)	202.7944 (219.4857)	700.6392 (727.2074)	592.4112 (592.4112)

5. Conclusions

A method has been presented which uses a μGA to generate operating procedures. The proposed approach is characterized by (1) creating a good solution that is placed in the initial population; (2) chromosomes of variable size; (3) small population sizes. Numeric results show that the proposed method surpasses traditional genetic algorithms both in terms of the quality of the solution and computational effort. In addition to the advantage in convergence speed, less memory is required to store the population.

Abstract

In this work, a two-dimensional model for a conventional packed-bed membrane reactor (CPBMR) is developed for the oxidative coupling of methane, which uses a non-selective porous membrane to continuously feed oxygen to the catalytic bed. The model incorporates radial diffusion and thermal conduction and assumes convective transport for the axial direction. In addition, two 10cm long cooling segments for the CPBMR were implemented based on the idea of a fixed cooling temperature outside the reactor shell. The resulting model is discretized using two-dimensional orthogonal collocation on finite elements with a combination of Hermite polynomials for the radial and Lagrangian polynomials for the axial coordinate. The simulation study shows that it is necessary to make all transport coefficients dependent on local temperatures and compositions. This leads to a simulation with roughly 130,000 variables, which is then used to generate initial points for the optimization of the CPBMR stand-alone operation. In addition, inequality constraints and variable bounds are introduced so as to avoid potentially hazardous mixtures of methane and oxygen in both shell and tube as well as to keep the temperatures below levels stressing reactor materials (< 1,100°C). Moreover, membrane thickness, feed compositions, temperatures at the reactor inlet and for the cooling segments, diameters of tube and shell, and finally the amount of inert packing in the reactor are considered as decision variables. The optimization procedure uses IPOPT as a solver. Afterwards, the 2D model is integrated into a membrane reactor network (MRN) proposed by H. Godini et al. in 2010 which is simulated. Finally, attempts are made to optimize its operation.

Keywords: OCM, MRN, CPBMR, large-scale NLP, IPOPT

1. Motivation and Problem Statement

For remote, isolated wells of natural gas, an energy-intensive combination of steam reforming and Fischer-Tropsch synthesis is often applied to turn methane into more easily transportable and chemically processable hydrocarbons. An alternative to this process is the oxidative coupling of methane (OCM), which has the potential to become a key technology in the chemical industry. The OCM process allows for direct production of alkenes (olefins) or alkanes from methane (CH_4).Fig. 1 shows the network proposed by H. Godini et al. in 2010. Many different types of catalysts and reactor configurations have been discussed in previous works. This paper will focus on the afore-mentioned network and the application of the La_2O_3/CaO-catalyst, which has shown promising behavior for OCM to C_2 products both in fixed-bed (FBR) and packed-bed membrane reactors (PBMRs). Thus, a fixed-bed reactor and a conventional packed-bed membrane reactor are run alongside each other in the network and

connected through a proposed packed-bed membrane reactor (PPBMR). The latter differs from a CPBMR only with respect to the feeding of nitrogen and methane to its shell-side. The proposed network allows for an increase in both yield and selectivity in C_2 hydrocarbons. To further investigate the network, this work will employ non-isothermal models and start with a two-dimensional model of the CPBMR to reevaluate the reported findings.

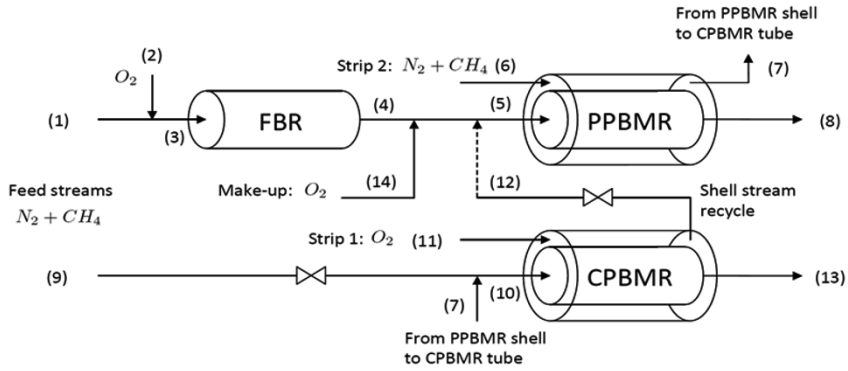

Figure 1: Membrane reactor network (**MRN**) proposed by H. Godini et al., 2010. The network consists of a fixed-bed reactor (**FBR**), a conventional packed-bed membrane reactor (**CPBMR**) and a proposed packed-bed membrane reactor, which is run with an alternative feeding policy (**PPBMR**).

2. Model for the CPBMR

The CPBMR is modeled two-dimensionally incorporating radial diffusion and thermal conduction, as well as common convective transport along the axis. In addition, a basic heating/cooling concept is introduced in all three reactors. A fixed temperature outside the reactor's lateral shell is used to generate a heat flux from or into the reactor.

In accordance with findings by D. Lafarga et al., 1994, Knudsen flux describes the diffusion through the membrane. Heat transfer through the membrane and the outer shell are described using heat transfer coefficients for the membrane derived from deliberations by V. Specchia et al., 1980, and for the outer shell initially assumed to be similar to the heat transfer coefficient in a tubular heat exchanger. In addition, the enthalpy flow caused by the molar flow through the membrane is calculated. Thermal conductivities and effective radial diffusivities are implemented as functions depending on local temperatures and compositions based on correlations published by R.J. Kee et al., 2003, E. Tsotsas et al., 1988, B.E. Poling et al., 2001, and R. Bauer et al., 1978.All reactor models need to be discretized in order to turn the set of differential and algebraic equations into a solely algebraicone. Because of its advantageous stability properties collocation on finite elements is chosen. The one-dimensional models are discretized using third order Lagrangian polynomials on finite elements employing shifted Radau roots so as to guarantee for the continuity of the collocated variable across finite elements. All two-dimensional models appearing in this work contain second order radial derivatives. Therefore, it is required to include the continuity of the first order radial derivative. This is usually achieved by introducing further equality constraints. An alternative approach is the usage of Hermite polynomials instead of Lagrangian for the radial coordinate, which through the forwarding of two collocation coefficients to an adjoining finite element automatically provide the continuity of the collocated variable itself and the first derivative.

3. Stand-alone Operation of the CPBMR

Given its configuration, radial effects can be expected to be most important in the CPBMR. Therefore, the new proposed two-dimensional model is closely examined and optimization studies are carried out to estimate the performance of the stand-alone operation. Starting with two different feeding configurations, isothermal, adiabatic, and heated/cooled models are first compared. The difference between all three models is not negligibly small. For an initial reactor configuration, the isothermal case shows the best possible performance. However, the adiabatic model proves, how unstable this performance is, if no heat is removed from the system as the yield in C_2 hydrocarbons drops from 39% to 6%. Two cases with a fixed heating/cooling temperature along the entire radius show a performance of the CPBMR almost as good as promised by the isothermal case.

In general, the one-dimensional (1D) case features a methane conversion, which is compared to the two-dimensional system considerably higher (up to 20 percentage points), whereas selectivity in C_2 hydrocarbons differs by only a few percentage points.

Given the dependence of most transport coefficients and fluid properties on local temperatures and concentrations, the equation system describing the CPBMR will always be a large-scale NLP. Because of the lack of second order derivatives in the axial direction, this does not cause much of a problem for the simulation as axial finite elements may be simulated sequentially. For any optimization, however, a too large system will slow down the solver or even make it impossible to find any optimal solution at all. For this reason, simulation studies are carried out varying the number of both radial and axial finite elements while examining their influence on the calculated performance of the reactor and the size of the errors of both mass and atom-balances. In addition, simple optimization studies with a degree of freedom of one were carried out to investigate whether any optimal solution could be found in the respective set-up. This procedure led to five radial and 12 axial finite elements so as to describe the reactor with a length of 20cm, a width of the tube-side of 7mm, and a diameter of 10mm. 10 of the 12 axial finite elements have a length of 2cm each, while the other two are 0.1mm long: one positioned at the inlet, the other one at the switching point between cooling temperatures I and II. This leads to an NLP with roughly 130 000 variables describing the CPBMR. Both the simulations and the subsequent optimization studies are carried out using IPOPT as a solver. Given the second order derivatives, fluid properties, and transport parameters appearing in the NLP, the problem is badly scaled. Attempts to fix this problem were unsuccessful. Nevertheless, IPOPT's internal gradient based scaling in contrast to CONOPT copes well with this system despite numerous line searches and regularization efforts.

3.1. Optimization Studies of the CPBMR

The simulation of the CPBMR is used to generate initial values for the general optimization of the reactor. To avoid the formation of unsustainable temperature hot-spots, inequality constraints are introduced to keep the temperature at any point in the reactor below 1100°C. On top of that, precautions need to be taken to avoid explosive mixtures of oxygen and most of all methane in the reactor. Therefore, further equality constraints ensure that the molar methane concentration is either below or equal to 5% of the oxygen concentration or greater than or equal to the oxygen concentration. Membrane thickness, the afore-mentioned feed compositions, feed and heating/cooling temperatures, diameters of both tube- and shell-side, amount of catalyst, and inert packing are considered as decision variables. A pressure difference between shell- and tube-side of 1bar is assumed and the superficial velocity is set to 1m/s.

Table 1. Optimization results – decision variables

	Temp., inlet, shell	Temp., inlet, tube	Temp.,cooling,I	Temp., cooling, II	Mol. frac., O_2, shell	Mol. frac., CH_4, tube
	[K]	[K]	[K]	[K]	[–]	[–]
Initial	1023	1023	1023	1023	0.128	0.170
Final	970	1013	970	970	0.157	0.128
	Diameter, tube	Diameter shell	Catalyst density	Catalyst vol.frac.	Membrane thickness	
	[mm]	[mm]	[kg/m^3]	[–]	[μm]	
Initial	7.0	10.0	3600	0.64	50	
Final	6.0	7.8	3700	0.70	65	

In this final optimization step, the stand-alone operation of the CPBMR shows a yield of 46.9%, a selectivity of 63.3%, and a methane conversion of 74.0%.The reactor's tube-side shows an almost isothermal performance. Apart from the cooling and the modified inlet temperatures, this is made possible by the slightly higher dilution with nitrogen in the packed-bed and the thicker membrane, which reduces the amount of oxygen passing to the tube-side. Sensitivity analyses show that influences of catalyst density and volume fraction are negligibly small. Further relaxation of decision variable bounds could yield even better performance, but the process becomes too time-consuming.

4. Simulation of the Membrane Reactor Network

Despite the surprisingly good performance of the CPBMR, the reactor is integrated into the entire network.

4.1. Implementation of FBR and PPBMR Models and Network Integration

One-dimensional models are used for both FBR and PPBMR. As the CPBMR examination showed that the 1D model overestimates Knudsen flux through the membrane, the flux is reduced by a fixed factor of 0.30 for the PPBMR. As methane and oxygen are co-fed to the catalytic bed of both reactors, hot-spot formation becomes a problem. Hence, a denser collocation is required: 25 finite elements prove to be sufficient for the PPBMR (0.5cm long) and 100 for the FBR (1cm long). On top of that, both reactors require a dilution with nitrogen greater than 85% and a reduction of the catalyst density to 900kg/m^3, which is achieved by more inert packing so as to avoid unsustainable temperature levels or hot-spots, which cause the entire amount of oxygen to react. For the integration into the network, a methane-to-oxygen ratio for the FBR inlet of 1:1 is chosen and the superficial velocity is reduced to 0.4m/s such that the entire stream no.7 (Fig. 1) can be fed to the tube-side of the CPBMR. Only 5% of stream no.12 is initially injected into the PPBMR's tube-side.

4.2. Simulation of the Membrane Reactor Network

Given the size of the NLP describing the MRN, a sequential approach is developed for the simulation of the network. All three reactors are calculated step by step starting with each first axial finite element while all other equality constraints are dropped and variables are fixed to their previous values. Afterwards, the network part, meaning all outlets and streams are calculated providing new inlets for the reactors, which then have to be recalculated. This is done until all sub-problems converge in the 0th iteration step.

Lastly, the entire system is handed over to IPOPT, which should converge to the optimal solution instantly. Table 2 contains the performance of the MRN and individual reactors in that set-up.

Table 2. Performance of reactors and network in initial simulation

Component	Yield in C2 hydrocarbons	Selectivity in C2 hydrocarbons	Methane conversion
FBR	4.77%	19.47%	24.48%
PPBMR	0.86%	14.22%	6.02%
CPBMR	41.83%	60.39%	69.27%
MRN	29.39%	43.05%	68.26%

5. Conclusions and Outlook

Several conclusions can be drawn from this work: First of all, a two-dimensional, non-isothermal model for the CPBMR is required and shows a considerably different behavior compared to previous studies. Secondly, the stand-alone operation of the CPBMR can be improved by further increasing the dilution of the catalytic bed with nitrogen, increasing the cooling, and reducing the oxygen flux through the membrane. Thirdly, yield and selectivity found for the CPBMR are higher than expected and make it debatable whether there is actually any point in considering a further network integration. However, there is one issue, which certainly has to be discussed in future work, and that is the accuracy of the kinetic system at low oxygen levels. Most kinetics are derived from experiments in micro-catalytic packed-beds and it has to be examined in what way the low oxygen influx, meaning permanently low oxygen concentrations along the reactor, might cause a different outcome.

Abstract

In this paper, *maximum conversion (Xn)* dynamic optimization problem is formulated and solved for solution polymerization of Methyl Methacrylate (MMA) in batch reactors. Control Vector Parameterization (CVP) technique is used to pose the dynamic optimization problem as nonlinear programming problem and to find the optimal temperature profile that will maximize the monomer conversion (*Xn*) for a given number average molecular weight (*Mn*) at fixed batch time within gPROMS (general Process Modelling System) software. Note, the decomposition of initiator molecules at the beginning of the process (to form very active primary radicals) depends on the initiator efficiency, *f*. The effect of constant and time-varying *f* on the performance of the batch reactors is also evaluated.

Keywords: initiator efficiency, batch reactors, Methyl Methacrylate

1. Introduction

Solution polymerization uses solvent in the reactor to enhance heat transfer (Odian, 2004). At the beginning of the process, the initiator and the solvent are added into the reactor. Initiator will initiate the polymerization process by decomposition to form primary free radicals. These free radicals will then react with the monomer added in the reactor in homogeneous solution until the end of the process. The decomposition of the initiator molecules depends on the initiator efficiency, *f*. Not all the initiator molecules decompose to form primary radicals since some of them might either have self-terminate or react with other reactants in the system which make the initiator efficiency less than 100%. In the past some used a constant value for *f* in their studies (Achilias and Kiparissides, 1992) while others used variable *f* (Xia and Matyjaszewski, 1997; Achilias, 2007). In this work, the process model from the work of Ekpo and Mujtaba (2008) is improved for the solution polymerization of MMA by using the free volume theory to calculate the initiator efficiency based on Fan et al. (2003).
The optimal temperature profiles that will maximize the monomer conversion (X_n) for a given number average molecular weight (M_n) and fixed batch time are determined for both constant and time varying value of *f*. The batch time is divided into a finite number of intervals, and a piecewise constant temperature is used in each interval. In each interval, the temperature and length of the interval are optimized.

2. Reaction Kinetics and Dynamic Model

The process model used for the solution polymerization of MMA in batch reactors, using 2,2 azobisisobutyronitrile catalyst (AIBN) as the initiator and Toluene as the

solvent by Ekpo and Mujtaba (2008) is presented in Figure 1 in compact form. Further details can be found in Fan et al. (2003) and Ekpo and Mujtaba (2008).

$$k_d = 1.58\ x\ 10^{15} exp\left(-1.2874\ x\ 10^5/R_gT\right) \qquad \frac{dC_i}{dt} = -k_dC_i$$

$$k_{p0} = 7.0\ x\ 10^6 exp\left(-2.6334\ x\ 10^4/R_gT\right) \qquad \frac{dC_m}{dt} = -\left(k_p + k_{fm}\right)C_m\xi_0$$

$$k_{t0} = 1.76\ x\ 10^9 exp\left(-1.1704\ x\ 10^4/R_gT\right) \qquad \frac{d\xi_0}{dt} = 2fk_dC_i - k_t\xi_0^2$$

$$k_{fm} = 4.661\ x\ 10^9 exp\left(-7.4479\ x\ 10^4/R_gT\right) \qquad \frac{d\xi_1}{dt} = 2fk_dC_i - k_pC_m\xi_0 + \left(k_{fm}C_m + k_{fs}C_s\right)(\xi_0 - \xi_1) - k_t\xi_0\xi_1$$

$$k_{fs} = 1.49\ x\ 10^9 exp\left(-6.6197\ x\ 10^4/R_gT\right) \qquad \frac{d\xi_2}{dt} = 2fk_dC_i - (2\xi_0 - \xi_1)k_pC_m + \left(k_{fm}C_m + k_{fs}C_s\right)(\xi_0 - \xi_1) - k_t\xi_0\xi_2$$

$$k_{\theta p} = 3.0233\ x\ 10^{13} exp\left(-1.1700\ x\ 10^5/R_gT\right) \qquad \frac{d\mu_0}{dt} = \left(k_{fm}C_m + k_{fs}C_s\right)\xi_0 + (0.5k_t)\xi_0^2$$

$$k_{\theta t} = 1.4540\ x\ 10^{20}\ C_{i0}\ exp\left(-1.4584\ x\ 10^5/R_gT\right) \qquad \frac{d\mu_1}{dt} = \left(k_{fm}C_m + k_{fs}C_s + k_t\xi_0\right)\xi_1$$

$$k_p = k_{p0}/\left(1 + k_{p0}/Dk_{\theta p}\right) \qquad \frac{d\mu_2}{dt} = \left(k_{fm}C_m + k_{fs}C_s\right)\xi_2 + k_t\xi_0\xi_2 + k_t\xi_1^2$$

$$k_t = k_{t0}/(1 + k_{t0}/Dk_{\theta t}) \qquad PD = \frac{M_w}{M_n}$$

$$\frac{dT}{dt} = \frac{(-\Delta H_r)R_p}{C_p\rho_{mix}} - \frac{UA\left(T - T_J\right)}{C_pV\rho_{mix}} \qquad \frac{dT_J}{dt} = \frac{\left(T_{Jsp} - T_J\right)}{\tau_J} - \frac{UA\left(T - T_J\right)}{C_{pJ}V_J\rho_J}$$

$$D = exp\left[\frac{2.303\left(1 - \emptyset_p\right)}{0.168 - 8.21\ x\ 10^{-6}(T - 387)^2 + 0.03\left(T - \emptyset_p\right)}\right]$$

Figure 1: Process model

T_{Jsp} is the jacket temperature set point and is used as the control variable in place of reaction temperature in the energy balance model (as considered by Ekpo and Mujtaba, 2008). τ_J is the jacket time constant while R_p is the rates of polymerization. Table 1 shows the constants and values used in this model.

Achilias and Kiparissides (1992) had reported that there are quite a lot of published paper has treated the initiator efficiency, f as a constant value. However, it may decrease significantly with the high viscosity of reaction mixture (Russell et al., 1988). Ekpo and Mujtaba (2008) used a constant value of 0.53 for the initiator efficiency. However, it is believed that the initiator efficiency is not constant and will decrease as the viscosity inside the reactor increases (Ghosh et al., 1998). Dube et al. (1997) have used the free volume theory to model the changing of initiator efficiency as shown below:

$$f = f_0 exp\left(-C_f\left(\frac{1}{V_F} - \frac{1}{V_{F,crit}}\right)\right) \tag{1}$$

Where f_0 is the initial initiator efficiency, C_f is a parameter which modifies the rate of change of the efficiency, V_F is free volume and $V_{F,crit}$ is critical free volume. The value of C_f and f_0 are 0.006 and 0.53 respectively (Fan et al., 2003). The free volume (V_F) and critical free volume ($V_{F,crit}$) equations were given by Fan et al. (2003) as below:

$$V_F = 0.025 + 0.001(T - 167)\emptyset_m + 0.00048(T - 387)\emptyset_p + 0.00048(T - 249)\emptyset_s \tag{2}$$

$$V_{Fcrit} = 0.1856 - 2.965x10^{-4}(T - 273) \quad (3)$$

where $\boldsymbol{\emptyset_m}, \boldsymbol{\emptyset_p}$ and $\boldsymbol{\emptyset_s}$ are the volume fraction of monomer, polymer and solvent which can be obtained by the equations below:

$$\emptyset_s = C_m MW_m/\rho_m \quad (4)$$
$$\emptyset_p = \mu_1 MW_m/\rho_p \quad (5)$$
$$\emptyset_s = 1 - \emptyset_m - \emptyset_p \quad (6)$$

Table 1: Constants and values from the detail model of MMA polymerization

A = 0.0774 m2	*ρm = 915.1 kg/m3*	*VJ = 1.5 L*
CP,J = 4.184 kJ/kg.K	*ρp = 1200 kg/m3*	*-ΔHr = 5.78 x 104*
CP,m = 1.648 kJ/kg.K	*MWs = 106.17 kg/kmol*	*kJ/kmol*
CP,P = 1.47 kJ/kg.K	*MWm = 100.12 kg/kmol*	*ρJ = 997 kg/m3*
CP,S = 1.70 kJ/kg.K	*V = 2 L*	*U = 2.55 kJ/s.m2.K*
MWi = 164.21 kg/kmol	*τJ = 50s*	

3. Dynamic Optimization Problem Formulation

Mathematically the optimization problem for *maximum conversion* problem can be represented as:

$$\begin{aligned} &\textit{Max} && \textit{Xn} \\ &\textit{Tjsp(t), Ci0} && \\ &\textit{s.t.} && f(t, x'(t), x(t), u(t), v) = 0, \quad [t_0, t_f] \quad \textit{model equations} \\ & && \textit{Mn} = \textit{Mn}^* \\ & && t_f = t_f^* \\ & && 0.0001 < \textit{Ci0} < 0.150 \\ & && 1.5 < \textit{PD} < 1.8 \\ & && 320\ \textit{K} < \textit{Tjsp} < 373\ \textit{K} \\ & && 320\ \textit{K} < \textit{T} < 398\ \textit{K} \end{aligned}$$

The total batch time is discretized into 3 control intervals within which *Ci0* (initial initiator concentration) and *Tjsp* are assumed to be piecewise constant and are optimized for maximum conversion problem for fixed (denoted by *) number average molecular weight (M_n^*) at fixed batch time (3000s, 5000s and 10000s). PD denotes polydispersity. Note, more than 3 control intervals can also be chosen.

4. Results and Discussions

Results are presented in Table 2 and Figure 2. As expected, monomer conversion increased with increased final batch time since more time is available for the monomer to react inside the reactor. Initial initiator concentration also increased with increased final batch time to ensure that there are more initiators to initiate the polymer process and for the propagation process to happen at longer batch time.

Figure 2 show the optimum reactor temperature set point (*Tjsp*) profile and the monomer conversion (*Xn*) profile of run 7, 8 and 9 (batch time 10000s). The optimum *Tjsp* profiles (Figure 2a) show that the temperature is higher for lower molecular weight. This higher temperature is required to decompose higher concentration of *Ci0*.

Monomer conversion decreased with increased molecular weight (Figure 2b), because to achieve higher molecular weight, low initial initiator are needed at the beginning of the process so the monomer will continue the propagation process rather than initiate a

new polymerization process with the initiator. This can be seen where initial initiator concentration (C_{i0}) decreased with increased molecular weight (Table 2).

Table 2: Results for maximum conversion at fixed batch time, t_f*

Run	*Xn, %*	*Mn (kg/kmol)*	*Mn*(kg/kmol)*	*t_f*(s)*	*PD*	*Ci0 (x10^{-3})*
1	*76.5*	*50 000*	*50 000*	*3000*	*1.8*	*2.898*
2	*72.5*	*100 000*	*100 000*	*3000*	*1.8*	*1.729*
3	*56.1*	*150 000*	*150 000*	*3000*	*1.8*	*1.448*
4	*91.7*	*50 000*	*50 000*	*5000*	*1.8*	*3.171*
5	*81.3*	*100 000*	*100 000*	*5000*	*1.8*	*2.378*
6	*69.3*	*150 000*	*150 000*	*5000*	*1.8*	*1.907*
7	*95.5*	*50 000*	*50 000*	*10 000*	*1.8*	*4.646*
8	*91.6*	*100 000*	*100 000*	*10 000*	*1.8*	*3.378*
9	*81.8*	*150 000*	*150 000*	*10 000*	*1.8*	*2.859*

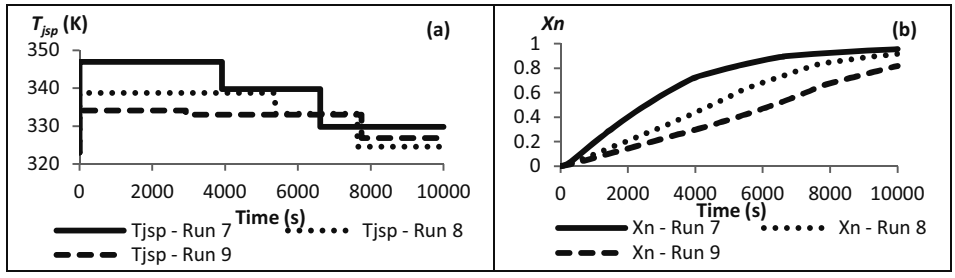

Figure 2: Optimum reactor temperature set point profiles (T_{jsp}) and monomer conversion (X_n) profiles for Run 7, 8 and 9.

The same optimization problem is solved to achieve number average molecular weight (M_n) 150000 kg/kmol in fixed batch time of 5000s using constant value of f (0.53) (F1) and time varying f (F2). The original process model of Ekpo and Mujtba (2008) and the revised model are used for this purpose. This case is same as that in Run 6 of Table 2 but with wider polydispersity. The results are shown in Table 3 and Figure 3.

Table 3: Results for different initiator efficiency, f

Run	*f*	*X_n*	*M_n*	*M_n**	*t_f(s)*	*PD*	*C_{i0} (x10^{-3})*
1	*F1*	*96.64*	*149901.5*	*150000*	*5000*	*2.249012*	*1.00*
2	*F2*	*90.18*	*149989.8*	*150000*	*5000*	*2.048531*	*1.00*

The results, clearly shows the effect of constant and variable f on X_n and PD even though C_{i0} was same. The use of constant f in the model will mislead the expected results as it does not represent the real phenomenon in the process.
The optimum profile for jacket temperature set point (T_{jsp}) for three control intervals is shown in Figure 3a. The figure clearly shows that T_{jsp} for time varying f (F2) is higher than that for constant f (F1) for each interval. Figure 3b shows that f (F2) decreases as the monomer conversion increases. Figure 3c and 3d provide corresponding reactor and jacket temperatures.

5. Conclusions

Dynamic optimization of solution polymerization process of methyl methacrylate in batch reactors is considered here. Conversion is maximized for different batch times by

controlling reactor temperature. Monomer conversion (X_n) is found to increase with the increasing batch time as expected. The results show that initiator efficiency, f is not constant but decrease with the increase of monomer conversion along the process in the solution polymerization of MMA when the free volume theory was applied. The effects of different initiator efficiency, f was also examined. The results were compared between two approaches which confirm that T_{jsp} for time varying f (F2) is higher than that for constant f (F1) for each time interval.

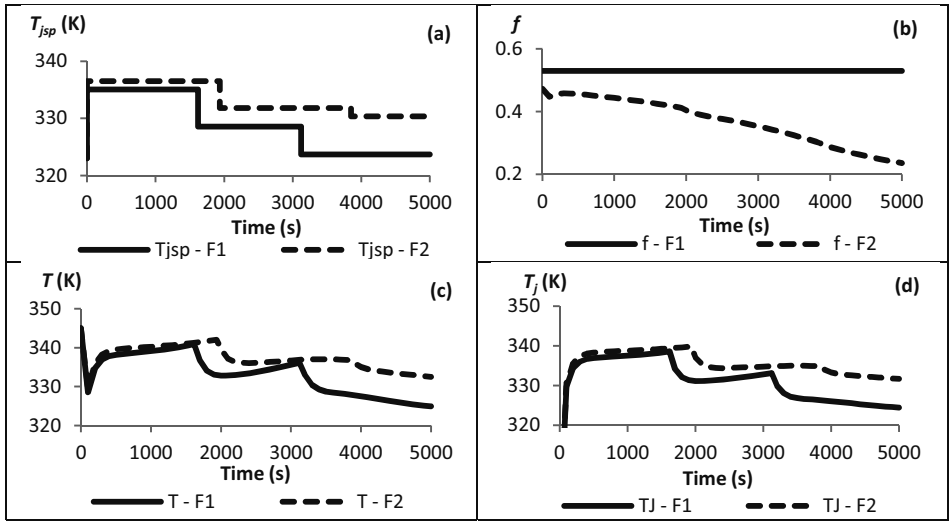

Figure 3: Results for case study 4 (Run 1 and Run 2): (a) Optimal profile of jacket temperature set point (T_{jsp}); (b) initiator efficiency (f); (c) reactor temperature T; (d) jacket temperature (T_j)

Abstract

Hydrogen is an important feedstock and fuel in the refining and petrochemical industries. In this paper, we address the optimal synthesis of inter-plant hydrogen networks by modifying the superstructure-based one-plant model of Elkamel et al. (2011). The bilinear terms involved in the component balance equations of this model give rise to a nonconvex mixed integer nonlinear program (MINLP). A specialized outer-approximation algorithm is developed for solving this optimal synthesis problem to global optimality, where the lower bound on the global optimum is obtained by means of piecewise under-and-over estimators for the bilinear terms. We propose and compare several integration schemes to demonstrate significant cost savings.

Keywords: Hydrogen networks, global optimization, superstructure

1. Introduction

The escalating prices of crude oil and petroleum products have forced the refiners and petrochemical producers to operate under tight margins. In a bid to reduce costs, these industries continually seek innovative methods to conserve and manage their resources. Hydrogen is an important utility that is acquiring significant importance due to its cost and stringent environmental regulations. In a refinery, it is critical to design and operate the individual hydrocracker and hydrotreater units so as to minimize waste. However, it is equally or even more critical to optimize the usage of hydrogen throughout the whole refinery network. One common technique for optimal hydrogen management in a refinery is to perform a hydrogen pinch analysis to set targets for minimum hydrogen need. Recently, mathematical superstructure-based optimization methods have also been applied for optimizing the hydrogen consumption within a refinery. Most work so far has addressed hydrogen management within a single refinery. In refining / petrochemical complexes such as Jubail, Jurong Island, Houston, and Rotterdam, where multiple refineries and petrochemical plants exist in close proximity, it is better to expand the scope of integration and coordination from intra-plant to inter-plant. This may allow one to exploit inter-plant synergies and reduce costs.

Resource/utility conservation and process integration have attracted much interest in the process industries to improve process sustainability. A properly designed inter-plant hydrogen network could play a significant role in reducing costs (economics), minimizing energy consumption (energy), and also conserving the environment by reducing the CO_2 emissions associated with hydrogen production. Such integration efforts are in line with the flurry of research activities involving the integration of various utilities in a refinery such as fuel gas (Hasan et al., 2011) and water (Chew et al.

(2008), Chen et al. (2010)). Chew et al. (2010a, 2010b) have also considered inter-plant resource conservation. The benefits of integration in refinery planning (Al-Qahtani and Elkamel 2008, 2009) has also prompted many researchers to work in the area of resource conservation owing to its potential benefits.
In this work, we address retrofit-design and operation of optimal inter-refinery or multi-plant hydrogen networks. However, the approach is also extendable to grass-root design as well. The objective is to minimize the total annualized cost of the entire system with the help of a mathematical superstructure-based optimization. We also propose and evaluate several schemes of this integration using a realistic case study.

2. Problem statement

A petrochemical complex has several plants with processing units that produce, consume, or purify hydrogen. Let *i* denote a source that produces hydrogen, *j* denote a sink that uses hydrogen gas as fuel, *u* denote a hydroprocessing unit that needs hydrogen as feed, and *k* denote an existing compressor that can pressurize a hydrogen stream to supply to various consumers. The plants may also have some PSA (Pressure Swing Adsorption) units that can separate relatively pure hydrogen from a hydrogen-containing feed. Let *m* denote a PSA unit that could be installed in these plants. The goal is to determine (1) the PSA units to install and their sizes, (2) interconnections among various sources, sinks, and units, and (3) distribution of hydrogen flows among various units, so as to meet the hydrogen demands of all plants at minimal total annualized cost. The superstructure for this hydrogen network study can be obtained from Elkamel et al. (2011)

3. Model Formulation

Let F_{ij}, F_{ik}, F_{iu} and F_{im} represent the gas flows (MMscfd) from source *i* to sink *j*, compressor *k*, hydroprocessing unit *u*, and PSA unit *m* respectively. Similarly, let F_{kj}, F_{ku} and F_{km} denote the gas flows from compressor *k* to fuel gas sink *j*, hydroprocessing unit *u*, and purification unit *m* respectively. If $Fout_i$ is the total gas flow from source *i*, then the mass balance around source *i* gives us,

$$Fout_i = \sum_j F_{ij} + \sum_k F_{ik} + \sum_u F_{iu} + \sum_m F_{im} \tag{1}$$

Similarly, the mass and component balance around compressor *k* whose capacity FC_k is given by Eq. (2)-(5).

$$\sum_i F_{ik} + \sum_u F_{uk} + \sum_m F_{mk} = \sum_j F_{kj} + \sum_u F_{ku} + \sum_m F_{km} \tag{2}$$

$$\sum_i F_{ik}\, yout_i + \sum_u F_{uk}\, youtu_u + \sum_m F_{mk}\, yPPSA_m = (\sum_j F_{kj} + \sum_u F_{ku} + \sum_m F_{km})\, ycomp_k \tag{3}$$

$$Pwr_k = {CpT}/{\eta}\left(\left(\frac{P_o}{P_i}\right)^{\frac{\gamma-1}{\gamma}} - 1\right)(\sum_i F_{ik} + \sum_u F_{uk} + \sum_m F_{mk}) \tag{4}$$

$$\sum_i F_{ik} + \sum_u F_{uk} + \sum_m F_{mk} \le FC_k \tag{5}$$

Pwr_k is the power of the compressor which is directly related to the flow and the parameters namely inlet P_i and outlet pressures P_o, heat capacity Cp ,temperature T and

efficiency η and γ be the adiabatic index. F_{kj}, F_{ku}, F_{km} be the flow out from the compressor to fuel gas sink *j*, hydroprocessing unit *u*, and purification unit *m* respectively. F_{uk}, F_{mk} are the flows from the hydroprocessing unit *u* and purification unit *m* to the compressor *k*. The purity of hydrogen out from compressor, source and process unit are $ycomp_k$, $yout_i$, $youtu_u$ respectively. The hydroprocessing unit modeling equations is given in Eq. (6)-(8) where F_{uj} and F_{um} the flow from unit *u* to fuel gas sink *j*, and purification unit *m*. $F_{uu'}$ is the corresponding recycle stream to the processing unit. The flow and purity demand into the hydroprocessing unit is given by $Finu_u$ and $yinu_u$ respectively and flow out is denoted by $Foutu_u$. The equations for the purification unit are in Eq (9)-(12). F_{mk} and F_{mu} are the streams from the purification unit, whose recovery is $Rcvr$ and purity is $yPPSA_m$, going to existing compressor and hydroprocessing unit. F_{mj} is the residue stream from the purification unit whose purity is $yRPSA_m$. Eq.(13) and (14) is for fuel gas system.

$$Finu_u = \sum_i F_{iu} + \sum_k F_{ku} + \sum_m F_{mu} + \sum_{u'} F_{uu'} \tag{6}$$

$$Finu_u yinu_u = \sum_i F_{iu} yout_i + \sum_k F_{ku} ycomp_k + \sum_m F_{mu} yPPSA_m + \sum_{u'} F_{uu'} youtu_u \tag{7}$$

$$Foutu_u = \sum_j F_{uj} + \sum_k F_{uk} + \sum_m F_{um} + \sum_{u'} F_{uu'} \tag{8}$$

$$\sum_i F_{im} + \sum_u F_{um} + \sum_k F_{km} = \sum_j F_{mj} + \sum_k F_{mk} + \sum_u F_{mu} \tag{9}$$

$$\sum_i F_{im} yout_i + \sum_u F_{um} youtu_u + \sum_k F_{km} ycomp_k = \sum_j F_{mj} yRPSA_m + yPPSA_m (\sum_k F_{mk} + \sum_u F_{mu}) \tag{10}$$

$$Rcvr(\sum_i F_{im} yout_i + \sum_u F_{um} youtu_u + \sum_k F_{km} ycomp_k) = yPPSA_m (\sum_k F_{mk} + \sum_u F_{mu}) \tag{11}$$

$$(1 - Rcvr)(\sum_i F_{im} yout_i + \sum_u F_{um} youtu_u + \sum_k F_{km} ycomp_k) = \sum_j F_{mj} yRPSA_m \tag{12}$$

$$Finj_j = \sum_i F_{ij} + \sum_k F_{kj} + \sum_m F_{mj} + \sum_{u'} F_{uj} \tag{13}$$

$$Finj_j yinj_j = \sum_i F_{ij} yout_i + \sum_k F_{kj} ycomp_k + \sum_m F_{mj} yRPSA_m + \sum_{u'} F_{uj} youtu_u \tag{14}$$

Since the hydrogen network problem is a gas network, the flow from any source *p* in general to any sink *q*, is possible only when the pressure of source P_p is greater than or equal to sink pressure P_q. In case of units whose pressure is known, the flows between them are fixed to zero when the pressure of source P_p is less than pressure of sink P_q. In case of equipments which need to be retrofitted, the pressure is unknown and hence a binary variable X_{pq} is required to model the pressure difference between them. Elkamel et al.(2011) had not considered the piping cost in their model, so used only one type of binary variable to model the flow and pressure difference between the units. In our case, the piping cost becomes significant when considering refinery network integration. Hence we will require two levels of binary variables in our model one to show the existence of pressure difference X_{pq} and other depicting the flow between them XF_{pq}. Second, since we are interested in solving the model to global optimality, we

introduce redundant cut into the model which aids to solve the model to global optimality given by Eq. (15). Moreover the constraint to depict the inter-plant/refinery connection is given by Eq. (16) where the connection between source and sink among refineries may or may not exist based on type of integration and *r* is index for refinery. By modeling the system using Eq.(1)-(14), we reduce the number of bilinear terms in comparison to the model of Elkamel et al. (2011) by $[|K|+|U|+|M|]$ where $|K|$, $|U|$ and $|M|$ are the number of compressors, hydroprocessing units and purification units respectively. Inclusion of piping cost, solving model to global optimality, introduction of redundant bound strengthening cuts, reduction in number of bilinear terms and multi-refinery network integration represent significant additions to the previous work (Elkamel et al. (2011)).

$$Fout_i yout_i + Foutu_u youtu_u = Finu_u yinu_u + Finj_j yinj_j \tag{15}$$

$$\sum_{p\in p_r}\sum_{q\in q_{r'}} XF_{pq} = 0 \quad \forall r \neq r' \tag{16}$$

$$TAC = AF\Big(\sum_m (a_{PSA}X_{PSA} + b_{PSA}(\sum_i F_{im} + \sum_u F_{um} + \sum_k F_{km})) + \sum_{pq\in O_{new}} (a_{pipe}X_{pipe} + b_{pipe}F_{pq})\Big)$$

$$OD((Fout_i OCH_i) + OCE\sum_k Pwr_k) \tag{17}$$

Eq. (17) gives the total annualized cost as objective with a_{PSA}, b_{PSA}, a_{pipe}, OCH_i and OCE as cost coefficients for PSA, pipeline, hydrogen cost and electricity cost. OD and AF are operating days in year and annualization factor respectively. Eq.(1)-(17) is globally optimized using the specialized outer approximation framework (Karuppiah et al. (2007)) where the lower bound on the global optimal is is obtained by the piecewise under-and-over estimators by the convexification of bilinear terms (Wicaksono and Karimi, 2008). A bivariate partitioning scheme is employed based on the Incremental Cost formulation for bilinear terms (Hasan and Karimi, 2009). When the gap between the lower bound and upper bound is below specific tolerance, then the algorithm is terminated.

4. Case Study

Consider three existing different hydrogen networks. In this, we seek to retrofit these three hydrogen networks with purifier units namely the pressure swing adsorption unit. The objective used in all the comparison studies is the minimal total annualized cost (TAC). For the sake of convenience the results in Table 1 shows the costs as the total cost of three networks.

Table 1. Optimization results for the case study

Cost(k$)	No Integration	Indirect Scheme 1	Indirect Scheme 2	Indirect Scheme 3	Direct Integration
H_2	106036.150	104415.185	104328.315	104269.550	104236.700

PSA	23512.636	20457.954	20315.696	20046.700	19894.848
Capital	24374.144	24648.079	24706.465	24732.759	23313.339
TAC	112672.261	111018.670	110923.608	110864.576	110768.534
H_2(MMscfd)	53018.075	52207.775	52164.340	52134.775	52118.350
Gas to fuel gas(MMscfd)	6286.595	6016.295	5972.860	5943.295	5926.870

In case of direct integration, the entire combined network is solved in which all possible interconnections exist among all the refineries. The decrease in the requirement of hydrogen in all the integration schemes shows a significant step towards the conservation of environment and energy. Secondly, there is also an effective usage of the hydrogen gas in the combined integrated network. Hence, an advantage could be seen in the operational cost and also in the hydrogen consumption when the refinery hydrogen networks are integrated. In the indirect integration scheme, there exists a centralized purification unit (pressure swing adsorption) through which the refinery interactions take place. In the first case of indirect integration (scheme 1), all the refineries are connected to only the centralized pressure swing adsorption unit and no connections exist among the refineries. In the indirect integration scheme (scheme 2), the hydrogen producers namely the hydrogen plant is allowed to connect with the other units of other refineries. In the final case of indirect integration (scheme 3), all the sources are allowed to connect with the sinks. From the different patterns of the integration, we observe that the both direct and integration offers better cost savings when compared to the case of no integration.

5. Conclusion

A superstructure based mathematical optimization approach is developed for inter-plant/refinery hydrogen networks. Different integration schemes were studied and the results were analyzed. All the problems were solved to global optimality with specific tolerance. The results showed that significant savings could be achieved in case of integrated network in comparison to individual networks optimized separately.

Optimizing the PSA process of propylene/propane using Neuro-Fuzzy modeling

Mona Khalighi, S. Farooq, I.A. Karimi

Department of Chemical and Biomulecular Engineering, National University of Singapore, 4 Engineering Drive 4, Singapore 117576

Abstract

Cryogenic distillation is the common method for separating propylene/propane mixtures, but this is highly energy intensive. Some 8-ring silica zeolites, especially pure silica chabazite (SiCHA), are known to show high diffusivity ratio for propylene over propane. In this work, we study the separation of propylene/propane using pure silica chabazite (SiCHA) in a simple 4-step pressure swing adsorption process. An isothermal isobaric micropore diffusion model with concentration-dependent diffusivity has been developed to simulate this kinetically controlled separation. It is first developed and implemented in the multi-physics software COMSOL to simulate different modes of PSA process. In this study, we present a sequential optimization strategy based on neuro-fuzzy model and genetic algorithm (GA) with synergistic combination of COMSOL simulation model to maximize the purity of propylene and propane productions.

Keywords: propylene/propane separation, PSA, neuro-fuzzy model, optimization

1. Introduction

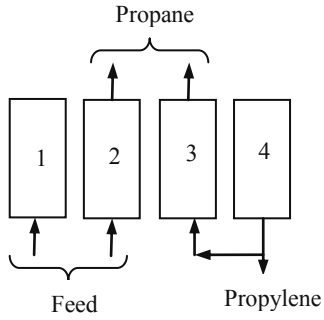
The recovery of light olefins from the off-gas of catalytic crackers is an important process in the petrochemical industry. This includes the separation of propane/propylene mixtures. In most applications, it is desirable to obtain propylene and propane with high purities. For instance, 99% propylene is the raw material for polypropylene production, a polymer of extensive applications. Propane can be either recycled to the cracking step or used separately for various purposes such as fuel for engines, oxy-gas torches, barbecues, etc.

Recently, Grande et al. (2010) proposed a new strategy to separate propane and propylene stream by VPSA technology producing polymer-grade propylene (PGP) at high recovery. In this separation process, they used dual-VPSA units operating in series using 4A zeolite. The first VPSA unit (front unit) was designed to achieve PGP. The 3-column front VPSA unit consisted of feed, depressurization, and rinse with purified propylene, second depressurization, evacuation, pressure equalization, and pressurization with feed. The simulation of the front unit predicted 99.6% purity and 67% recovery for propylene. In order to improve propylene recovery, they utilized an additional VPSA tail unit. The second VPSA unit had two columns operated on a modified Skarstrom cycle (feed, depressurization, evacuation, purge, pressure equalization, and pressurization). This unit produced purified propane and recycled the recovered propylene as feed to the front unit. The set-up with the two VPSA units in series produced PGP with recovery of 95.9% propylene. Moreover, the size of the separation unit could be reduced with this new strategy compared to the traditional

distillation process. However, the power consumption of this process was higher (~20% more) than the distillation process indicating the need for further research.

Most studies on propylene/propane separation have not been able to produce high purity propylene and propane simultaneously with low energy consumption. In other words, significant room exists for improving and optimizing adsorption-based processes for this separation. This work represents the first attempt, to our knowledge, to study the feasibility of separating propylene/propane mixture by SiCHA to obtain high purity products. We propose a 4-step PSA process with the following steps: pressurization, high-pressure adsorption, rinse with propylene rich product and counter-current evacuation. Since the pore size of SiCHA is small, we expect micropores to control the diffusion process. Thus, we develop and implement a micropore diffusion model with concentration-dependent diffusivity (Farooq and Ruthven, 1991) to simulate our proposed process.

To realize the full potential of a PSA process using SiCHA as the adsorbent to separate propylene/propane mixture, it is imperative to optimize its performance. However, this optimization poses many challenges due to the highly nonlinear algebraic and partial differential equations. This rigor along with the computational time required for the PSA process to reach the cyclic steady state make rigorous optimization difficult. Agarwal et al. (2010) presented a novel PSA superstructure to design optimal PSA cycle configurations and evaluate CO_2 capture strategy. They used a complete discretization methodology to convert partial differential equations (PDEs) to nonlinear algebraic equations for post-combustion CO_2 capture. Their proposed model is very complicated and they just consider LDF model to simulate the PSA process. Faruque Hasan et al. (2011) used sequential optimization strategy based on response surface models with design and analysis of computer experiments (DACE). They minimized the total cost of CO_2 capture in a VSA-based CO_2 capture and sequestration chain. Their method is time consuming and it has less accuracy with higher number of input parameters. Lewandowski et al. (1998) used artificial neural network (ANN) model to simulate the nitrogen unit and they minimized the nitrogen production cost using nonlinear optimization. ANN method needs more number of samples to be well trained and its accuracy depends on the number of input variables.



Optimum process parameters:

$p_H = 1.0$ atm	$t_{re} = 377$ s
$p_L = 0.06$ atm	$t_{bd} = 259$ s
$t_{pr} = 442$ s	$v_0 = 1.89$ cm/s
$t_{ad} = 778$ s	

Figure 1. Schematic diagram of the PSA cycle: 1) Pressurization 2) high pressure adsorption 3) rinse 4) countercurrent evacuation. Column length = 90 cm, ID = 2.1 cm.

Since optimization using the full-fledged simulation model is not feasible, we replace the simulation model by an approximate neuro-fuzzy model. The operating parameters such as step durations, operating pressures, and feed velocity are changed in this black box model to reach the optimum process using GA. The objective is to maximize the

propylene productivity of the process subject to the purity requirements of 99 mol% propylene and 90 mol% propane.

2. PSA Modeling and Simulation

We propose a 4-step PSA process (Figure 1) involving (1) pressurization, (2) high-pressure adsorption, (3) rinse with recycle product from step 4, and (4) countercurrent evacuation. Since micropore diffusion is expected to control the adsorption process, we implemented the pore diffusion model of Farooq and Ruthven (1991) with concentration-dependent diffusivity in COMSOL to simulate this process (Table 1).

Table 1. A comprehensive micropore diffusion model using Langmuir isotherm.

Model equations:	Boundary conditions:
Fluid phase mass balance: $-D_l\frac{\partial^2 c_i}{\partial Z^2}\pm v\frac{\partial c_i}{\partial Z}\pm c_i\frac{\partial v}{\partial Z}+\frac{\partial c_i}{\partial t}+\frac{1-\varepsilon}{\varepsilon}(\frac{\partial \overline{q}_{pi}}{\partial t})=0$ Mass balance inside the macropore: $\frac{\partial \overline{q}_{pi}}{\partial t}=\varepsilon_p\frac{\partial c_i}{\partial t}+(1-\varepsilon_p)\frac{\partial \overline{q}_{ci}}{\partial t}$ Mass transfer rate in micropore: $\frac{\partial \overline{q}_{ci}}{\partial t}=\frac{3}{r_c}D_i\left.\frac{\partial q_{ci}}{\partial r}\right\|_{r=r_c}$ Overall mass balance: $\pm C\frac{\partial v}{\partial Z}+\frac{1-\varepsilon}{\varepsilon}\sum_i\frac{\partial \overline{q}_{pi}}{\partial t}=0$ High pressure adsorption and rinse steps $\pm C\frac{\partial v}{\partial Z}+\frac{\partial C}{\partial t}+\frac{1-\varepsilon}{\varepsilon}\sum_i\frac{\partial \overline{q}_{pi}}{\partial t}=0$ Pressurization and evacuation steps Particle balance: $\frac{\partial q_{ci}}{\partial t}=\frac{1}{r^2}\left[\frac{\partial}{\partial r}\left(r^2D_i\frac{\partial q_{ci}}{\partial r}\right)\right]$ $D_i=\frac{D_{i0}}{1-\theta_i-\theta_j}\left[(1-\theta_j)+\theta_i\frac{\partial q_j/\partial r}{\partial q_i/\partial r}\right]$ For the variable pressure steps, we use exponential function as proposed by Farooq et al. (1993): Pressurization $P=P_H-(P_H-P_L)exp(-a_1t)$ Blowdown $P=P_L+(P_H-P_L)exp(-a_2t)$	Pressurization, feed, rinse steps: $D_l\left.\frac{\partial^2 y_i}{\partial z^2}\right\|_{z=0}=-v\|_{z=0}(y_i\|_{z=0^-}-y_i\|_{z=0})$ $\left.\frac{\partial y_i}{\partial z}\right\|_{z=L}=0$ Evacuation steps: $\left.\frac{\partial y_i}{\partial z}\right\|_{z=0}=0$ $\left.\frac{\partial y_i}{\partial z}\right\|_{z=L}=0$ Boundary conditions for velocity: $v\|_{z=L}=0$ step 1 $v\|_{z=1}=v_0$ step 2 $v\|_{z=1}=Gv_0$ step 3 $v\|_{z=L}=0$ step 4 Particle boundary conditions (Langmuir isotherm): $\left.\frac{\partial q_i}{\partial r}\right\|_{r=0}=0$ $\frac{q_i\|_{r=R_c}}{q_{is}}=\theta_i=\frac{b_ic_i\|_{r=R_c}}{1+\sum_i b_ic_i\|_{r=R_c}}$

3. PSA Optimization Using Neuro-Fuzzy

We choose the upper and lower bounds of design and operating variables such as, cycle pressures (p_H, p_L), cycle durations (t_{pr}, t_{ads}, t_{re}, t_{bd}) and feed velocity (v_0) considering the
